# Preface to the Third Edition

I am pleased to welcome Professor Stan Lemon to the editorial group for the third edition of *Viral Hepatitis*: he brings considerable expertise in molecular virology to the editing process. Since the second edition was published in 1998, an additional 14,000 peer-reviewed papers have been published in this field, and many important advances have been made. The book includes over 50 chapters, ranging from new contributions on hepatic stem cell biology and the liver's immune system, through to updated reviews of the basic virology of the five hepatitis viruses and the increasing importance of viral variants, insights into the pathogenesis of persistent infection and the role of hepatitis B and C in tumorogenesis.

To appeal to the clinician, we have included more specialized chapters on the treatment of fulminant hepatitis, liver cancer, persistent hepatitis in children and in haemophiliacs, treatment of the extra-hepatic manifestations of hepatitis B and C, and of the specific problems occurring in HIV-infected patients with viral liver disease. Two of the more important chapters for the clinician will be those dealing with the treatment of chronic hepatitis B and C written by clinicians practising in Europe and North America. Finally, we have included a new chapter on occupational health issues, and reviewed the subjects of sterilisation and prevention by vaccination.

We hope the book will appeal to virologists, immunologists, clinicians in infectious diseases, hepatology and gastroenterology and, of course, to public health and occupational health physicians. It is a book for healthcare workers addressing today's problems and researchers projecting us forward to solve the remaining issues in a disease area affecting over half a billion of the world's population!

Recognising the rapidity with which this field is evolving, we would welcome your suggestions on how the Journal and Textbooks of *Viral Hepatitis*, both now published by Blackwell's, might interact to better serve your needs in this electronic publishing era.

*Howard Thomas*
*March 2005*

# Section I
# Introduction to Liver Biology

# Chapter 1
# Liver stem cells in persistent viral infection, liver regeneration and cancer

Stuart Forbes, Malcolm Alison

## Stem cells: definitions and properties

It is widely believed that the most versatile stem cells are embryonic stem (ES) cells, which are isolated from the inner cell mass (ICM) of the early blastocyst or fetal gonadal tissue. These blastocysts are usually 'spares' from IVF programmes, although some have been deliberately created. Tissues generated from such ES cells have still to overcome the problem of histocompatibility, but somatic cell nuclear transfer techniques (SCNT – also called therapeutic cloning) offer the possibility of using the patient's own genome to generate ES cells and so overcome this obstacle.[1]

### A hierarchy of potential

Stem cells have varying degrees of potential. The most versatile is of course the fertilized oocyte (the zygote) and the descendants of the first two divisions. These cells are *totipotent*, able to form the embryo and the trophoblasts of the placenta. After about 4 days these totipotent cells begin to specialize, forming a hollow ball of cells, the blastocyst, and a cluster of cells called the ICM from which the embryo develops. The ICM cells are considered to be *pluripotent*, able to differentiate into almost all cells that arise from the three germ layers, but not the embryo because they are unable to give rise to the placenta and supporting tissues. A large number of studies point to the fact that these ES cells are able to differentiate down the hepatocyte lineage.[2–5] Another cell with pluripotency is the so-called 'multipotent adult progenitor cell' (MAPC) that has been isolated by Catherine Verfaillie and colleagues from mesenchymal cell cultures obtained from human and rodent bone marrow.[6,7] These MAPCs are capable of in excess of a hundred population doublings, and can be induced to differentiate not only into mesenchymal lineages, but also into endothelial, neuroectodermal cells (neurones, astrocytes and oligodendrocytes) and endodermal cells (hepatocytes).

Most adult tissues have *multipotential* stem cells, which are capable of producing a limited range of differentiated cell lineages appropriate to their location, e.g. small intestinal stem cells can produce all four indigenous lineages (Paneth, goblet, absorptive columnar and entero-endocrine). Central nervous system (CNS) stem cells have trilineage potential generating neurones, oligodendrocytes and astrocytes,[8] while the recently discovered stem cells of the heart can give rise to cardiomyocytes, endothelial cells and smooth muscle.[9] In the liver, such multipotential stem cells are found in the canals of Hering, giving rise to a transit amplifying population of cells called either oval cells or hepatic progenitor cells (HPCs). Ordinarily, these cells are essentially bipotent, giving rise to hepatocytes and biliary epithelial cells, but under some circumstances they can give rise to other cell types, notably cells of an intestinal phenotype. The least versatile of stem cells are *unipotential* stem cells, which are capable of generating one specific cell type. Into this category we could place epidermal stem cells in the basal layer that produce only keratinized squamous cells and certain adult hepatocytes that have long-term repopulating ability. Some would argue that there is no such thing as a unipotential stem cell, and really these cells should be called *committed progenitors*. While there is no doubt that in some tissues, e.g. the gastrointestinal tract and haematopoietic renewal systems, there are committed stem cells (progenitors) with more limited division potential than their multipotent predecessors, in the liver there do appear to be some unipotent cells with a very large clonogenic potential.[10]

### Self-maintenance

In many renewing tissues the ability of stem cells to self-renew is one of the most defining characteristics. Stem cells are normally located in a protected environment (niche; *Fr*. recess), and in a tissue such as the small intestine where the cell flux is in one direction, they are

found at the origin of the flux. In the heart, they are located in areas of least haemodynamic stress. Although only a small percentage of a tissue's total cellularity, stem cells maintain their numbers if, on average, each stem cell division gives rise to one replacement stem cell and one transit amplifying cell (an *asymmetric* cell division). The interactions with the stem cell niche are likely to be crucial to this process. We are still largely ignorant about the identity of both multipotential and unipotential stem cells in the liver and so any discussion of a stem cell niche is premature.

### Proliferation, clonogenicity and genomic integrity

In renewing tissues, stem cells are slowly cycling but highly clonogenic. Teleologically, it would seem prudent to restrict stem cell division because DNA synthesis can be error-prone. Thus, in many tissues stem cells divide less frequently than transit amplifying cells. In the intestine, stem cells cycle less frequently than the more luminally located transit amplifying cells, and in the human epidermis basal cells highly expressive of the β1-integrin (receptor for type IV collagen) have a lower level of proliferation than the other basal cells. In hair follicles, the hair shaft and its surrounding sheaths are produced by the hair matrix that is itself replenished by the bulge stem cells. As befits true stem cells, the bulge cells divide less frequently but are more clonogenic than the transit amplifying cells of the hair matrix. Combined with an infrequently dividing nature, stem cells would also appear to have devised a strategy for maintaining genome integrity. Termed the immortal strand hypothesis or Cairns hypothesis, stem cells can apparently designate one of the two strands of DNA in each chromosome as a template strand, such that in each round of DNA synthesis while both strands of DNA are copied, only the template strand and its copy are allocated to the daughter cell that remains a stem cell.[11] Thus, any errors in replication are readily transferred (within one generation) to transit amplifying cells that are soon lost from the population. Such a mechanism probably accounts for the ability of stem cells to be 'label-retaining cells' (LRCs) after injection of DNA labels when stem cells are being formed. As the healthy adult liver is very largely proliferatively quiescent, the foregoing stem cell attributes (apart from clonogenicity) are not readily identified within the liver.

### Molecular control of stem cell behaviour

It appears likely that the local microenvironment, through a combination of cells and extracellular matrix components, will govern all aspects of stem cell behaviour. This led to the concept of the stem cell niche (not yet identified in the liver) that supports and controls stem cell activity. Wnt signalling, in particular, seems critical to stem cell self-renewal in many tissues. The active Wnt pathway maintains the pluripotency of ES cells,[12] myofibroblast-secreted Wnts preserve the intestinal stem cell phenotype,[13] while haematopoietic stem cell (HSC) self-renewal also requires Wnts, in particular Wnt-3A.[14] Interestingly, Wnt-3A has been implicated in the maintenance of a hepatobiliary (reservoir) cell with bipotential capabilities in cultures derived from fetal liver.[15]

### Adult stem cell plasticity

There is some evidence to support the idea that certain adult stem cells, particularly those of bone marrow origin, can engraft alternative locations (e.g. non-haematopoietic organs), particularly when the recipient organ is damaged, and transdifferentiate into phenotypes appropriate to their new location. However, the field is not without its critics.[16] The reason for this is twofold: 1) certain instances of so-called plasticity have now been attributed to cell fusion between bone marrow cells and cells of the recipient organ (see below), and 2) several remarkable claims have not been able to be confirmed, including conflicting reports regarding the ability of HSCs to contribute to hepatocyte replacement in the damaged liver (see below).

### Stem cell diseases – metaplasia, fibrosis and cancer

Under normal circumstances tissue-specific stem cells generate the range of cell types appropriate to their location. However, chronic inflammation and damage are often accompanied by metaplastic change – a major switch in tissue differentiation, and it is reasonable to suppose that this switch occurs at the level of stem cells rather than between terminally differentiated cells. Adult stem cells, and particularly HSCs, may also contribute to organ fibrosis including liver cirrhosis (see below). It is also likely that many cancers, including primary liver tumours are of stem cell origin (see below).

## Liver stem cells: hepatocytes

Hepatocytes are highly differentiated cells with multiple synthetic and metabolic functions. They are also the functional stem cell in the liver under most circumstances. In health, individual hepatocytes have a life expectancy of over a year. Therefore, in the normal adult liver there is little cell proliferation detectable with only 0.01% of hepatocytes in the cell cycle at any one time. However, in response to parenchymal cell loss, the hepatocytes restore the liver mass by self-replication. This is a very efficient system, and in rodents when two-thirds of

the liver is resected the remaining remnant can re-grow to the original liver size in approximately 10 days. This model has been intensively studied and has provided many data on the mechanisms controlling liver regeneration.[17] In response to this stimulus the hepatocytes initially hypertrophy, accumulate triglycerides and amino acids and activate enzymes that are associated with cell proliferation. The normally quiescent hepatocytes leave G0 to enter the cell cycle under the influence of growth factors and cell cycle-dependent kinases. The hepatocyte proliferation begins in the periportal region of the liver and spreads to the central region of the lobule. This situation requires the hepatocytes to undergo on average less than two rounds of replication to restore the liver to its original size. However, this does not mean that the hepatocytes have a replication potential limited to this degree. Hepatocyte transplantation models in mice have shown that the transplanted cells are capable of significant clonal expansion within the diseased livers of experimental animals. In the FAH-deficient mouse, a model of hereditary type 1 tyrosinaemia, there is strong positive selection pressure on the transplanted wild-type cells as the host hepatocytes are metabolically deficient. This phenotype is lethal unless the mice are administered the compound 2-(2-nitro-4-trifluoromethylbenzoyl)-1,3-cyclohexanedione (NTBC), which prevents the accumulation of toxic metabolites in the tyrosine catabolic pathway. When $10^4$ normal hepatocytes from congenic male wild-type mice are intrasplenically injected into mutant female mice and the NTBC treatment is withdrawn, these cells colonize the mutant liver efficiently.[10] Moreover, serial transplantations from these colonized livers to other mutant livers indicated that at least 69 hepatocyte doublings can occur, thereby confirming the clonogenic potential of hepatocytes and fulfilling a crucial property required of stem cells.

The clonogenic ability of human hepatocytes in chronic hepatitis can be indirectly estimated. Using mathematical modelling of viral kinetics it has been estimated that in chronic hepatitis B between 0.3% and 3% of all hepatocytes are killed and therefore replaced each day to maintain a stable liver cell mass (this approximates to $10^9$ of the liver's $2 \times 10^{11}$ hepatocytes).[18] This estimation accords with proliferation indices seen in chronic hepatitis B and C with proliferating cell nuclear antigen indices of 0.1–3.6% of hepatocytes and Ki-67 labelling indices in hepatitis C of 1–14%.[19,20] In chronic hepatitis the parenchymal mass can therefore be maintained through hepatocyte self-replication.

The hepatocyte proliferation rate increases in hepatitis C with increasing histological damage until cirrhosis is reached when the proliferation rates fall.[21] The reason for this fall in hepatocyte proliferation rate is not fully resolved. It may represent the hepatocytes coming to the end of their replicative potential and indeed Wiemann *et al*. have found that in cirrhosis the hepatocyte telomerase shortening correlates with cell cycle senescence and the degree of fibrosis.[22] However, other factors contributing to the inhibition of hepatocyte proliferation seen in cirrhosis may be the accumulation of hepatic collagen and activated stellate cells acting to inhibit hepatocyte proliferation,[23] or simply the distortion of the lobular anatomy and blood flow seen in cirrhosis. Whatever the reason, the reductions in hepatocyte proliferation indices in cirrhosis are coincident with the production of cells from a second potential stem cell compartment, located within the smallest branches of the intrahepatic biliary tree. This so-called 'oval cell' compartment identified in rodent models has historically been termed the 'ductular reaction' when seen in human liver disease. The development of the oval cell reaction in response to hepatocyte replicative senescence has recently been demonstrated in a transgenic mouse model of fatty liver and DNA damage. In this model the mice developed fatty livers and a large number of senescent hepatocytes. A striking oval cell response developed in these mice which related to the number of senescent mature hepatocytes.[24]

## Liver stem cells: oval cells

### Rodent models

Following very extensive liver damage or in situations where hepatocyte regeneration after damage is compromised, a potential stem cell compartment located within the smallest branches of the intrahepatic biliary tree is activated. This 'oval cell' or 'ductular reaction' amplifies a biliary population that has a bipotential capacity capable of differentiating into either hepatocytes or cholangiocytes. Most rodent models of oval cell activation have employed potential carcinogens to inhibit hepatocyte replication in the face of a regenerative stimulus. For example in the rat, protocols have included administering 2-acetylaminofluorene (2-AAF) to inhibit hepatocyte proliferation before creating a demand for hepatocyte proliferation by partial hepatectomy or a necrogenic dose of carbon tetrachloride. The need to maintain parenchymal cell mass results in the development of an oval cell response in the mouse liver that spreads from the canals of Hering into the parenchyma. The oval cells initially express cell surface markers of both hepatocytes and biliary epithelia, but over time the oval cells differentiate into a hepatocyte phenotype.[25] Oval cells are small cells with a large nucleus to cytoplasm ratio, in which the nucleus also has a distinctive ovoid shape. A wide range of markers has been used to identify oval cells including gamma-glutathione transferase and glutathione-S-transferase activity, along with a host of monoclonal antibodies raised against cy-

**Table 1.1** Markers that have aided in the identification of oval cells

| Marker/antibody | Nature |
|---|---|
| OV-6 | Monoclonal antibody generated by immunizing mice with cell preparations isolated from carcinogen-treated rat livers |
| OC.2, OC.3 | Biliary/oval cell antigens |
| BDS7 | Monoclonal antibody generated against surface-exposed components of bile ductular cells |
| Thy-1 | Haematopoietic stem cell marker |
| c-kit | Haematopoietic stem cell marker/receptor for stem cell factor |
| CD34 | Haematopoietic stem cell marker |
| ABCG2/BRCP1 | ATP-binding cassette transporter |
| Connexin 43 | Gap-junction proteins |
| CK7, CK19, CK14 | Intermediate filament proteins that impart mechanical strength to cells |
| AFP (alpha-fetoprotein) | The predominant serum protein produced during early liver development, replaced later in development by albumin |
| Gamma-glutamyl transpeptidase (GGT) | A major enzyme of glutathione homeostasis present in normal adult liver in bile duct epithelium and membranes of bile canaliculi |
| Placental form of glutathione-S-transferase (GST-P) | Dimeric proteins involved in the intracellular transport of hydrophobic molecules and the metabolism of toxic compounds |
| Flt-3 | Receptor with tyrosine kinase activity present on haematopoietic stem cells |
| DMBT1 | Deleted in malignant brain tumour 1: proteins involved in the mucosal defence system and epithelial differentiation |
| (M2-PK) | Antibody against the fetal M2 isoform of pyruvate-kinase |

toskeletal proteins and surface antigens (see Table 1.1). Of great interest was the finding that oval cells express antigens traditionally associated with haematopoietic cells such as c-kit, Flt-3, Thy-1 and CD34.[26–28] This led to speculation that some hepatic oval cells may be directly derived from a precursor of bone marrow origin, particularly when the biliary tree is damaged[29] and this will be reviewed in the following section. Most researchers believe that the location of a stem cell niche for oval cells is in the canals of Hering, which is a transitional zone between the periportal hepatocytes and the biliary cells lining the smallest terminal bile ducts. In rats and mice, the canals of Hering barely extend beyond the limiting plate, but the resultant oval cell proliferation can result in branching ducts that express alpha-fetoprotein (AFP) and stretch to the midzonal areas before these cells differentiate into hepatocytes in the hepatic parenchyma (see Plate 1.1, facing p.786). Using oval cell transplant experiments into the FAH-deficient mouse Wang *et al*. found that the oval cells from metabolically competent mice repopulated the mutant livers at least as efficiently as mature hepatocytes, demonstrating their hepatocyte differentiation potential.[30]

## Human liver

The human counterparts to the oval cells described in rodent models are often referred to as hepatic progenitor cells. These have been studied after severe hepatocellular necrosis, chronic viral hepatitis, alcoholic liver disease and non-alcoholic fatty liver disease. It is thought that activation of hepatic progenitor cells and differentiation towards the biliary lineage leads to formation of reactive ductules, which are anastomosing strands of immature biliary cells with an oval nucleus and a small rim of cytoplasm.

Differentiation towards the hepatocyte lineage occurs via intermediate hepatocytes. These are polygonal cells with a size and phenotype intermediate between progenitor cells and hepatocytes.[31] After submassive liver cell necrosis, reactive ductules, in continuity with intermediate hepatocytes, are seen at the periphery of the necrotic areas. In patients studied with sequential liver biopsies, intermediate hepatocytes become more numerous with time and extend further into the liver lobule. This sequence of changes suggests gradual differentiation of human putative progenitor cells into intermediate hepatocytes, analogous with what is seen in rat models of chemical injury associated with impaired hepatocyte replication. In chronic viral hepatitis, progenitor cells are activated, even in mild degrees of inflammation. The number of progenitor cells (the degree of activation) correlates with the degree of inflammatory activity.[32] Intermediate hepatocytes are only seen when a certain level of inflammation is reached, suggesting that progenitor cells only differentiate towards hepatocytes when a certain threshold of damage is reached.

Elegant three-dimensional reconstructions of serial sections of human liver immunostained for cytokeratin-19 have shown that the smallest biliary ducts, the canals

of Hering, normally extend into the proximal third of the lobule (unlike those in rodents), and it is envisaged that these canals react to massive liver damage (akin to a tripwire), proliferating and then differentiating into hepatocytes[33] (see Plate 1.2, facing p.786). Oval cell numbers in human liver rise with increasing severity of liver disease[34] and this ductular reaction is thought to be a stem cell response rather than a ductular metaplasia of 'damaged' hepatocytes. However, others have argued that this cellular gradient does not necessarily represent differentiation of a progenitor cell, but rather a de-differentiation of mature hepatocytes towards a biliary phenotype. Falkowski *et al*.[21] have clarified this issue in human liver. Using serial sections and three-dimensional reconstructions they found in human liver cirrhosis that in most cases (94%) the intraseptal hepatocyte buds (small nodules of hepatocytes) were connected to areas of ductular reaction. Furthermore, they found that 'cholestatic' hepatocytes were very largely not associated with a ductular reaction, clearly supporting the notion that ductular reactions represent a stem cell response.

Recently, human bipotent cell lines have been identified from human liver; the HepaRG cell line has been established from a liver tumour associated with chronic hepatitis C. These cells display both hepatocyte-like and biliary-like epithelial phenotypes, but hepatocyte differentiation can be produced by culture with epidermal growth factor (EGF).[35] Hopefully, the study of cell lines such as this will aid the understanding of the molecular mechanisms of stem cell differentiation

## Liver stem cells: bone marrow cells

### Rodent data

Within an adult tissue, the locally resident stem cells were formerly considered to be capable of only giving rise to the cell lineage(s) normally present. However, adult haematopoietic stem cells (HSCs) in particular may be more flexible: removed from their usual niche, they are capable of differentiating into non-haematopoietic lineages. Oval cells/hepatocytes were first thought to be derived from circulating bone marrow cells in the rat. Petersen *et al*.[29] followed the fate of syngeneic male bone marrow cells transplanted into lethally irradiated female recipient animals whose livers were subsequently injured by carbon tetrachloride (to cause hepatocyte necrosis) in the presence of 2-acetylaminofluorene (to block hepatocyte regeneration) in order to induce an oval cell activation. Y chromosome-positive-containing cells were tracked by *in situ* hybridization. Oval cells and hepatocytes that were Y chromosome-positive were identified at 9 and 13 days, respectively. Additional evidence for hepatic engraftment of bone marrow cells was sought from a rat whole liver transplant model. Lewis rats expressing the major histocompatibility complex (MHC) class II antigen L21-6 received liver transplants from Brown Norway rats that were negative for L21-6. Subsequently, ductular structures in the transplants contained both L21-6-negative and L21-6-positive cells, indicating that the biliary epithelium was of both donor and recipient origin. These cells of host origin were thought to originate from circulating bone marrow cells. Using a similar gender mismatch bone marrow transplantation model (female mice transplanted with male bone marrow), Theise *et al*.[36] reported that, over a 6-month period, 1–2% of hepatocytes in the murine liver may be derived from bone marrow in the absence of any obvious liver damage, suggesting that bone marrow contributes to normal 'wear and tear' renewal of the liver. In the most striking demonstration of the potential therapeutic utility of bone marrow, FAH-deficient mice (see above) were rescued biochemically by a million unfractionated bone marrow cells that were wild-type for FAH. Moreover, only purified HSCs (c-kit$^{high}$Thy$^{low}$Lin$^{-}$Sca-1$^{+}$) were capable of this functional repopulation, with as few as 50 of these cells being capable of hepatic engraftment when haematopoiesis was supported by $2 \times 10^5$ fah–/– congenic adult female bone marrow cells.[37] Importantly, although the initial engraftment was low, approximately one bone marrow cell for every million indigenous hepatocytes, the strong selection pressure exerted (induced liver failure) thereafter on the engrafted bone marrow cells resulted in their expansion to eventually occupy almost half the liver. However, it was later found that the healthy liver cells in the fah–/– mouse contained chromosomes from both the recipient and donor cells, with presumably the donor haematopoietic cell nuclei being reprogrammed when they fused with the unhealthy fah–/– hepatocyte nuclei to become functional.[38,39] The key to this discovery was to perform the gender mismatch bone marrow transplantation experiments between female donors and male recipients. In one experiment, a million donor bone marrow cells (fah+/+) from Fanconi anaemia group C (fancc–/–) homozygous mutant mice were serially transplanted into lethally irradiated fah–/– recipients.[39] The usual repopulation (approximately 50%) of the mutant liver by Fah-positive hepatocytes was noted, but Southern blot analysis of the purified repopulating cells revealed that they were heterozygous for alleles (fah+/+; fancc–/–) that were unique to the donor marrow – fusion with host liver cells must have occurred. To confirm this conclusion, in a second experiment, fah+/+ bone marrow from ROSA26 female mice was transplanted into male fah knockout mice. Cytogenetic analysis of the LacZ-positive, sorted bone marrow-derived hepatocytes revealed that most if not all had a Y chromosome, thus confirming fusion. Before bone marrow transplant, most host hepatocytes had a karyotype of either 40,XY or 80,XXYY, but after transplantation

with fah+/+ bone marrow, the commonest karyotype of Fah-positive hepatocytes was either 80,XXXY, suggesting fusion between a diploid female donor cell and a diploid male host cell, or 120,XXXXYY, suggesting fusion between a female donor diploid blood cell and a tetraploid male host hepatocyte. However, a substantial proportion of bone marrow-derived hepatocytes were aneuploid, suggesting that fusion had created some sort of genetic instability with the hybrid cells randomly shedding chromosomes. In the companion paper (Vassilopoulos *et al*.[38]) to that of Grompe and colleagues,[39] lineage-depleted wild-type bone marrow was transplanted into lethally irradiated female fah–/– mice and, following withdrawal of NTBC, the usual Fah-positive nodules emerged 4–5 months later. When restriction enzyme-digested genomic DNA from these nodules was probed for fah sequences, the mean level of donor DNA was found to be only 26%, again leading to the conclusion that the donor haematopoietic cells had fused with the host fah–/–, generating polyploid hepatocytes.

Fusion of bone marrow cells has also been found to occur in the normal mouse, not only with hepatocytes, but also with Purkinje cells and cardiomyocytes.[40] These were very elegant studies *in vivo* and *in vitro* in which a reporter gene was activated only when cells fused. However, unlike the Fah null mouse, no selection pressure (liver damage) was operative, and even after 10 months only 9–59 fused cells/$5.5 \times 10^5$ hepatocytes were found. Importantly, they also found evidence that with time donor genes had been either inactivated or eliminated, again suggestive of genetic instability in heterokaryons.

Mouse bone 'marrow-derived' hepatocytes can also be expanded selectively if they are engineered to overexpress Bcl-2, and then the indigenous cells are targeted for destruction by an anti-Fas antibody. It is as yet unknown whether cell fusion operates in this model.[41]

Not all murine studies are consistent. Terai *et al*.[42] reported an impressive 25% contribution of bone marrow to the parenchyma after CCL4-induced injury, but Kanazawa and Verma[43] failed to find any evidence for bone marrow engraftment in three models of chronic liver injury, including CCL4 (see Table 1.2).[29,37–39,41–53] However, many studies have testified to the ability of human cord blood cells to transdifferentiate into hepatocytes in the liver of the immunodeficient mouse (Table 1.2), albeit at a low level.[48,49,51–53] While it seems logical to believe that parenchymal damage is a stimulus to hepatic engraftment by HSCs, the molecules that mediate this homing reaction to the liver are not well understood. Petrenko *et al*.[54] speculated that in mice the molecule AA4 (murine homologue of the C1q receptor protein) may be involved in the homing of haematopoietic progenitors to the fetal liver – it may be that this receptor protein is expressed on HSCs that engraft to the damaged liver. An alternative explanation is that cells in the liver express the stem cell chemoattractant 'stromal derived factor-1' (SDF-1) for which HSCs have the appropriate receptor known as CXCR4.[55] Hatch *et al*.[56] have provided persuasive evidence that SDF-1 is involved in oval cell activation, furthermore speculating that this chemokine may secondarily recruit bone marrow to the injured liver. More definitive proof was provided by Kollet *et al*.[53] who observed increased SDF-1 expression (particularly in biliary epithelia) after parenchymal damage, and concomitant with such damage was increased HGF production, a cytokine that was very effective in promoting protrusion formation and CXCR4 up-regulation in human CD34+ haematopoietic progenitors. Intriguingly, Ratajczak *et al*.[57] have identified a population of cells in the bone marrow of normal mice that have features of hepatocyte differentiation (alpha-fetoprotein and cytokeratin-19 production). They speculated that the bone marrow could be a location for already differentiated CXCR4-positive tissue-committed stem/progenitor cells to reside. Furthermore, following organ specific damage, SDF-1 is unregulated, the cells follow the SDF-1 gradient, mobilize into peripheral blood and subsequently take part in organ regeneration.

Other cells found to have an origin, at least in part, from the bone marrow are the hepatic stellate cells. Baba *et al*.[58] used bone marrow transplants from mice transgenic for green fluorescent protein (GFP) into non-transgenic recipients prior to injections with carbon tetrachloride to induce liver fibrosis. Surprisingly, they found that a third of the stellate cells in recipients were GFP-positive and therefore likely to be from the bone marrow. This is in accord with recent data in mice where myofibroblasts in various organs including gut, lung and skin were identified to be of bone marrow origin.[59,60]

## Human data

In two contemporaneous papers, Alison *et al*.[61] and Theise *et al*.[62] demonstrated that hepatocytes can also be derived from bone marrow cell populations in humans (see Table 1.3).[61–67] Two approaches were adopted – firstly, the livers of female patients who had previously received a bone marrow transplant from a male donor were examined for cells of donor origin using a DNA probe specific for the Y chromosome, localized using *in situ* hybridization. Secondly, Y chromosome-positive cells were sought in female livers engrafted into male patients but which were later removed for recurrent disease. In both sets of patients, Y chromosome-positive hepatocytes were readily identified, but the degree of hepatic engraftment of HSCs into human liver was highly variable. Most probably related to the severity of parenchymal damage, up to 40% of hepatocytes and cholangiocytes appeared to be derived from bone marrow in a liver transplant recipient with recurrent hepati-

tis.[62] Subsequent human investigations with granulocyte colony-stimulating factor (G-CSF) mobilized peripheral blood CD34+ stem cells have shown that these cells are also apparently able to transdifferentiate into hepatocytes, with 4–7% of hepatocytes in female livers being Y chromosome-positive after the cell transplant from male donors.[63] However, it is worth noting that some other studies, examining the contribution of recipient cells to liver allografts in humans, have failed to register any real engraftment in the allografted liver (see Table 1.3).[65–67] Given the rodent data suggesting that the mechanism of these observations is likely to be cell fusion (except the NOD/SCID experiments), it is possible that cell fusion explains these observations. Technical difficulties make it hard to demonstrate clearly whether all these 'marrow-derived hepatocytes' are the result of fusion, transdifferentiation or a mixture of both.

While there is a limited degree of differentiation of bone marrow cells into hepatocytes, there is a more robust axis of regeneration of non-parenchymal cells from the bone marrow. It has been well described that, within the liver, the Kupffer cells and inflammatory cells traffic between the host's bone marrow and the liver graft. Gao *et al*.[68] demonstrated that in human liver grafts the hepatic endothelium became replaced by cells of recipient origin. This was studied further in female mice that had received a male bone marrow transplant, and it was demonstrated that it was the bone marrow-derived cells that were responsible for repopulating the liver endothelium, in contrast to the endothelium of the heart, kidney or musculature. The contribution of the bone marrow to hepatic myofibroblasts in humans has been demonstrated by Forbes *et al*.[69] who analysed male patients who received female liver transplants and then developed recurrent hepatitis and fibrosis. Here, up to 40% of the liver's myofibroblasts were of male origin. In order to identify the origin of these circulating extrahepatic cells, liver tissue was analysed from a female patient who had undergone a male bone marrow transplant before developing hepatitis C-induced cirrhosis. In this case a quarter of the liver's myofibroblasts were of bone marrow origin. The exact relationship between the bone marrow and the Ito cells/quiescent stellate cells remains to be determined, but it may be that both contribute to the collagen-forming cells (myofibroblasts) in cirrhosis.

## Stem cells and cancer

There is no doubt that the integration of hepatitis B virus (HBV)-DNA into the human genome is a significant event in hepatocarcinogenesis.[70,71] Moreover, inspection of viral integration sites among tumour cells clearly indicates that each tumour is monoclonal, i.e. is derived from a single cell.[72,73] The important question is, which cell? Stem cell biology and cancer are inextricably linked. In continually renewing tissues such as the intestinal mucosa and epidermis, where a steady flux of cells occurs from the stem cell zone to the terminally differentiated cells that are imminently to be lost, it is widely accepted that cancer is a disease of stem cells because these are the only cells that persist in the tissue for a sufficient length of time to acquire the requisite number of genetic changes for neoplastic development. In the liver, the identity of the founder cells for the two major primary tumours, hepatocellular carcinoma (HCC) and cholangiocarcinoma (CC), is more problematic. The reason for this is that no such unidirectional flux occurs in the liver. Moreover, the existence of bipotential hepatic progenitor cells (HPCs), often called oval cells, along with hepatocytes endowed with longevity and long-term repopulating potential, suggests that there may be more than one type of carcinogen target cell. Irrespective of

which target cell is involved, what is clear is that cell proliferation at the time of carcinogen exposure is pivotal for 'fixation' of the genotoxic injury into a heritable form. Taking this view, Sell has opined that in models of experimental hepatocarcinogenesis as a whole, there may be at least four distinct cell lineages susceptible to neoplastic transformation.[74,75] This supposition is based on the fact that there is considerable heterogeneity in the proliferative responses that ensue after injury in the many different models of hepatocarcinogenesis. Thus, hepatocytes are implicated in some models of HCC, direct injury to the biliary epithelium implicates unipotent cholangiocytes in some models of cholangiocarcinoma, while HPC/oval cell activation accompanies very many instances of liver damage irrespective of aetiology, making such cells very likely carcinogen targets. A fourth cell type that might be susceptible to neoplastic transformation is the so-called nondescript periductular cell that responds to periportal injury. The suggestion that such a cell may be of bone marrow origin would be experimentally verifiable in the context of a sex-mismatch bone marrow transplantation (see above) and the appropriate carcinogenic regimen.

The direct involvement of hepatocytes in hepatocarcinogenesis has been clearly established in rats. Gournay *et al*.[76] found that some preneoplastic foci (expressing gamma glutamyl-transpeptidase and the placental form of glutathione-S-transferase) were directly descended from hepatocytes. This was achieved by stably labelling hepatocytes at 1 day after a two-thirds partial hepatectomy, with β-galactosidase, using a recombinant retroviral vector containing the β-galactosidase gene. Subsequent feeding with 2-acetylaminofluorene led to foci, some of which were composed of β-galactosidase-expressing cells. Using the same labelling protocol, Bralet *et al*.[77] observed that 18% of hepatocytes expressed β-galactosidase at the completion of regeneration after a two-thirds partial hepatectomy. Subsequent chronic treatment with diethylnitrosamine (DEN) resulted in many HCCs of which 17.7% of the tumours expressed β-galactosidase, leading to the conclusion that a random clonal origin of HCC from mature hepatocytes was operative in the model.

As discussed above, there is now compelling evidence that oval cells/HPCs are at the very least bipotent, capable of giving rise to both hepatocytes and cholangiocytes. The fact that oval cell activation (ductular cell reaction) precedes the development of HCC in almost all models of hepatocarcinogenesis and invariably accompanies chronic liver damage in humans,[21,31,34,78] makes it almost certain that the mature hepatocyte is not the cell of origin of all HCCs, indeed perhaps only a small minority of HCCs are derived from the mature hepatocyte. The fact that oval cells/HPCs can be infected with HBV is also consistent with a possible histogenesis of HCC from such cells.[79] An origin of HCC from HPCs is often inferred from the fact that many tumours contain an admixture of mature cells and cells phenotypically similar to HPCs. This would include small oval-shaped cells expressing OV-6, CK7 and 19, and chromogranin-A, along with cells with a phenotype intermediate between HPCs and the more mature malignant hepatocytes.[80] Likewise, foci of small cell dysplasia (possible preneoplastic lesions) have an HPC phenotype while foci of large-cell dysplasia, whose relationship to HCC is unclear, do not have an HPC phenotype.[81] Cells resembling HPCs (OV-1+ or OV-6+) have also been noted in hepatoblastoma.[78] This tumour, the most common liver tumour in childhood, is widely believed to be derived from a multipotent progenitor cell, and can even have structures mimicking intrahepatic bile duct formation with the formation of a ductal plate-like structure.[82] Cells with an HPC phenotype have also been noted in a relatively rare subset of hepatic malignancies where there are clearly two major components, an HCC component and a cholangiocarcinoma component, again suggestive of an origin from a bipotential progenitor.[83] Direct evidence of a role for oval cells in the histogenesis of HCC can also be obtained experimentally. Dumble *et al*.[84] isolated oval cells from p53 null mice and when the cells were transplanted into athymic nude mice they produced HCCs. Thus, HCCs in particular, like many tumours, are heterogeneous populations in which many cells are probably terminally differentiated (reproductively sterile) or transit amplifying cells with limited division potential, while at the same time some cells may have stem cell-like properties. In many human tumours, it is becoming apparent that only tumour stem cells are capable of 'transferring the disease'. For example, in human acute myeloid leukaemia, only the CD34+CD38– cells are capable of transferring the disease to NOD/SCID mice, while in human breast cancer, the CD44+ESA+CD24–/low fraction has a similar potential.[85] It would be of enormous interest to know if HPCs in HCCs are the only cells capable of propagating the tumour in immunodeficient mice.

## Conclusions

In this chapter we have tried to summarize the role of the several cell lineages that might be involved in liver regeneration in the virally infected and chronically damaged liver (see Plate 1.3, facing p.786). The ability of hepatocytes, the unipotent cholangiocytes and the bipotent oval/HPCs to contribute to liver regeneration is not in doubt, although the identity of the cells within the parenchymal mass and biliary tree deserving of the appellation of 'stem cells,' is still unclear. The role of extrahepatic cells in liver regeneration, in particular HSCs, is also uncertain with claims for and against a participation in the regenerative process. However, HSCs do

contribute to the scarring which is an inevitable feature of the chronically damaged liver and the evidence proffered for an origin of many HCCs from oval/HPCs is becoming increasingly persuasive.

# Chapter 2
# Hepatic immunology

Cliona O'Farrelly, Robert H Pierce, Nicholas Crispe

## Overview

The liver represents a unique immunological environment, and this has major implications for our understanding of liver pathology. Until recently, the immune system has been viewed as a single circulating system, with cellular and molecular components designed to patrol the body, constantly on the alert to detect potential harm. However, a more sophisticated view of immunology is emerging, in which the unique features of specific regional immune systems function, sometimes to preempt and sometimes to complement systemic immune mechanisms. Several organs in the body, including the gut, lungs, uterus and of course the liver, are now recognized to have specialized local immune systems that respond to specific immunological challenges offered by distinctive sets of locally presented antigens, both harmful and harmless. The large volume of blood from the gastrointestinal tract bearing dietary antigens and those derived from commensal microbes, and potentially laced with pathogens and toxins, provides specific challenges for the hepatic immune system. The fact that the intestine is a frequent site of carcinogenesis and the large circulating blood supply constantly exposes the liver to encounter with any possible metastatic cells, makes it a potentially important site of tumour surveillance. The liver's role in detoxification of ingested toxins may also contribute to increased risk of local malignancy, due to exposure to and metabolic activation of carcinogens. In addition, neo-antigens may result from active hepatic xenobiotic metabolism (particularly by the P450 oxidase system), running the risk of inadvertent haptenation of self proteins, thus promoting autoimmune-type reactivity.

Cellular and molecular components of innate and adaptive immunity that function locally, some of which may originate locally, combine with elements of the circulating immune system to provide the liver with its own, distinctive regional immune system. This regional immune system is not quietly dozing, waiting for some signal to become active, but is continuously in action, constantly surveying and sampling, distinguishing harmful from harmless stimuli, thus providing persistent protection against infection and malignancy, but tolerating dietary, commensal-derived and self-antigens.

## Relevance of hepatic structure to immunological function

The location, structure and physiological role of the liver are all critical to its immunological function. The liver is the largest solid organ in the body, comprising approximately 2% of the adult body weight, and is responsible for a remarkable variety of functions, including anabolic and catabolic metabolism, exocrine, endocrine, reticuloendothelial and immunologic functions.[1] The liver represents a unique tissue microenvironment, reflecting its anatomic location as well as its physiologic and metabolic roles, many of which are hepatocytic, although important liver functions also reside in other cell types. All of these activities require a high-capacitance and low-velocity vascular bed to facilitate exchange between the cellular components of the liver and blood.

### Gross anatomy and blood flow

The gross and microscopic anatomy represent the morphologic solution to multiple physiological demands. The roughly wedge-shaped liver is covered by a fibrous tissue capsule, containing type I collagen, which invaginates into the portal hilus and continues to invest the portal tracts with supportive connective tissue as the portal tracts sequentially arborize, ultimately ending in the portal triad of the hepatic lobule, the functional anatomic subunit of the liver. Within the connective tissue of the portal tracts run similarly arborizing branches of the hepatic artery, portal vein, bile duct and lymphatics.[2] This dual blood supply (portal venous and arterial blood) to the liver is significant for many aspects of hepatic biology and is of particular importance in understanding the liver as a unique immunologic microenvironment. In humans, the liver receives more than a quarter of the total cardiovascular output. Approximately 25–30% of hepatic blood is well oxygenated arterial

blood from the hepatic artery branch of the abdominal aorta.[3] The remaining blood supply comes from the portal vein, which drains the intestines and spleen. This venous blood is low in $O_2$ tension, low pressure and high in dietary products as well as products derived from the commensal gut flora, such as lipopolysaccharide (LPS). In addition, portal venous blood brings bile-derived material reabsorbed from the gut back to the liver, the so-called enterohepatic circulation.[3] As such, the liver is the portal through which foreign molecules from the outside world of the gut must pass on their way to the general circulation.

## The functional subunit: the hepatic lobule

The functional anatomic unit of the liver has been variably described as the 'lobule' or 'acinus', made up of hepatocyte plates and multiple portal triads surrounding a single central vein.[4] The portal structures (the portal venules, hepatic arterioles, bile duct and associated ductules as well as lymphatic channels) are embedded within supportive connective tissue within the portal tract. This connective tissue contains abundant structural fibres of type I collagen (Plate 2.1, found between p.786–7). Under normal circumstances, type 1 collagen is not present to any significant degree in the parenchyma of the lobule.[4] The portal tract vasculature is of the usual, non-fenestrated type and is invested with a basement membrane, which includes collagens type IV and V. Bile ducts and lymphatic channels also have associated basement membrane.[5] The portal tracts must allow for transport of blood into the sinusoidal spaces of the lobule as well as allow bile and lymph to move in the opposite direction, from the lobule to the portal tract. Although there is some evidence suggesting that a small minority (5–10%) of sinusoids receive only arterial blood, it is clear that the majority of the sinusoids contain mixed portal venous and hepatic arterial blood.[6]

The portal tract is delimited by a single ring of adjacent hepatocytes, termed the limiting plate. In addition to hepatocytes, the cells of the hepatic lobule include a specialized type of endothelial cell (liver sinusoidal endothelial cells, LSECs), resident liver macrophages called Kupffer cells, myofibroblast-like hepatic stellate cells (also known as the Ito cell, or the hepatic lipocyte) and resident natural killer (NK) cells (formerly known as 'pit cells'). The LSECs and Kupffer cells are interspersed in a mosaic fashion to make up the sinusoidal lining, although Kupffer cells can also be highly motile and travel within the intravascular sinusoidal space and in the subendothelial space of Disse. Liver resident NK cells and stellate cells reside within the space of Disse. Each of these cell types will be described below, with particular emphasis on their role in modulating immunobiological parameters in the liver.

## The unique vascular architecture of the lobule and its functional consequences

Blood in the lobule slowly percolates along the sinusoidal space within an anastomosing network of hepatic cords or plates, moving towards the central vein. The flow is dynamic and can be affected locally by a number of factors, including contraction of actin-filament-containing stellate cells.[7] Not only do the high-capacitance and low-flow haemodynamics of the lobule facilitate diffusion of molecules between the blood and cells of the lobule, but exchange is further augmented by a unique ultrastructural feature of the LSEC, the fenestrae, or pores (~ 0.1 nm in diameter) which often cluster into sieve-plates.[8] Unlike most other vascular beds, the LSECs lining the sinusoids do not rest on a continuous basement membrane, but rather on a fine, discontinuous scaffolding of collagen type IV and fibronectin.[9] This fine meshwork of collagen IV is dramatically increased during cirrhosis (Plate 2.2, found between p.786–7). Although the cellular components of blood are excluded from passage through the fenestrae, plasma components can freely diffuse into the subendothelial space of Disse and gain access to the apical hepatocyte cell membrane, which is rich in microvilli, increasing the surface area of hepatocyte/plasma interactions. As can be readily appreciated in scanning electron micrographs, the space of Disse in the normal liver is a potential space (expanded pathologically at times by oedema, fibrosis or cellular infiltrates). Scanning electron micrographs show that Kupffer cell pseudopodia often extend into the vascular space to explore passing erythrocytes and other intravascular cells, while other pseudopodia penetrate into the subendothelial space of Disse, where they may make contact with hepatocytes or other cells.[10]

## Hepatic lymph flow and drainage

One consequence of the extraordinary permeability of the normal sinusoidal vasculature is the production of large quantities of protein-rich lymph (~6 g/dL or 80–90% of plasma levels). Under resting conditions, approximately 50% of lymph is formed in the liver and drains from the space of Disse into the portal tract lymphatic channels. Recently, collagen-lined channels have been described which penetrate the hepatocytes of the limiting plate and act as a conduit for the passage of interstitial fluid and, presumably, dendritic cells, into the portal lymphatic space.[11] Large-calibre, efferent lymphatics are also found within the large portal tracts as well as in the subcapsular region.[12]

### Plasma proteins, complement, coagulation factors and acute phase reactants: innate immunity in the liver

Innate immunity is the initial rapid response to potentially dangerous stimuli, including pathogens, tissue injury, stress and malignancy. The liver is the primary site of systemic innate immune responses and hepatocytes and their products are major players. Expression of receptors for inflammatory cytokines and bacterial constituents by hepatocytes mediates the response to systemic inflammatory stimuli by stimulating synthesis and secretion of inflammatory cytokines, acute phase proteins and antimicrobial peptides. Hepatocytes are also the primary producers of complement proteins, key molecular mediators of the innate immune response. The complement system consists of a tightly regulated group of serum zymogens. Activation of the complement cascade can lead to the production of activated protein fragments with a variety of functions, including chemotaxis, opsonization, activation of immune cells as well as target cell lysis. They are also important for liver repair after toxic injury: the complement components C3 and C5 have been shown to be essential for liver regeneration, and to mediate their effect by interacting with key signalling networks that promote hepatocyte proliferation. Mice lacking C3 or C5 exhibited high mortality, parenchymal damage and impaired liver regeneration after partial hepatectomy.[13] In response to pro-inflammatory cytokines – particularly tumour necrosis factor-alpha (TNF-α) and interleukin (IL)-6 – hepatocytes increase the synthesis of plasma acute phase reactants such as C-reactive protein, amyloid and fibrinogen, which facilitate tissue regeneration as part of the systemic immune activation. These cytokines and granulocyte-macrophage colony-stimulating factor (GM-CSF) are also known to have an important role in liver regeneration.[14] Hepatocytes also produce serum mannose-binding lectin, which recognizes microbial-specific sugar motifs, leading to activation of the immune system and microbial clearance through opsonization.[15]

## Hepatic reticuloendothelial cells

Kupffer cells represent the largest population of tissue-resident macrophages in the body. They are interspersed with LSECs in a mosaic fashion to make up the cellular aspect of the sinusoidal lining (Plate 2.3, found between p.786–7). They can be highly motile and are active phagocytes, playing an important role in surveillance and uptake of intravascular debris, including effete cells (particularly erythrocytes), bacteria and other blood-borne particulates.[16,17] Taken together, the intra-sinusoidal location of the Kupffer cells, the high-capacitance/low-flow haemodynamics of the liver, the location of the liver 'downstream' of the portal circulation and the diverse sets of cell surface receptors present on the Kupffer cells, all significantly contribute to making the liver an efficient 'filtration system' for the blood. The hepatic reticuloendothelial system is not simply a passive filter, but also functions as a sentinel to identify microbial threats and activate both innate and adaptive immune responses.

The consensus is that that Kupffer cells are derived from circulating bone marrow-derived monocytes. However, myeloid stem cells have been demonstrated in adult liver,[18] suggesting local development of perhaps some populations and Kupffer cells may also be capable of limited self-renewal.[19] It is likely therefore that there are several populations of Kupffer cells and it is not surprising that there is considerable overlap in phenotypic markers between Kupffer cells and 'newly recruited' monocytes/macrophages, or for that matter, other closely related myeloid-derived cell types such as liver dendritic cells.[20] In mice and rats, the presence of F4/80 antigen (which becomes expressed as monocytes mature into tissue resident macrophages) on sinusoidal liver cells has been used to 'define' Kupffer cells, but low levels of F4/80 have also been reported to be expressed on dendritic cells as well. Using electron microscopy, Kupffer cells can be identified by endogenous peroxidase localized to the rough endoplasmic reticulum and perinuclear envelope.[21]

### Kupffer cells as reticuloendothelial phagocytes

To facilitate this reticuloendothelial function, Kupffer cells are endowed with a number of cell surface receptors and receptor complexes, including a variety of complement receptors (CR), Fc-receptors and receptors for lectin-containing opsonins such as plasma mannose-binding lectin. Human Kupffer cells also express CR1 (CD35), CR3 (Mac-1; CD11b/CD18) and CR4 (CD11c/CD18, p150/95).[22] These receptors appear to have multiple ligands apart from complement-derived proteins, including intercellular adhesion molecule-1 (ICAM-1) and polysaccharides of microbial and host origin.[23] Murine Kupffer cells appear to have some significant differences in receptor expression patterns. For instance, it has been reported that Kupffer cells in mice do not express significant amounts of CD11c.[24] Kupffer cells express both high-affinity Fcγ receptors, which facilitate phagocytosis of IgG-coated particles, and receptors for IgA.[25,26] This ability to bind IgA-coated particles is thought to represent an important 'second line of defence' in the case of a breach of lower gastrointestinal mucosal immune barriers. In addition to these opsonin receptors, Kupffer cells express galactose and mannose receptors[27] and scavenger receptors, which are capable of directly binding microbial surface compo-

nents such as sugars and polyanionic moieties,[28] as well as receptors for bacterial N-formylmethione-containing peptides.[29] The capacity of Kupffer cells to phagocytose intravenously-injected latex microspheres is illustrated in Plate 2.4 (found between p.786–7).

## Toll-like receptors: sentinels of innate immunity

Toll-like receptors (TLRs) represent an evolutionarily conserved group of molecular pattern recognition receptors, which bind different microbe-derived molecules and activate phagocytes including Kupffer cells.[30] At the time of writing, 10 mammalian TLRs have been identified, all of which function through receptor-associated kinases.[31] The TLR may associate with other non-TLR cell surface receptors (such as CD14 in TLR4-binding of enodotoxin [lipopolysaccaride, LPS]) or may form heterodimers with other TLRs to achieve unique binding specificities. In the prototypic LPS-driven activation of TLR4 signalling in macrophages, NF-κB is activated, leading to production of pro-inflammatory cytokines (TNF-α, IL-10, IL-12, interferon-gamma – IFN-γ), as well as upregulation of microbicidal mechanisms such as the production of reactive oxygen and nitrogen species. Kupffer cells may represent a unique population of tissue-resident macrophages in that they are subjected to unusually high basal levels of gut-derived TLR ligands such as LPS.[32,33] As a consequence of this chronic LPS stimulation, Kupffer cells are thought to constitutively produce IL-10, leading to the establishment of the predominant anti-inflammatory cytokine milieu in the liver.[34]

## Linking to adaptive immunity: cytokines, chemokines and antigen presentation

Like other macrophage populations, Kupffer cells play an important role in activating adaptive immune responses and integrating adaptive and innate immune functions. Depending on the context, Kupffer cells can produce pro- and anti-inflammatory cytokines as well as other immune-regulatory molecules such as prostaglandins, reactive oxygen and nitrogen species and chemokines.[35] In fact, Kupffer cell-derived chemokines have been shown to play an important role in the recruitment of NK cells, dendritic cells, macrophages, neutrophils and lymphocytes in various experimental settings.[36–40] Kupffer cells have also been shown to play a role in the determination as to whether inflammation in the liver is biased towards a Th1- or Th2-type response.[41,42] In addition to the production of immunemodulatory molecules, Kupffer cells can play a direct role in adaptive immunity by functioning as antigen-presenting cells. Numerous studies have shown that Kupffer cells can cross-present antigen, and present antigen both in the context of major histocompatibility complex (MHC) class I[43] and class II molecules.[44] Although in certain experimental conditions, Kupffer cells are capable of expressing positive co-stimulatory molecules and stimulating naïve CD4 and CD8 T cells,[45] antigen presentation by Kupffer cells is generally found to be tolerogenic, and this may involve expression of negative co-stimulatory molecules such as PD-L1.[46]

## Dendritic cells

Dendritic cells (DCs) are bone marrow-derived cells, which are thought to represent the critical antigen-presenting cell required for the stimulation of naïve T cells. Morphologically, DCs show thin membranous projections and are currently believed to be derived from both myeloid and lymphoid lineages, although the latter is controversial. Immature DCs can be found residing within the epithelial compartment of organs such as the gut, skin and lungs, well positioned to intercept microbial antigens. After capturing antigen, DCs begin to mature, and transport the antigens to draining lymph nodes to initiate an adaptive immune response.[47] The regional lymph nodes draining the liver to which the DCs presumably migrate include the hilar, hepatoduodenal ligament lymph nodes and the caval lymph nodes, which include the hepatic artery and portal vein nodes.

The maturation of DCs depends on signals from the environment, including cytokines and the engagement of pattern-recognition receptors that respond to conserved structural motifs of viruses and bacteria.[48] Thus, microbial endotoxin engages TLR4 and TLR2, while structural features of microbial DNA (CpG) engage TLR9. In the presence of these signals, full maturation of DCs occurs. In contrast, if such signals are absent, DCs may differentiate to a semi-mature state, in which they will interact with T cells to promote abortive T-cell differentiation, or suppressor rather than effector T-cell function.[49]

Only recently have investigators begun to focus on liver-specific DC populations, and the evidence suggests that distinct subpopulations of liver dendritic cells bias the immunological microenvironment of the liver towards tolerance. Hepatic DCs are present in very low numbers in fresh tissue but they can be expanded upon stimulation with Flt3-ligand. They are then found to have the phenotype of immature DCs, expressing low MHC class II as well as low levels of the co-stimulatory molecules CD80 and CD86. These cells are likely to induce tolerance rather than activation of CD4+ cells.[50–52] Also, a recent study comparing human DCs obtained from surgical explants of skin and liver demonstrated that liver-derived DCs lack CD1a, produce IL-10 and are less efficient at stimulating naïve T cells.[53] There is evidence to suggest that hepatic DCs may differentiate locally in the liver from stem cells. Normal liver is rich in

differentiating haematopoietic stem cells[54–56] and some express the myeloid differentiation marker CD33.[18] Cytokines required for haematopoietic lineage cell proliferation are also found in adult liver including TGF-β, IL-7, IL-10, IL-15 and GM-CSF.[57,58] The normal liver therefore has a cytokine milieu conducive to DC differentiation. Interestingly, transforming growth factor-beta (TGF-β), possibly expressed by hepatocytes, inhibits the maturation of DCs, thus preventing them from becoming activating antigen-presenting cells, while promoting their expansion in GM-CSF.[51]

### Antigen presentation by liver sinusoidal endothelial cells

The immunological role of liver sinusoidal endothelial cells (LSECs) is a subject of debate. Presentation of antigen and activation of T cells has been shown to be a property of LSECs.[59] Physiologically, LSECs play an important role in filtration, endocytosis and regulation of sinusoidal blood flow. Although they possess fenestrations with a mean diameter of approximately 100 nm, particles are excluded. Thus, LSECs function as a barrier between the macromolecules in the sinusoidal lumen and hepatocytes. Receptor-mediated uptake of macromolecules occurs quickly and efficiently via various pattern-recognizing receptors such as mannose receptors. LSECs have a unique immune phenotype, expressing markers typical of cells of myeloid lineage (CD1, CD4, CD11c), even though the evidence suggests that these cells differentiate from hepatocyte progenitors. Thus, LSECs resemble immature DCs more than typical microvascular endothelial cells from other organs, and seem to be a new type of organ-specific antigen-presenting cell.[60] LSECs constitutively express MHC class II molecules together with CD80, CD86 and CD40, indicating an antigen-presenting function that will result in activation of CD4+ T cells.[61] However, CD4+ T cells primed by antigen-presenting LSECs fail to differentiate towards effector Th1 cells but express high levels of immunosuppressive cytokines, including IL-10 and IL-4. This may be due to the prostenoids and TGF-β secreted by LSECs, both of which are known to limit T-cell activation. Interestingly, antigen presentation to CD8+ T cells by LSECs *in vivo* leads to CD8+ cell proliferation followed by the development of antigen-specific tolerance. These cells also lose their ability to respond to specific antigen upon restimulation.[62,63]

## Hepatic lymphocytes

### Circulating T cells with α/β antigen receptors

T lymphocytes expressing clonotypic receptors coded for by rearranged genes normally circulate through the blood, lymphatic vessels and lymphoid organs in a resting state. Activation depends on encounter with a cell that expresses an HLA (human leucocyte antigen) molecule with which the T cell can interact, carrying a peptide for which the T-cell receptor (TCR) is specific. Thus, CD4+ T cells may only be activated by cells bearing HLA class II molecules, while CD8+ T cells may be activated by cells expressing HLA class I molecules. In addition to the signal through the TCR, the outcome of T-cell activation is determined by a series of other intercellular signals, collectively termed co-stimulation. T cells subjected to TCR signals in the presence of strong co-stimulation typically proliferate, mature and become able to deliver defensive immune functions, and may further differentiate into memory cells that provide enhanced protection against a second encounter with the same antigen.

When fully activated, CD8+ T cells display two known functions: cytotoxic killing of target cells, and the synthesis of cytokines including IL-2, IFN-γ and TNF-α. The cytotoxic function is mediated by two distinct mechanisms: the cell surface expression of a cytotoxic ligand, FasL, and the targeted delivery by exocytosis of perforin and granzymes. All of these mechanisms cause apoptosis of the target cell.[64] The defensive function of CD8+ T-cell cytotoxicity is manifest as the elimination of virus-infected cells early in the infection cycle, before the assembly of new infectious virions, but this mechanism may also cause immunopathology. Thus, in a transgenic mouse model of hepatitis B, the capacity of CD8+ T cells to synthesize IFN-γ was important in suppressing viral RNA transcription, while the cytotoxic function was more closely linked to hepatocyte damage.[65]

Activated CD4+ T cells are potentially cytotoxic through their expression of FasL, but they do not secrete granules containing perforin and granzymes. They do secrete cytokines and chemokines. Individual CD4+ T cells may secrete a wide variety of cytokines, or they may become polarized to secrete pro-inflammatory cytokines including IFN-γ and TNF-α (in Th1 cells). Alternatively, they produce a set of cytokines that promote B-cell differentiation and parasite expulsion, but suppress inflammation (in Th2 cells). The signature cytokines of Th2 cells are IL-4, IL-5 and IL-10. A population of activated cells frequently becomes polarized such that either Th1 or Th2 cells predominate. Mixtures containing both kinds of T cells are unstable, as Th1 cells suppress Th2 function, and vice versa.[66] Activated CD4+ T cells may also acquire regulatory function, in which they suppress the activation of other T cells. A subset of regulatory CD4+ T cells differentiates as a result of encounter with self-antigens in the medulla of the thymus, where many self-proteins from diverse tissues are expressed as a mosaic, each in a small proportion of medullary epithelial cells.[67] It is controversial whether peripheral encounter

with antigens on tissue cells or semi-mature DCs simply activates pre-existing regulatory CD4+ T cells, or instead drives undifferentiated CD4+ T-cell precursors to acquire regulatory function.[68]

## α/β T cells in the liver

The normal, healthy liver contains a resident population of α/β T cells, which are found in the sinusoids, in the space of Disse, and in the portal tracts. However, this population differs from the circulating T-cell pool in several respects. First, the normal ratio of CD4+ to CD8+ T cells is reversed (Plate 2.5, found between p.786–7) and CD8+ T cells outnumber the CD4+ T cells in the liver.[69] Second, liver T cells include a high frequency of cells expressing activation markers, and of cells secreting cytokines.[70] Third, liver T cells contain an unusually high frequency of cells undergoing apoptosis.[71]

Many hepatic T cells are cytotoxic effector cells, and kill target cells upon TCR ligation. The majority rapidly secrete cytokines of the inflammatory (Th1/Tc1) type upon pharmacological stimulation or CD3/TCR cross-linking.[72] These include IFN-γ, TNF-α and/or IL-2. Production of pro-inflammatory cytokines by hepatocytes and Kupffer cells is clearly critical for activation of local T-cell populations in the liver, and promotes the inflammatory Th1 context characteristic of the healthy liver.[73] About 5% of human hepatic T cells produce IL-4, a cytokine of the Th2/Tc2 (helper) type, but do not produce IL-5.[72,74] Interestingly, while cytokine production is generally polarized at other sites to the mutually inhibitory Th1/Tc1 or Th2/Tc2 profiles, the majority of hepatic T cells that produce IL-4 also produce IFN-γ, indicating that they are of the Th0 type, rather than conventional Th2 cells. Th0 cells are thought to either be undifferentiated or regulatory cells and there is evidence that both of these T-cell types are present in the liver.

The excess of CD8+ T cells over CD4+ T cells among the resident liver lymphocytes is likely to reflect activation of specific recruiting mechanisms from the peripheral blood. The cytokine milieu and expression of adhesion molecules particularly by liver sinusoidal endothelium will affect this process.[75] Liver sinusoidal endothelium expresses a high level of ICAM-1 as well as vascular cell adhesion molecule-1 (VCAM-1) and vascular adhesion protein-1 (VAP-1).[76–78] Activated T cells express lymphocyte function antigen-1 (LFA-1), the counter-receptor for ICAM-1, and CD8+ T cells express more than CD4+ T cells.[79] The VAP-1 molecule also preferentially promotes CD8+ T cell adhesion. On this basis, the liver will preferentially trap activated CD8+ T cells from a mixture that passes through the sinusoids.[80]

The presence of activated T cells in the normal liver is mysterious. A large proportion of lymphocytes in the healthy gastrointestinal tract – another important site of regional immunity – express high levels of activation markers, suggesting ongoing immunological activity.[81] Another possibility is that liver T cells share some features with resident T cells in other non-lymphoid tissues. It has recently become clear that many tissues, including skeletal muscle, body fat, kidney, lungs and brain, contain T cells, and that many of these have an activated and/or memory phenotype. Some of the tissue T cells result from the 'diaspora', a redistribution of memory T cells from lymphoid to non-lymphoid tissue at the end of a primary immune response.[82,83] Tissue memory T cells differ from lymphoid (central) memory cells, in that they have more functional activity *ex vivo*, and a lower rate of apoptosis.[84] The activation status of liver T cells places them in this category, although they also contain a high frequency of cells undergoing apoptosis.

The activation and apoptosis of liver T cells could be linked, as part of the induction of liver tolerance. The liver is involved in T-cell tolerance on several levels. First, the process of oral tolerance maintains T-cell unresponsiveness to harmless antigenic components in food. Oral tolerance depends on the portal circulation, which carries food antigens and antigen-presenting cells from the gut to the liver. Thus, a surgical porta-caval anastomosis prevents the induction of oral tolerance, while injection of antigen-presenting cells into the portal vein promotes systemic tolerance.[85] The co-existence of activated and apoptotic T cells in the liver could be explained partly by the induction of oral tolerance. The activation and apoptosis of liver T cells also co-exist during liver transplantation tolerance. In many mammalian species, including mice, rats and humans, a liver allograft may be accepted without immunosuppression, and the tolerance induced by the liver graft is systemic, because it promotes the survival of normally immunogenic allografts from the same donor, such as kidney grafts. In a recently allografted liver, there is a large T-cell influx, but these T cells undergo apoptosis, leaving the liver graft unharmed.[86] This has been interpreted as the induction of tolerance through activation-induced cell death in the T cells.

Apoptotic CD8+ T cells are also found in the liver as a consequence of the activation of T cells at other sites. Thus, in experimental influenza infection in mice, the use of a peptide-MHC tetramer to identify CD8+ T cells specific for a particular flu-encoded epitope found these cells in the lungs at the time of peak virus infection, but subsequently in the liver.[87] Similarly, the activation of mouse CD8+ T cells using an antigenic peptide causes massive pooling of dying T cells in the liver.[88] The extent to which these phenomena are liver-specific is controversial, but the accumulation of activated CD8+ T cells during systemic T-cell activation is sufficient to cause hepatocyte damage, evident both histologically

and in terms of elevated serum amino-transaminase enzymes.[89]

## Non-classical lymphoid populations in the liver

While conventional single-positive CD4+CD8– and CD8+CD4– αβ T cells account for many hepatic CD3+ T cells, the liver also contains significant numbers of T cells that express neither CD4 nor CD8 (double-negative) and T cells that are double-positive for both CD4 and CD8, as well as T cells that express the CD8α chain in the absence of the β chain (CD8 $\alpha^{+}\beta^{-}$ cells[90]). A significant proportion of T cells with unconventional CD4/CD8 expression express the γ/δ TCR. Indeed, healthy human liver has a surprisingly high population of γ/δ TCR+ T cells.[91,92]

## T cells with γ/δ antigen receptors.

The identification of the genes encoding the TCR α and β chains resulted in the accidental discovery of a second pair of TCR genes, γ and δ. These genes encode a distinct category of antigen receptors that are expressed on early fetal thymocytes, in γ/δ T lymphocytes resident in many epithelia, and on a small subset of T cells in the circulation, the lymphoid organs, and many tissues including the liver. The specificity and function of γ/δ T cells are much less well understood than is the case for α/β T cells. Many γ/δ T cells arise early in ontogeny, and express TCRs of limited diversity. They are found in significant numbers in the intestinal epithelium, skin, lungs and the pregnant uterus where they respond to the stress-inducible proteins MICA and MICB and CD1c and contribute to tissue remodelling as well as immune surveillance.[93,94] It appears that different γ/δ T-cell subsets have distinct cytokine secretion patterns and thus may have several functions as well as targets.[95] In the mouse, dendritic epidermal T cells of the skin express invariant γ/δ receptors, while cells that populate the female genital tract and tongue also show limited γ/δ receptor diversity. A large population of γ/δ cells is found among the intestinal intra-epithelial lymphocytes, and these cells express more diverse receptors.[92] The availability of gene-targeted mice that specifically lack γ/δ T cells has not revealed a clear and uniform role in the resistance to infection. A full discussion of this issue is outside the scope of the present brief summary, but several contradictory examples are given in the following section on liver γ/δ cells. One aspect of γ/δ T cell function seems to be the maintenance of tissue integrity. The dendritic epidermal T cells of mice respond to stressed keratinocytes in tissue culture, and secrete keratinocyte growth factor. The lack of these cells in gene-targeted mice impairs the healing of skin wounds.[95] In the intestine, infection with the parasitic protozoan *Eimeria vermiformis* usually results in minimal damage to the intestinal mucosa, but in the absence of γ/δ T cells this damage is more severe.[96] The failure to contain *Klebsiella pneumoniae* in the lungs of infected mice that lacked γ/δ cells could also be seen as a failure of tissue integrity,[98] while the correlation of γ/δ cell frequencies with the severity of liver damage in several studies (see below) is also consistent with this view of γ/δ cell function.

## γ/δ T cells in the liver

Up to 35% of hepatic T cells express γ/δ TCRs, making the liver one of the richest sources of γ/δ T cells in the body. There is a striking appearance of γ/δ T lymphocytes in the liver of mice after birth. The majority of hepatic γ/δ T cells express CD8+ or double-negative (DN) phenotypes and NK cell markers (CD56, CD161, KIRs, CD94) and they account for up to 60% of the population of hepatic T cells that co-express NK receptors. Despite their unusually large percentage in normal liver, the role of hepatic γ/δ T cells is unclear, although their heterogeneity suggests several functions. Unlike conventional α/β T cells, γ/δ T cells express oligoclonal or invariant TCRs that recognize soluble non-peptide antigens and stress-inducible proteins, sometimes without the need for MHC restriction. This suggests that T-cell responses to non-peptide antigens through non-classical mechanisms may be of greater importance in the liver than in other organs. Antigenic ligands recognized by γ/δ T cells include phosphorylated thymidine metabolites derived from mycobacteria,[99] bacterial and plant alkylamines[100] and viral glycoproteins.[101] The antigenic targets of hepatic γ/δ T cells are not known, but their high frequency in the liver suggests that they may have an important role in the rapid elimination of microbes and virally infected and tumour cells from the liver, an interface where a large number of external antigens are constantly sampled. The presence of CD1c in the liver has not been definitively documented. Therefore, it is unclear if this molecule plays a role in hepatic γ/δ T-cell activation or if these cells recognize alternative ligands in the liver.[102]

Like intrahepatic α/β T cells, liver γ/δ T cells are activated and appear as large blast cells that proliferate *ex vivo*. In the mouse, liver γ/δ cells are enriched for a subset of receptors encoded by Vγ1 and Vδ6,[103] while in the human, the majority of hepatic γ/δ T cells express Vγ9 and/or Vδ2 chains.[92] Unlike γ/δ cells of the skin, these receptors are neither exclusive to this site nor predominant in it. However, over 20% of hepatic γ/δ T cells do express Vδ3, a receptor rarely found in the blood, suggesting a possible antigen-specific expansion of this cell population within the liver. In tumour-bearing hepatic tissue, there was an expansion of Vδ1+ γ/δ cells which recognize the stress-inducible MICA and MICB molecules that are upregulated as a result of tumour transformation and virus infection.[105]

Bacterial infection of mice with two very different pathogens, *Listeria monocytogenes* and *Leishmania major*, resulted in an increase in the frequency of activated liver γ/δ T cells,[105,106] but it is not clear whether this was a specific response to the infection, or an effect of the accompanying tissue destruction. In the specific setting of very young (14-day-old) mice, the lack of γ/δ T cells caused increased susceptibility to *Listeria* infection.[107] However, in adult mice, specific depletion of the Vγ1 subset of γ/δ cells improved resistance to *Listeria* infection. Thus, different subsets of γ/δ cells might augment or suppress antibacterial immunity.

While γ/δ T cells are thought to have a role in antiviral immunity in the liver, their involvement in hepatitis C is particularly difficult to decipher. In humans infected with hepatitis C virus (HCV), T cells grown from the liver in a cytokine cocktail were enriched in γ/δ cells.[109] In another study, there was an increased frequency of γ/δ T cells using the Vδ1 chain, and this frequency correlated with hepatocellular damage.[110] In contrast, in liver biopsies of humans infected with HCV, quantitative real-time reverse transcriptase-polymerase chain reaction (RT-PCR) indicated a reduction in TCRδ chain RNA compared with markers of α/β T cells.[111] Another study showed selective expansion of classical CD4+ α/β T cells in HCV-infected livers.[112] These data, and many others, are contradictory even on the simple question as to whether HCV causes an increase, or a decrease, in liver γ/δ T cells. It is therefore very difficult to accommodate the data within a unified model.

## Natural killer cells

Natural killer (NK) cells, key players in non-adaptive immune responses, are the predominant innate immunocyte population in the livers of mice and humans, accounting for up to 50% of the total lymphoid pool in the non-diseased liver. The first description of hepatic NK cells used immunohistological analyses of liver tissue from rats to describe large granular cells present in the liver sinusoids. These cells, originally termed pit cells, are capable of spontaneously lysing tumour cell lines and participate in innate immune responses against viruses, intracellular bacteria, parasites and transformed cells.[113–115] The higher numbers of NK cells in liver compared with blood is reflected by higher levels of NK cytotoxic activity that are associated with hepatic mononuclear cells. NK cells are even more elevated in patients with hepatic malignancy.[116–119] NK cells do not have antigen-specific receptors but detect changes in membrane glycoprotein expression on target cells. Their activity is controlled by receptors that mediate activation or inhibition upon ligation of surface molecules on target cells, and by cytokines in the environment such as IFN-γ, IL-2, IL-12 and IL-15. In mice, the NKR-P1 family of molecules, which includes NK1.1, mediates NK cell activation. The only known human NKR-P1 molecule, CD161, does not, although it is present on most NK cells. Human NK receptors that mediate activation include CD16, the Fc receptor for IgG, responsible for antibody-dependent cellular cytotoxicity (ADCC) and cytokine secretion upon ligation by antibody-coated target cells; and the NKG2D molecule which binds to the stress-inducible MICA molecule on target cells. In addition, several other co-stimulatory and adhesion molecules including CD2, CD11a/CD18 (LFA-1), CD69 and CD49d/CD29 (VLA-4) have been implicated in NK cell activation.[120] MHC class I ligation of NK surface molecules (p58.1/p50.1, p58.2/p50.2 and CD94) can result in either activation or inactivation of NK cells with the inhibitory signal exerting a dominant effect over the activating signal. The complex interactions between NK receptors and classical human leucocyte antigen (HLA) class I molecules which present intracytoplasmic peptides (markers of self), between CD94 and the non-classical HLA-E molecule which presents peptides derived from classical class I molecules (a marker of class I turnover), and between NKG2D and the MHC class I-like MICA molecule (a marker of stress) allow NK cells to respond to subtle changes in MHC class I expression and antigen presentation which may occur in tumour cells and virus-infected cells.

### *Natural T cells*

A large proportion of γ/δ T cells in the liver co-express NK markers, as do a significant proportion of α/β T cells. T lymphocytes that co-express NK receptors include phenotypically and functionally diverse populations of cells that can account for more than half of all hepatic CD3+ cells. These T cells have restriction patterns, antigen recognition mechanisms, cytokine profiles and responses to stimulation which differ significantly from conventional T lymphocyte populations and are shared with NK cells. Thus, these cells are called natural T (NT) or NKR+T cells and are thought to represent an evolutionary and functional bridge between innate and adaptive immunity.[90]

### *NKT cells*

In the mouse, a significant population of hepatic NKR+ T cells expresses an invariant TCR consisting of the Vα14Jα281 TCRα chain with little or no N region additions, and a limited number of β chains (Vβ2, Vβ7 and Vβ8). These cells are restricted by CD1.[121,122] They comprise CD4+ or CD4–CD8–DN T cells and express TCR levels intermediate between those on immature and mature thymocytes (and have thus been termed $TCR^{int}$ cells) as well as the NK receptors, NK1.1, Ly49

and IL-2Rα (therefore, they are also known as NK1.1T cells). These cells are characterized by their potent effector function, revealed by their ability to kill tumour cells in the absence of prior antigenic stimulation, and to rapidly produce high levels of both Th1 and Th2 cytokines upon activation through their TCR or NK1.1 molecules. This can mobilize NK cells, other lymphocytes and additional components of the innate and adaptive immune response. Murine NKT cells rapidly produce IL-4 and were thought to have a role in the initiation and regulation of Th2 cell differentiation and antibody isotype switching,[123] although they are not Th2-like as they can also produce IFN-γ, as well as IL-5 and IL-10. NKT cells respond to IL-12 and IL-18, and the liver has been shown to be a rich source of these cytokines. NKT cells cross-reactively recognize α-galactosylceramide (α-Gal-Cer), a glycolipid antigen found in marine sponges. Such recognition is restricted by the MHC-like molecule, CD1d. However, the natural hepatic ligand for CD1d-restricted T cells remains a mystery. There is evidence that NKT cells accumulate in the liver, and it has also been shown that the liver and marginal zones appear to be preferential sites of NKT activation and early NKT cell cytokine production.[124] Preferential residence in the liver raises questions about the reasons and consequences for the accumulation of NKT cells at this site.

There is now significant evidence that NKT cells have a major role in tumour surveillance. Stimulation of Vα14Jα281+ T cells in mice by α-Gal-Cer or IL-12 can result in the prevention of tumour metastasis by a mechanism that is dependent upon IFN-γ production and/or anti-tumour cytotoxicity by NKT cells.[125–128] These findings have encouraged the use of both IL-12 and α-Gal-Cer in patients with malignancy, and phase I trials using both compounds in human patients are ongoing. In contrast to mice, human NKT cells are found in small numbers in healthy liver (0.5% of CD3+ cells) and are not expanded in tumour-bearing tissue.[129] Most human hepatic Vα24+ NKT cells express the Vβ11 chain. They include CD4+, CD8+, and CD4–, CD8– cells, and many express the NK cell markers CD56, CD161 and/or CD69. Importantly, human hepatic Vα24+ T cells are potent producers of IFN-γ and TNF-α, but not IL-2 or IL-4, when stimulated pharmacologically or with α-Gal-Cer.[129]

## Hepatic immunoregulation

The liver appears to represent a tolerogenic local immune environment, based both on transplantation and portal vein tolerance models, in which initial exposure to antigens delivered to the gut and/or directly into the portal circulation preferentially lead to the induction of tolerance rather than immunity.[33] It is well known that liver transplant patients require less immunosuppression than the recipients of other organs. Moreover, additional organs are more likely to be tolerated if transplanted at the same time as the liver, indicating generation of systemic tolerance to antigens expressed on the liver.[130] Several mechanisms are likely to contribute to local tolerogenic effects, all of which will influence hepatic immune responses to local pathological challenge.[33,45,49,61] Recent work has focused on the mechanisms of activation of T cells in the hepatic environment and the subsequent generation of systemic tolerance.[131] There is growing appreciation for the contribution of various lymphoid and antigen-presenting cell populations to local regulation of hepatic immunity and its influence on systemic responses.

### Immune regulation and tolerance: contribution of hepatic NKR+T cells

It is becoming apparent that NKR+T cells are extremely heterogeneous and highly versatile and have important immunoregulatory activities.[132] The high levels of inflammatory cytokines and high proportions of hepatic T cells that display activation/memory phenotypes and exhibit potent lymphocyte-activated killer (LAK) cytotoxic activity suggest that rigorous immunoregulatory control is required in the healthy liver. One such mechanism is via signals through the MHC class I molecules (KIRs and CD94) on NKR+T cells. These receptors (p58.1/p50.1, p58.2/p50.2, p70 and CD94) are expressed by similar frequencies of hepatic NKT cells and NK cells.[119] As outlined above, identical signals can induce activating or inhibitory signals to the cell depending on the nature of the cytoplasmic domains of these receptors. However, KIR cross-linking has been shown to result in an overall net inhibition of TCR-mediated cytotoxicity by hepatic NKT cells, rather than activation.[119] This would suggest either that hepatic NKT cells express more inhibitory than activating KIR receptors, or that the inhibitory signals exert a dominant effect over the activating signals. The contradictory cytokine elaboration patterns of these cells reflect the complexity of their immunoregulatory role.

### The immunoregulatory role of Kupffer cells and hepatic DCs

Kupffer cells play a key role in establishing the tolerogenic milieu of the liver[133–135] and both co-stimulation,[136] and direct killing of activated antigen/alloreactive T cells by Kupffer cells have been shown to be involved.[135] Kupffer cells make pro- and anti-inflammatory cytokines and present antigen. In addition to phagocytosis (Plate 2.4, found between p.786–7), an important role for Kupffer cells is the production of inflammatory cytokines. In the IFN-γ rich hepatic environment, high levels of class II

molecules are constitutively expressed, making Kupffer cells potentially important in the presentation of antigen to CD4+ as well as CD8+ T cells of the adaptive immune system. Kupffer cells and T cells form structured inflammatory foci in the liver in various conditions (Plates 2.6 and 2.7, found between p.786–7). The relative proportions of IL-10, IL-12 and IFN-γ in the cytokine environment of the liver, together with the phenotype of the responding T-cell population, determines whether the outcome of activation will be the generation of an effector T-cell response, or tolerance.

IL-12[136] produced constitutively by hepatic myeloid cells, including monocytes, Kupffer cells and DCs, contributes to the local inflammatory environment. High levels of IL-12 have been demonstrated in healthy liver and it is upregulated in tumour-bearing tissue.[137] IL-12 influences the maturation of NK cells, CD8+ T cells and NKT cells, all of which have potent cytotoxic activities. Murine studies have shown that liver DCs induce IL-10 and IL-4 secretion by mononuclear cells.[138] By contrast, comparatively high numbers of IFN-γ+ cells are induced by bone marrow DCs. Modulation of Th2 cytokine production by donor-derived DCs is likely to contribute to the comparative immune privilege of hepatic allografts.

### Non-classical antigen presentation and its consequences

Expression of the classical restriction elements class I and class II MHC molecules that present small peptides to conventional CD4+ and CD8+ T cells is well described in human liver. The presentation of antigen to other non-classical populations of hepatic T cells has not been explored in any great detail. This issue is particularly complicated as the targets for these T cells may not even be exclusively protein in nature. NKT cells respond to the glycolipid α-Gal-Cer presented by CD1d, but other human non-invariant NT cell clones from the liver, peripheral blood and bone marrow are also restricted by CD1.[139,140] Human CD1 molecules, CD1a, CD1b, CD1c and CD1d, are structurally related to MHC molecules and can bind lipid molecules and present them to T cells leading to their activation. CD1a, CD1b and CD1c can present various lipid and glycolipid components of bacterial cell walls, including mycolic acids, inositol-containing phospholipids, and mycolyl glycolipids, to CD8+ and double-negative CD4–CD8– T cells while the significantly more divergent CD1d isoform presents glycosylceramide and glycosyl-phosphatidylinositols antigens to Vα24JαQ+ T cells. Recently, CD1a has been shown to present lipopeptides derived from *Mycobacterium tuberculosis*.[141] While the human liver contains CD1d-reactive Vα24JαQ+ T cells and γ/δ T cells of unknown restriction, additional populations of CD1a, CD1b, CD1c and CD1d-reactive T cells may also be present. The high numbers of multiple populations of DN cells, NT cells and γ/δ T cells, all of which have been shown in various systems to recognize CD1 isotypes, suggest that the liver is a specialized site of CD1-restricted T cells that respond to lipid and glycolipid antigens. Populations of γ/δ T cells of limited TCR variability are restricted by MICA and MICB. It is unknown whether these restriction elements are expressed in the liver, although it is likely that these and additional recognition molecules will be described, leading to the identification of further populations of lymphocytes of limited TCR variability. Although liver DCs have lower CD1d surface expression than hepatocytes, they have been shown to be potent stimulators of IFN-γ and IL-4 release by liver NKT cells when pulsed with α-Gal-Cer *in vitro* or *in vivo*.[142] Liver DCs are thus potent stimulators of pro-inflammatory cytokine release by NKT cells, are activated themselves in the process of NKT cell activation, and express an activated phenotype after the NKT cell population is eliminated following α-Gal-Cer stimulation.

### Leucocyte circulation and hepatic infiltration

Hepatic-specific accumulation of lymphocyte populations will inevitably influence subsequent immune responses. Molecular and physiological features determine which subpopulations are selected.[75] The sinusoids allow oxygenated blood arriving from the portal tract to percolate slowly past the hepatocyte cell plates, allowing maximal exchange of cells and materials before the blood leaves the liver through the central vein branches that run to the hepatic vein (described above). Thus, cells entering the liver can arrive through vascular endothelial cells lining the portal vein in the portal tract, through the microvascular endothelial cells that line the sinusoids or through the terminal hepatic veins. Expression of adhesion molecules including chemokines and their receptors, by LSECs and circulating lymphocytes plays a determining role in controlling leucocyte infiltration of hepatic tissue. For example, expression of CCL21 in association with mucosal addressin cell adhesion molecule-1 (MADCAM-1) in the portal tracts of patients with primary sclerosing cholangitis promotes recruitment and retention of CCR7+ mucosal lymphocytes, leading to the establishment of chronic portal inflammation and expanded portal-associated lymphoid tissue typical of this hepatic autoimmune disease.[143]

## Hepatic influence on the systemic immune system

### Generation of tolerance

The transplantation of an allogeneic liver appears to induce systemic immune tolerance, which is specific for antigens expressed on the transplanted liver.[144] This may be manifest as acceptance of a kidney allograft or a skin

graft expressing the same antigens. Such tolerance is antigen-specific, as third-party allografts expressing distinct antigens are rejected.[145] This tolerance may result from multiple mechanisms, including T-cell inactivation, or the activation of anti-inflammatory T cells following antigen presentation by liver DCs, Kupffer cells or LSECs (see above). An alternative hypothesis is that liver transplantation tolerance is due to the dispersal of small numbers of liver-derived tolerance-promoting antigen-presenting cells throughout the host ('microchimerism').[146] This hypothesis requires that such liver-derived cells should have distinctive properties, as the 'passenger leucocytes' of other solid organ allografts, such as kidney grafts, promote immunity and graft rejection rather than tolerance.[147]

The induction of liver transplantation tolerance raises the possibility that other antigens expressed in the liver, including exogenous antigens encoded by pathogens, could induce systemic tolerance. One remarkable example where this may occur is in HCV infection. In experiments in which peptide-MHC tetramers were used to identify circulating HCV-specific CD8+ T cells, these cells were unable to synthesize IFN-γ in response to stimulation, while other CD8+ T cells specific for different pathogens responded well.[148] As a strong CD8+ T-cell response is associated with virus elimination in both human and chimpanzee HCV infections,[149,150] this selective CD8+ T-cell inactivation may promote virus persistence. The possible involvement of liver-specific tolerance mechanisms in the persistence of other infections of the liver, such as malaria, has not been extensively investigated.

### Deletion of activated T cells

An important biological property of the liver linked to systemic immune regulation is the accumulation and apoptosis of CD8+ T cells that occurs during a systemic immune response. This effect has been observed in diverse immune responses: during the lymphopenia associated with diabetes in BB rats;[151] in the immune response of TCR transgenic T cells to a systemically administered peptide;[152,153] and during the response to influenza infection that is localized to the respiratory system.[154] This trapping phenomenon is augmented when the liver vasculature is able to present the antigen, but is not dependent on it.[155] Activated CD8+ T cells bind in part to ICAM-1 and in part to VCAM-1, both of which are expressed in the liver.[156] Once trapped in the liver, the T cells die by unknown mechanisms. Interestingly, the liver in the diabetes-prone BB rat is deficient in NKT cells, suggesting a role for these cells in the regulation of this process.[157] The significance for the overall kinetics and magnitude of systemic immune responses is not understood. One possibility is that the liver acts as a 'sink' for activated T cells, limiting the numbers that are able to participate in a defensive response, or competing against the formation of memory cells that migrate into other tissues and take up long-term residence.[158]

## Concluding remarks

In this chapter, we have summarized the distinctive features of innate immunity, natural lymphocytes and adaptive immune cells that occur in the liver. The haemodynamics and micro-architecture of the liver promote interactions with circulating immune cells, while the passage of material from the intestine presents problems in balancing immune tolerance with host defence, and reactive environmental toxins from the same source may create new antigens and pose a risk of oncogenesis. As a result of these multiple conflicting demands, the liver has evolved a baseline state of mixed tolerance and immunity. The immunity is manifest in the adhesion and antigen-presenting properties of the LSECs, the high frequency of activated T cells, and the abundance of inflammatory cytokines including IFN-γ and TNF-α. The tolerance is manifest during CD8+ T cell apoptosis, in liver transplantation tolerance, by high levels of inhibitory cytokines including IL-10 and TGF-β and possibly in the persistence of some liver pathogens including HCV. The task for the future is to determine how these contradictory states can co-exist in the liver, and what this means for the understanding and amelioration of liver disease.

# Section II
# Clinical Aspects of Viral Hepatitis

# Chapter 3
# Clinical features of hepatitis

Arie Regev, Eugene R Schiff

Viral hepatitis A through E may be associated with a wide spectrum of hepatic and extrahepatic clinical manifestations. Hepatitis A and E are both self-limited, faecally spread diseases, whereas hepatitis B, C and D are transmitted parenterally and may occasionally lead to chronic hepatitis. In contrast to hepatitis B, C and D, hepatitis A and E have never been shown to evolve into a chronic liver disease. Hepatitis B has a low chronicity rate (<5%) in healthy adults and a high chronicity rate (>90%) in infants, whereas hepatitis C has a high chronicity rate (80–85%) in all age groups. Hepatitis D affects only individuals with hepatitis B infection. Despite distinct differences in many clinical aspects, general clinical features are common to all the viral hepatitides.[1–3]

## General features

### Acute viral hepatitis

Acute hepatitis A to E run similar clinical courses, and there are no features that unequivocally distinguish the individual types. Typically, most patients experience a mild disease, usually without symptoms, that is marked only by a rise in serum aminotransferase levels. Alternatively, the patient may be anicteric but suffer gastrointestinal and influenza-like symptoms. Such patients are likely to remain undiagnosed unless there is a clear history of exposure. Increasing grades of severity are then encountered, ranging from a mild icteric disease, which is associated with almost universal recovery, to fulminant, fatal viral hepatitis.

#### *Prodromal phase*

The usual icteric disease in adults is marked by a prodromal period of low-grade fever, malaise, myalgia and headache. This presentation may follow an incubation period that may range from 2 weeks to 6 months. Although the incubation periods of the various hepatitis viruses differ, they can overlap sufficiently to prevent an accurate diagnosis. Anorexia, nausea and vomiting commonly occur early in the illness. Right upper abdominal discomfort and ache may develop but severe abdominal pain is unusual. There may be changes in taste and smell with resultant aversion to food and often to cigarettes and alcohol. Less commonly, pharyngitis and cough may also occur. Low-grade fever is common, although rigors are unusual. The prodromal phase usually lasts from 3 to 7 days, but may continue for up to 3 weeks. Occasionally, headache may be severe and, in children, may be associated with photophobia and neck rigidity. Protein and lymphocytes in the cerebrospinal fluid (CSF) may be raised. In approximately a quarter of the patients, predominantly but not exclusively those with hepatitis B, the early prodromal phase is characterized by a serum sickness-like syndrome, consisting of fever, arthralgia, arthritis, rash and angioneurotic oedema. These symptoms usually begin 2–3 weeks before jaundice develops and resolve before jaundice becomes apparent. Less frequently, they may persist for variable periods during the course of the acute illness.

Laboratory findings during the prodromal phase commonly include leukopenia and relative lymphocytosis, frequently with atypical lymphocytes. The most sensitive tests to identify the development of hepatitis are serum levels of alanine aminotransferase (ALT) and aspartate aminotransferase (AST). Serum ALT and AST are the first biochemical tests to become abnormal, typically preceding the development of jaundice. They may reach levels greater than 100 times the upper limit of normal, ALT levels usually being higher than AST. The serum level of alkaline phosphatase (AlkP) is abnormal in most cases however, it rarely exceeds four times the upper limit of normal. The exception is the uncommon variant of cholestatic viral hepatitis, which has been described in hepatitis A, B and C. Serum levels of lactate dehydrogenase (LDH) are usually elevated, but the increase is mild compared with the elevation of the aminotransferases.

### *Icteric phase*

The prodromal period is followed by darkening of the urine and lightening of the faeces. Symptoms subside slowly and jaundice develops. The temperature returns to normal within a few days and bradycardia may develop. Appetite returns, and abdominal discomfort and vomiting cease. At this time, pruritus may appear transiently for a few days. In some patients the prodromal symptoms may subside without a subsequent jaundice. This anicteric form appears to be more common among children with hepatitis A and individuals with hepatitis C. The duration of the icteric period ranges from a few days to 6 weeks. During the active illness physical examination may be unrevealing or may identify mild lymphadenopathy (involving particularly the posterior cervical region), mild hepatomegaly and occasionally splenomegaly. Generalized lymphadenopathy is not a feature of acute viral hepatitis. The liver is palpable in 70% of patients however, marked enlargement is uncommon. The liver edge is usually smooth, soft and slightly tender to palpation. The spleen is palpable in 10–20% of patients. A significant weight loss may occur during the acute illness and a few vascular spiders may appear transiently on rare occasions. The appearance of jaundice in the icteric phase usually indicates serum bilirubin level in excess of 2.5 mg/dL. Both conjugated and unconjugated bilirubin levels are elevated, but total serum bilirubin level usually does not exceed 20 mg/dL. A level in excess of 30 mg/dL suggests an additional bilirubin load due to overproduction (haemolysis) or impaired secretion (renal failure). Serum levels of alpha-fetoprotein (AFP) may increase, possibly due to hepatocellular regeneration.[4] AFP levels may be higher in patients with fulminant hepatitis.

### *Convalescent phase*

After the icteric period most patients make an uninterrupted recovery. In children, improvement is particularly rapid. The stools regain their colour, appetite becomes normal and pruritus abates. After the resolution of jaundice, lassitude and fatigue may persist for several weeks. The enlarged liver and spleen begin to shrink gradually. Clinical and biochemical recovery is usual within 6 months of the onset in almost all patients with acute hepatitis A, in the majority of adult patients with hepatitis B (>95%) and in a minority of patients with hepatitis C (15–20%).

### *Acute (fulminant) liver failure*

All types of viral hepatitis may lead to acute (fulminant) liver failure, although it is an uncommon complication in healthy individuals. Acute liver failure occurs more frequently in individuals who become infected past the age of 40 years and in those with a pre-existing chronic liver disease.[5–8] Hepatitis C is considered a very rare cause of acute liver failure in the Western world. Fulminant hepatitis usually develops within 10 days in patients with viral hepatitis. The patients may become hyperkinetic and combative. This may develop so rapidly that jaundice is inconspicuous, and the diagnosis is confused with an acute psychosis or meningoencephalitis. Alternatively, the patient, after a typical acute onset, becomes deeply jaundiced. Ominous signs are repeated vomiting, fetor hepaticus, confusion and drowsiness. The flapping tremor may be only transient, but rigidity is usual. Coma supervenes rapidly, and the picture becomes that of acute liver failure. Temperature rises, jaundice deepens and the liver shrinks. Widespread haemorrhage may develop.

## Chronic hepatitis

The symptoms of chronic viral hepatitis are generally vague, non-specific and in many cases intermittent. They do not distinguish between chronic hepatitis B, C or D. Many patients are completely asymptomatic, and in some patients symptoms do not develop until cirrhosis is present.[1–3] Consequently, many patients with chronic viral hepatitis are identified incidentally through routine blood tests or evaluation for an unrelated problem. The most common symptom of chronic viral hepatitis is fatigue, which can be variously described as malaise, weakness or lack of stamina.

Other less common symptoms include: right upper quadrant pain or discomfort, decreased appetite, nausea, muscle pain and joint pain. The severity of symptoms does not correlate with the severity of liver disease, with the level of serum aminotransferases or with the histologic activity.

Symptoms of extrahepatic involvement occur in a small percentage of the patients.

Most patients have few, if any, physical signs. The examination is usually normal or may show mild hepatomegaly or hepatic tenderness. Splenomegaly is an early sign suggestive of cirrhosis.

The characteristic laboratory finding is elevation in serum levels of both ALT and AST, usually to a similar degree. Typically, the ALT is mildly higher than the AST, the ratio ranging from 1:1 to 2:1. In some patients with cirrhosis this ratio may decrease to slightly less than 1:1.[9] The serum levels of AlkP and gamma-glutamyl transpeptidase (GGT) are usually within normal limits, but may be moderately elevated in patients with cirrhosis, usually to less than twice the upper limit of normal. Jaundice is rare in chronic hepatitis except for severe exacerbation or when liver failure occurs. Serum albumin levels and prothrombin time remain normal until late in

the course of the disease, and become abnormal in cirrhotic patients with the development of decompensated liver disease. Mild hyperglobulinaemia is common in chronic viral hepatitis, with immunoglobulin G (IgG) being the most elevated, usually in the range of 2.0–3.0 g/dL.[10] These levels are lower than those found in autoimmune hepatitis. Anti-nuclear antibodies and anti-smooth muscle antibodies may be detected in 10–20% and 20–40% of the patients, respectively, typically in low titres.[11] Anti-liver kidney microsomal antibody type 1 (anti-LKM-1) has also been detected in viral hepatitis. Platelet and white blood cell count may be mildly decreased in patients with chronic hepatitis, although markedly decreased counts suggest cirrhosis and hypersplenism.

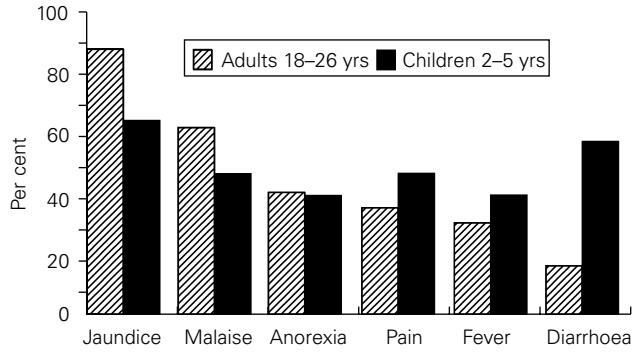

**Figure 3.1** Symptoms and signs associated with acute hepatitis A. (From: Lemon SM. Type A viral hepatitis: new developments in an old disease. *N Engl J Med* 1985;**313**:1059–67, with permission.)

## Hepatitis A

The incidence of hepatitis A virus (HAV) infection has decreased substantially worldwide over the last decades, mostly due to improved standards of living. However, due to the decreasing incidence of natural immunity, hepatitis A is more often encountered as a severe disease in adults. In urban areas, about 30% of adults show IgG anti-HAV, whereas in underdeveloped countries, 90% of children have the antibody by the age of 10. Hepatitis A occurs sporadically or in epidemic form. It is usually spread by the faecal–oral route. Parenteral transmission is extremely rare, but can follow transfusion of blood from a donor who is in the incubation stage of the disease.[12] Young people, not previously exposed, visiting endemic areas, are increasingly becoming affected. In addition, there are multiple reports of outbreaks among men who have sex with men.[13–15] Age 5–14 years is the group most affected, and adults are often infected by spread from children as a result of overcrowding, poor hygiene and poor sanitation. The incubation time ranges from 15 to 50 days. Clinically evident hepatitis develops in fewer than 1 in 10 infected children under the age of 3 years, whereas the vast majority of infected adults are symptomatic, many of them (40–70%) with overt jaundice.[16] The typical prodromal period is manifested with low-grade fever, malaise anorexia and nausea. Headache and myalgia may occur, and diarrhoea is frequent, especially among children[17] (Fig. 3.1). Rash, arthralgia and, rarely, arthritis may be a component of the prodromal phase of HAV infection.[18] The serum ALT level varies but may be increased to 100-fold above normal in more severe cases (Fig. 3.2). The increase in ALT level is followed by an increase in the serum levels of bilirubin

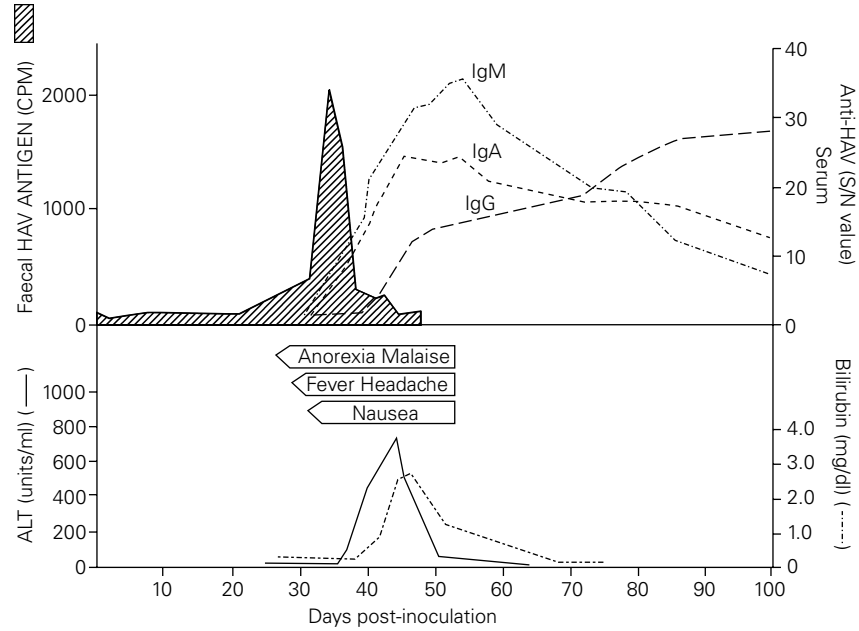

**Figure 3.2** Clinical course of HAV infection. (From: Lemon SM. Type A viral hepatitis: new developments in an old disease. *N Engl J Med* 1985;**313**:1059–67, with permission.

and AlkP. These biochemical abnormalities usually resolve within weeks, although it is not uncommon for the ALT level to remain mildly elevated for 3 months and occasionally longer. In the vast majority of patients the serum ALT level returns to normal within 6 months.

## Relapsing hepatitis

Relapses have been described in 1.8–15% of patients with acute hepatitis A, usually within several months after a typical acute infection (Fig. 3.3).[19] The relapse may occur 30–90 days after the initial presentation. In some, it is clinically similar to the original attack, usually in a milder form. More often, relapse presents mainly as an increase in serum aminotransferases and occasionally bilirubin. Serum IgM anti-HAV is positive, and there is continuous viraemia with shedding of the virus in the stools during the relapse phase.[19,20] Multiple episodes may occur, but recovery after relapse is almost invariably complete. Rarely, the relapse episode may be associated with arthritis, vasculitis and cryoglobulinaemia.[21,22]

## Cholestatic hepatitis

Occasionally, jaundice may be prolonged and may be associated with cholestatic features persisting for several weeks or more. The onset of disease is similar to that of the usual hepatitis patient however, the jaundice deepens and within 3 weeks the patient starts to itch. After the first few weeks, the patient feels better and gains weight. However, they continue to suffer from pruritus, and jaundice may persist for 8–29 weeks. This pattern is not indicative of severe hepatocellular disease. Subsequently, the jaundice subsides and the patients invariably make a complete recovery without sequelae.[23] This type of viral hepatitis must be differentiated from obstructive jaundice, and from drug-induced liver disease.

## HAV and autoimmune hepatitis

Several authors have reported rare cases of chronic autoimmune hepatitis possibly triggered by acute hepatitis A in susceptible individuals.[24,25] Autoimmune hepatitis type I developed within 5 months of the occurrence of acute hepatitis A. Individuals experiencing this rare sequence of events are likely to have an inherited defect of immune regulation.

## Extrahepatic manifestations

Extrahepatic manifestations of HAV infection include renal, neurological, pancreatic and haematological complications.

**Renal involvement** has been reported infrequently in association with HAV infection, and when present it is characterized by mild proteinuria, microscopic haematuria and slight urinary sediment abnormalities. Acute renal failure is a rare but well-described complication of non-fulminant HAV infection.[26–30] The nephrotic syndrome has been reported with immune complex-mesangial, proliferative glomerulonephritis.[30]

**Neurological complications** are uncommon. There are rare reports of aseptic meningitis, encephalitis, myelitis and seizures during the course of acute hepatitis A, in the absence of fulminant liver failure.[31,32] Several authors reported Guillain-Barré syndrome following acute HAV infection.[32]

**Pure red cell aplasia** is encountered rarely in patients with acute hepatitis A.[33,34] In most reported cases it is as-

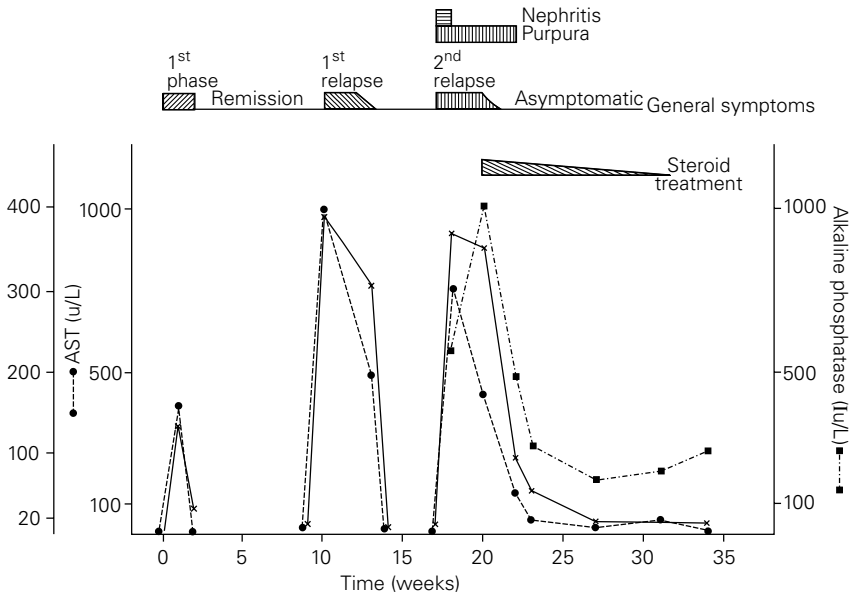

**Figure 3.3** Clinical and biochemical course of relapsing hepatitis A. (From: Glikson M *et al*. Relapsing hepatitis A. Review of 14 cases and literature survey. *Medicine (Baltimore)* 2002;**71**:14–23, with permission.)

sociated with a severe or fulminant hepatitis. Response to corticosteroids and immunosuppressant drugs is variable.[33,34]

### Fulminant hepatitis

HAV infection accounts for fewer than 10% of cases of acute liver failure (ALF) in most series. Although ALF due to severe hepatitis A is well documented in young children, it is significantly more frequent in middle-aged and older individuals and in those with underlying chronic liver disease.[5–8,35] The survival rate is probably better than other viral hepatitides, reported to be as high as 60% by some authors.[36,37]

## Hepatitis B

It is estimated that over 350 million people are chronically infected with hepatitis B virus (HBV) throughout the world. The carrier rate of hepatitis B surface antigen (HBsAg) varies worldwide from 0.1 to 0.2% in Britain, the United States and Scandinavia to more than 3% in Greece and Southern Italy, and up to 10–15% in Africa and the Far East. Carriage of HBsAg is even higher in some isolated communities such as Alaskan Eskimos and Australian Aborigines. HBV is typically transmitted parenterally, perinatally or by sexual contact. In low carriage rate areas the major risk factors for transmission are intravenous drug use and sexual contact. Historically, transfusion of blood products was an important risk factor. However, screening of donated blood for HBsAg has almost eliminated post-transfusion hepatitis B.[38] According to recent studies, the rare cases of transfusion-transmitted hepatitis B are mostly the results of donations collected from HBsAg-negative donors with acute HBV infection.[39] Blood transfusion continues to be an important cause of hepatitis B in countries where donor blood is not screened for HBsAg. Other modes of parenteral transmission include the use of unsterile instruments for dental treatment, ear piercing and manicures; prophylactic inoculations; subcutaneous injections; acupuncture; and tattooing. In high carriage rate areas, infection is acquired by vertical transmission at the time of birth and during close contact afterwards. The risk of transmission increases as term approaches and is greater in acute than in chronic carriers, and in replicating state than in inactive carriers state. HBs antigenaemia develops in the newborn within 2 months of birth and tends to persist.[40] There is an inverse relationship between the risk of chronicity and the age of infection. The chronicity rate for infections before the age of 1 year is 80–90%, and for infections in early childhood it is 20–50%, whereas HBV infection in healthy adults gives rise to a chronic infection or a carrier state in only 1–2%.[41,42]

### Acute hepatitis B

The incubation period ranges from 1 to 5 months, but it may be shorter in patients who were exposed to a large viral load.[43] During the prodromal phase serum sickness-like syndrome tends to occur more commonly than with the other hepatitis viruses. Polyarthralgia and polyarthritis may be seen involving mostly small joints of the upper extremities. Urticaria is occasionally present, and is associated with vascular deposition of circulating immune complexes containing HBeAg.[44] The clinical course of acute HBV infection is anicteric in the majority of infected individuals, which explains the high positivity rate of serum markers in those who give no history of acute HBV infection. It is well established that the anicteric patients are more liable to become chronically infected than the icteric ones. In patients who recover, the serum ALT levels usually return to normal values within 1–4 months. Persistent elevation of serum ALT for more than 6 months suggests chronic hepatitis and persistent infection.[42]

### Chronic hepatitis B

Chronic HBV infection accounts for 5–10% of cases of chronic liver disease and cirrhosis in the USA.[45] In most patients with chronic hepatitis B the acute phase had been mild or asymptomatic. In areas of low or intermittent prevalence, about 70% of patients with chronic hepatitis B do not have a history of acute hepatitis. The patients who have an explosive onset and deep jaundice usually recover completely. Similarly, survivors of fulminant hepatitis seldom, if ever, develop a chronic disease. The course of chronic hepatitis B generally consists of two phases: an earlier replicative phase with active liver disease and a later, non-replicative phase with remission of liver disease.[2] In patients with chronic HBV infection acquired during adulthood (Fig. 3.4A), the initial phase is characterized by active viral replication (presence of HBeAg and HBV DNA in serum), elevated ALT levels and chronic hepatitis in liver biopsy. During this phase the patient may be symptom-free, with only biochemical evidence of continued activity, or may have non-specific symptoms such as fatigue, or occasional right upper quandrant discomfort. Symptoms do not correlate with the severity of liver damage. The diagnosis is usually made on a routine blood test detecting mild elevation of serum aminotransferases. During the replicative phase patients may experience biochemical exacerbations (an abrupt increase in ALT levels), which may be asymptomatic or may mimic acute hepatitis, causing symptoms of fatigue, anorexia, nausea and jaundice. These exacerbations are often, but not always, associated with HBeAg seroconversion.[46,47] They may occasionally be misdiag-

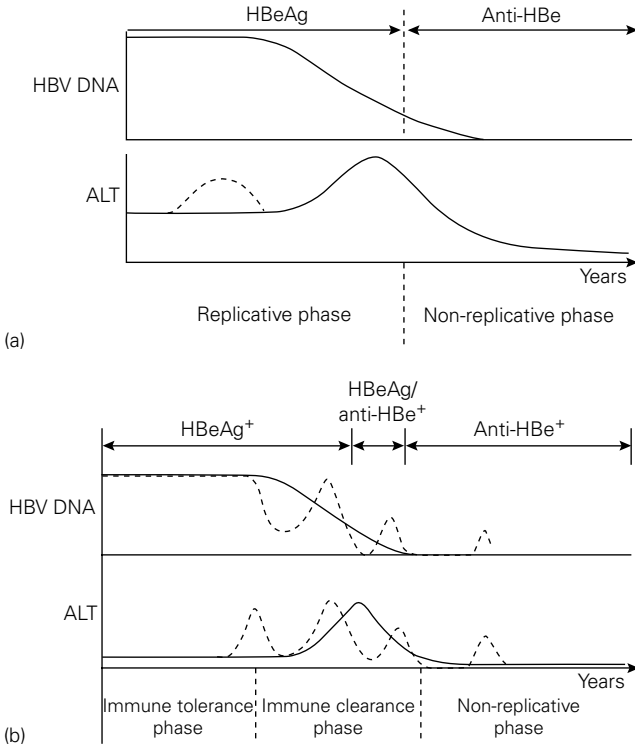

**Figure 3.4** Natural history of chronic HBV infection. (a) HBV infection acquired in adulthood. (b) Perinatally acquired HBV infection.

nosed as acute hepatitis B, due to elevated serum levels of IgM anti-HBc.[40,48–50] Exacerbations are occasionally associated with increased serum levels of AFP to >400 ng/mL,[50] and may rarely lead to hepatic decompensation.[51] In any severe exacerbation, superinfection with hepatitis D virus (HDV), HAV, or hepatitis C virus (HCV) must be considered. The second phase of chronic HBV infection is characterized by a marked decrease in serum HBV DNA levels and a spontaneous HBeAg seroconversion. This usually represents transition from chronic hepatitis B to an 'inactive carrier' state. In this phase the patients are almost invariably asymptomatic, and usually have inactive liver disease on liver biopsy. However, spontaneous reactivation from HBeAg-negative to HBeAg- and HBV DNA-positive has been described. The clinical picture ranges from absence of manifestations to fulminant liver failure.[46] Reactivation is particularly severe in immunosuppressed patients and patients who are human immunodeficiency virus (HIV)-positive. Many patients, usually with established stable cirrhosis, may present with hepatocellular carcinoma.

In perinatally acquired HBV infection (Fig. 3.4B) the initial replicative phase is characterized by virological features of active replication (high serum levels of HBV DNA and presence of HBeAg). However, these findings are not accompanied by signs or symptoms of liver disease, and are usually associated with normal levels of serum aminotransferases. This phase may last 10–30 years, and is most probably related to an early development of immune tolerance to HBV antigens.

The transition from the first to the second phase most commonly occurs between the ages of 15 and 35 years and is characterized by a high rate of spontaneous clearance of HBeAg (10–20% yearly). This phase is frequently accompanied by biochemical exacerbations, and occasionally by symptoms of acute hepatitis.

## Extrahepatic manifestations

### *Renal manifestations*

HBV infection has been associated with several forms of glomerulonephritis, including membranous glomerulonephritis, mesangial proliferative glomerulonephritis, minimal change nephropathy, membranoproliferative glomerulonephritis and IgA nephropathy. The most frequently reported kidney pathology is membranous glomerulonephritis, which has been described mostly in children. Proteinuria and nephritic syndrome are common manifestations.[52,53] In most of the patients the liver disease is mild, but HBeAg is usually positive. Immune complexes of HBsAg, HBeAg, anti-HBc or anti-HBe are found in glomerular and papillary basement membranes.[54,55] In children, the glomerulonephritis resolves spontaneously in most of the patients in 6 months to 2 years. However, in adults, the disease is usually more severe, gradually progressing to renal failure in up to 30% of the patients. Treatment with corticosteroids is not effective and may increase viral replication. However, in some patients alpha-interferon (IFN-α) treatment may lead to a remission.[56,57] In Chinese patients, treatment with IFN has been disappointing, spontaneous remission is uncommon, and the disease usually progresses relentlessly to renal failure.[53] Recent evidence suggests that the incidence of HBV-associated membranous nephropathy in children has declined significantly since the introduction of the HBV vaccine.[58]

### *Neurological manifestations*

The Guillain-Barré syndrome has been well described in patients with HBV infection.[32] In some patients, examination of the cerebrospinal fluid revealed the presence of HBsAg or immune complexes containing HBsAg.[59] The majority of the reported patients recovered with mild neurological residua.[32]

### *Polyarteritis nodosa (PAN)*

PAN is a rare complication of hepatitis B. However, approximately a third of patients with established PAN are HBsAg-positive. HBV-related PAN usually presents as

an acute disease shortly after the HBV infection, and has similar characteristics to classic PAN.[60] HBsAg, immunoglobulins (IgG and IgM), and complement have been demonstrated by immunofluorescence in exudative and fibrinoid vascular lesions.[60,61] Immune complexes may be present in the serum, and CH50 and C3 titres are typically low.

### *Aplastic anaemia*

Aplastic anaemia has been associated with HBV infection and is usually fatal.[62] Suppression of haematopoietic stem cells has been shown *in vitro* in HBV infection.[63]

### *Other extrahepatic manifestations*

There are rare reports of myocarditis[64] and pancreatitis[65] in association with HBV infection. It has been suggested that mixed cryoglobulinaemia may be initiated by HBV infection.[66] However, this association has not been unequivocally established.[67] Conversely, the association with HCV infection is well documented.[68–72]

## Fulminant hepatitis

Fulminant hepatic failure (FHF) may result from an acute HBV infection or from a reactivation of a chronic infection or carrier state. Reactivation has been described during or after withdrawal of immunosuppressive or cytotoxic chemotherapy, or with no apparent precipitating factor.[73–77] A fulminant course of hepatitis B is related to an enhanced immune response with more rapid clearing of the virus. In most cases replication of the virus ceases rapidly, and the majority of the patients lose the HBV DNA and HBeAg within a few days of clinical presentation.[78] Antibodies to surface and e antigen may be detected in high titres and the HBsAg may be in low titre or undetectable. The diagnosis in these cases may be made only by finding serum IgM anti-HBc. However, a Japanese study in patients with FHF have found that anti-HBc IgM was not detected in the serum in nearly 50% of patients in whom HBV DNA was detected by polymerase chain reaction (PCR) technique.[79] Several studies reported an association between the precore mutant HBV and fulminant liver failure,[80,81] although both the wild-type and mutant HBV strains may cause fulminant hepatitis.[82] Another viral hepatitis, superimposed on a symptomless hepatitis B carrier, may precipitate a fulminant course. The superimposed agent may be HAV, HDV or HCV.

## Clinical significance of HBV genotypes

HBV is classified into eight genotypes (A–H) based on inter-group divergence of 8% or more in the complete nucleotide sequence.[83,84] The predominant genotypes among patients born in the USA, Europe, the Far East, and Southeast Asia are A, D, C and B, respectively. In the USA genotype A is more common among whites and African Americans, whereas genotypes B and C are predominantly found in Asian Americans.[85,86] Unlike HCV genotyping, HBV genotyping is still used predominantly as a research tool. However, there is growing evidence that HBV genotype may correlate with the natural history of HBV infection and the severity of liver disease. Several authors have shown a strong relationship between HBV genotype and mutations in the precore and core promoter region that abolish or diminish the production of HBeAg.[35,87,88] For example, it has been suggested that precore mutations are found more commonly in patients with genotypes B, C and D but not in genotype A. This may account for the higher prevalence of HBeAg-negative chronic hepatitis B in Southern Europe and Asia. Recent studies suggest that HBV genotype B is associated with less active liver disease than genotype C, and that spontaneous HBeAg seroconversion occurs earlier and at a higher rate among patients with genotype B compared with patients with genotype C.[88–90] HBV genotype has also been related to response to IFN treatment, which was found to be higher in patients with genotype A or B than in those with genotype D or C, respectively.[91,92]

# Hepatitis C

It is estimated that about 5 million people have chronic HCV infection in Western Europe, which account for 40% of end-stage liver disease and 30% of liver transplant candidates.[93] In the USA, approximately 3.5 million people (1.8% of the population) have chronic HCV infections, but prospective surveillance studies indicate a marked decline in the incidence of new cases in the last two decades.[94–96] The most common risk factor for new infections is intravenous drug use. Other risk factors include injections with reusable non-sterilized needles, transfusion of blood products and transplantation of organs from infected donors before the introduction of screening in the early 1990s. Contaminated anti-rhesus D immunoglobulin (anti-D) has caused large outbreaks of HCV in Ireland[97] and Germany.[98] Current transmission methods may also include needle-stick accidents, tattoos, body piercing and intranasal cocaine use.[99] Haemodialysis patients have been at increased risk for HCV infection and the incidence of new cases of hepatitis C in the USA ranges from 1% to 3% yearly despite increased adherence to preventive measures.[100–102] The risk of HCV transmission after needle-stick injury varies in most studies from 2% to 5%.[103] The risk of vertical transmission is 2–5% and is related to the maternal viral titre. It is significantly increased when the mother is co-

infected with HIV.[104] HCV is not found in semen, and sexual transmission is rare. Sexual transmission among homosexual men appears to be infrequent[105] and infection of sexual partners in long-term relationships occurs rarely.[106,107]

## Acute hepatitis C

Acute hepatitis C represents less than 15% of all acute hepatitis cases in the USA.[108] The acute attack is usually mild and often unrecognized. Consequently, most patients with chronic hepatitis C infection lack a clinical history of acute hepatitis. When present, symptoms are often vague, such as anorexia, nausea or malaise. Often they are attributed to a gastrointestinal upset. Alternatively, there may be an abrupt onset with fever, arthralgia and abdominal discomfort. Less than 1% of HCV-infected patients report an acute illness associated with jaundice in relation to HCV infection. As there is no accepted serological definition of acute hepatitis C, and because many individuals will not have had documentation of a previously negative anti-HCV test, the diagnosis of acute hepatitis C is often difficult to establish. The incubation period of HCV ranges from 5 to 26 weeks. Serum hepatitis C RNA can be detected 1–2 weeks after infection.[109] Anti-HIV-positive patients and patients on immunosuppression therapy may have a rapidly progressive course.[110] A fulminant course, however, is rare, and co-infection with another virus must be considered. It is currently estimated that acute HCV infection clears in about 15–20% of cases. The chronicity rate in most patient populations is, therefore, 80–85%.[111,112] However, lower rates have been reported in specific cohorts. In children infected from blood transfusions, and in young healthy women infected from contaminated anti-D immune globulin chronicity rates have been only 50–60%.[113–115]

In addition, recent data have suggested that patients with symptomatic onset (especially flu-like symptoms and jaundice) are more likely to have self-limited disease.[116–118] Conversely, several studies have shown a chronicity rate greater than 90% in African American men.[119,120]

## Chronic hepatitis C

Most patients with chronic hepatitis C have asymptomatic elevation of serum aminotransferase levels, which is often discovered on a routine blood screen, and only about 6% have symptomatic liver disease.[121] Moreover, up to one-third of patients may have normal serum aminotransferases.[3,122,123] In most patients diagnosed with chronic hepatitis C the HCV infection may have been acquired 15–25 years previously. Long-term follow-up studies have shown that it takes 15–18 years to develop significant chronic hepatitis, 20 years to develop cirrhosis and 28 years to develop hepatocellular carcinoma.[123] Most infected patients will have mild to moderate liver disease, and only 20–35% will develop significant liver complications.[124] It is estimated that approximately 20% of the patients develop cirrhosis after 20 years' duration of infection. The patient may present insidiously with fatigue as the major symptom and right upper quadrant discomfort or pain as the second most common complaint. Other less common symptoms include anorexia, nausea, arthralgia, myalgia and pruritus. The course is slow, marked by fluctuating serum aminotransferase levels over many years. Serum bilirubin and albumin concentrations are usually normal until the late stages of liver failure. Serum gamma-glutamyl transpeptidase (GGT) and alkaline phosphatase levels show slight increases. Serum gamma-globulin levels are increased modestly but rarely exceed 2 g/L. Routine haematology is usually normal and prothrombin time remains within normal limits until the late stages of cirrhosis. Association with non-alcoholic fatty liver disease is common in the USA, and probably leads to accelerated progression of liver damage and increased frequency of cirrhosis in HCV patients.[125–127] Genotype 3 is an independent predictor of steatosis in patients with chronic hepatitis C.[126,128]

## Hepatitis C and HIV

Because the routes of transmission are similar, co-infection with HCV and HIV is frequent. In the USA and Europe 14–33% of HIV-infected patients are also infected with HCV.[129–131] The prevalence of HCV co-infection is highest in HIV-positive drug users, in whom it may reach 90%. Before the introduction of highly active antiretroviral therapy (HAART), HIV-infected patients died within 10 years from the consequences of AIDS. Currently, the morbidity and mortality in HIV seropositive patients are more frequently related to liver disease, and HCV-related liver disease is becoming the main cause of death in HIV patients.[132,133] Serum levels of HCV-RNA in HIV/HCV co-infected patient are about 10 times higher than in HIV-negative patients.[134,135] In addition, the progression of HCV-related liver disease in HIV/HCV co-infected patients is faster, with a consequent higher risk of liver cirrhosis, hepatic failure and hepatocellular carcinoma.[135–137] Several studies have suggested that the rate of liver fibrosis is related to CD4 cell depletion in HIV/HCV co-infected patients.[138] The presence of HIV decreases the likelihood of spontaneous clearance of HCV after acute infection, and the chronicity rate may be as high as 100%.[139] On the other hand, there is evidence to suggest that HCV infection is associated with more rapid progression to AIDS, reduced effect of HAART and increased hepatotoxicity during HAART therapy.[140]

It has been suggested that HIV co-infection may increase the risk of sexual transmission of HCV.[141,142] Co-infection with HIV has also been reported to increase the vertical transmission of HCV from 2–5% to 14–22%.[104,143,144] This may be related in part to the elevated HCV viraemia in HIV infection.

## Extrahepatic manifestations

HCV-related chronic liver disease may be associated with numerous extrahepatic features. For some of these the association with HCV infection has been well established, whereas for others it remains speculative (Tables 3.1 and 3.2).[145] A strong association has been recognized with mixed cryoglobulinaemia and various cryoglobulinaemic syndromes. The association is less strong, although well documented for disorders such as lymphoma, porphyria cutanea tarda, diabetes mellitus, thyroid disease, salivary gland disease corneal ulcers, lichen planus and pulmonary fibrosis.

### *Cryoglobulinaemia*

Mixed cryoglobulinaemia occurs in 36–59% of patients with HCV infection.[71,146,147] Although it was initially thought to be associated with HBV infection,[66] more recent studies have established that HCV accounts for 73–90% of all forms of mixed cryoglobulinaemia.[68–72] The IgM component of the cryoprecipitate causes high levels of rheumatoid factor activity, because it binds avidly to IgG to form immune complexes. In some laboratories the rheumatoid factor test may be more sensitive than the cryoglobulin test for detection of mixed cryoglobulinaemia. Serological evidence for activation of the complement system, such as low serum levels of C3, C4 and CH50, is commonly seen in HCV patients with mixed cryoglobulinaemia. C4 level is often lower than that of C3. It has been suggested that cryoglobulinaemia is more prevalent in patients with genotype 2 and 3, compared with genotype 1. However, this has not been established in large numbers of patients.[148] The clinical manifestations of mixed cryoglobulinaemia are caused by vascular deposition of the cryoprecipitate, which contains HCV RNA, low-density lipoprotein, polyclonal IgG and monoclonal IgM.[68] The cryoglobulinaemic syndromes may include various disorders, the most common of which are kidney disease, skin disease (Fig. 3.5), joint manifestations and neuropathy (Table 3.1). Nevertheless, many patients with detectable cryoglobulinaemia are asymptomatic.

| Idiopathic thrombocytopenic purpura | Uncommon |
| Fever | 3% |
| Weakness | 65% |

*Strongly associated with cryoglobulinaemia.

### *Kidney disease*

The most common kidney manifestation of HCV is membranoproliferative glomerulonephritis (MPGN):[101,149,150] 10–20% of the cases of MPGN in the USA and up to 60% in Japan are associated with HCV infection.[150] Over 85% of the HCV patients with MPGN have cryoglobulinaemia, and about 90% have abnormal liver histology. These patients present with proteinuria, often in the nephrotic range, and decreased kidney function. Complement levels are depressed in the majority of the patients.[70,149] Kid-

**Table 3.2.** Extrahepatic disorders associated with HCV in a sample of hospitalized veterans (1992–1999): results of multivariable logistic regression analysis

| Disorder | Parameter estimate | Adjusted odds ratio | 95% CI | *p* value |
|---|---|---|---|---|
| Membranous glomerulonephritis | 0.02 | 1.03 | 0.78–1.35 | 0.86 |

ney biopsy is consistent with immune complex disease, and glomerular deposits are mainly of IgG, IgM and C3. IFN treatment was reported to reduce proteinuria, usually with no significant improvement in kidney function. Less common kidney pathologies encountered in HCV patients are proliferative glomerulonephritis and membranous glomerulonephritis.[151]

### *Skin manifestations*

The most frequent cutaneous manifestation of mixed cryoglobulinaemia in HCV patients is palpable purpura of the lower extremities. Other skin areas such as upper extremities, abdomen and buttocks may also be involved. Histological examination reveals leucocytoclastic vasculitis in the majority of cases and fibrinoid necrotizing arteritis in a distinct minority. Urticaria and livedo reticularis are less common features sharing the same underlying histological abnormalities.[152] Rarely, the vasculitic process can progress to necrotizing skin lesions leading to painful ulcers, mostly in the lower extremities (Fig. 3.6).

Lichen planus has also been reported in association with chronic HCV infection.[153]

### *Neuropathy*

Peripheral neuropathy is by far the most common neurological manifestation of HCV. Most cases are related to cryoglobulinaemia, although some have been associated with polyarteritis nodosa-like lesions.[154,155] In most cases it is an axonal sensory polyneuropathy, often causing pain for months or years before motor deficits develop. Pure motor polyneuropathies have never been described. Rare cases of optic neuropathy and encephalopathy related to cryoglobulinaemia have been reported. The response to treatment has been disappointing.[156]

### *Joint manifestations*

Arthralgia is a relatively common symptom in HCV infection, although frank arthritis unrelated to cryoglobulinaemia is rare. The most common joint manifestation of mixed cryoglobulinaemia is mono- or oligo-articular non-destructive arthropathy, most often affecting the proximal interphalangeal joints, metacarpophalangeal joints and the knees. These patients are occasionally misdiagnosed as having rheumatoid arthritis, as many of them have elevated serum levels of rheumatoid factor.[72]

### *Lymphoma*

Many studies suggest a possible association between chronic HCV infection, mixed cryoglobulinaemia and non-Hodgkin's lymphoma. The reported incidence varies. According to some articles, approximately 25% of HCV patients who have active mixed cryoglobulinae-

**Figure 3.6** Skin lesions due to porphyria cutanea tarda (PCT) in a patient with chronic HCV infection. (Courtesy of E.G. McKay, MD.)

mia have a lymphoproliferative disorder evident on random bone marrow biopsies.[157,158] HCV infection usually precedes the lymphoma by many years. Many are low grade, although high-grade lymphoma may occur. Extranodal involvement is common.[159]

### *Porphyria cutanea tarda (PCT)*

The association of PCT with HCV infection has been found in some but not all countries. In several studies from the USA and Western Europe, HCV infection was found in 56–79% of PCT patients.[160–162] The patients present with vesicles, bullae and skin ulcers in sun-exposed areas. Skin pigmentation and hirsutism are also common features. Many of these patients (up to 73%) are also found to have mutations in the HFE gene. Conversely, PCT is uncommon in HCV patients, and elevated urinary uroporphyrin levels are detected in 0.5–22% of patients with chronic HCV infection.[160,163]

### *Diabetes mellitus*

Large retrospective studies from the USA and Europe found the prevalence of type 2 diabetes to be 21–24% in patients with HCV infection compared with 9–12% in patients with HBV infection. These differences were most prominent in cirrhotic patients.[164,165]

### *Other disorders*

Thyroid disease,[166,167] sicca syndrome, lymphocytic sialadenitis resembling Sjögren's syndrome,[71,168] Moorentype corneal ulcers,[169] idiopathic thrombocytopathic purpura[170] and fibromyalgia[171] have all been reported in patients with chronic HCV infection. However, these associations have yet to be confirmed in larger populations (Table 3.2).

## Hepatitis D (delta)

The hepatitis delta virus (HDV) is a small RNA particle that replicates effectively only in the presence of HBsAg. It is capable of infection only when activated by the presence of hepatitis B infection.[172] The interaction between the two viruses is complex. Synthesis of HDV may depress the appearance of hepatitis B viral markers in infected cells and even lead to elimination of active viral replication.[173] HBV and HDV infection may be simultaneous (co-infection) or HDV may infect a chronic HBsAg carrier (superinfection). HDV infection is acquired parenterally and via close personal contact in endemic areas. Infection is strongly associated with intravenous drug use, but can affect all risk groups for hepatitis B infection. It can spread sexually, and within families.[174]

HDV infection is found worldwide, but is particularly prevalent in Southern Europe, the Balkans, the Middle East, South India and parts of Africa. In general, it is rare in the Far East (including Japan) and South America. However, epidemics of HDV infection have been reported from the Amazon Basin, Brazil (Labrea fever), Colombia (Santa Marta hepatitis), Venezuela and equatorial Africa. In these areas, children of the indigent population are affected and mortality is high.

With co-infection, acute hepatitis D is usually self-limited, as HDV cannot outlive the transient HBV antigenaemia. Only 2% of cases of co-infection have been reported to evolve to chronicity. The clinical picture is usually indistinguishable from hepatitis resulting from HBV alone. However, a biphasic rise in ALT may be noted, the second rise being due to the acute effects of HDV.

Clinically, overt co-infection is usually severe and icteric, with full but transient expression of both viruses. Fulminant hepatitis is rare. After recovery, the patient acquires immunity to HDV.

With superinfection, the acute attack may be severe and may rapidly lead to liver failure in HBV carriers with pre-existing chronic liver disease. Alternatively, superinfection may be marked only by a rise in serum transaminase levels. Delta infection should always be considered in any HBV carrier, usually clinically stable, who has a relapse. Superinfected HBV carriers are at high risk of becoming chronic carriers of HDV. Superinfection is followed by progression to chronicity in more than 90% of the patients. In the remaining cases, the superinfection resolves, with persistence of the original HBV infection, or clearance of HBsAg. In the early stages of chronic HDV infection, HDV has a marked inhibitory effect on HBV, and HBV DNA may not be detectable even by sensitive PCR assays.

The natural history of chronic HDV infection has been a matter of controversy. Although early studies linked HDV to severe and progressive liver disease, more recent surveys in a large population have shown that HDV infection may be present without causing liver damage. A large study from the Greek island of Rhodes showed that only a minority of delta-infected persons had liver disease, and the majority were healthy carriers.[175] In contrast, chronic hepatitis D may run a rapidly progressive course, leading to liver failure within several months to 2 years, in drug addicts with HBV and HDV co-infection.[176]

The HBV-infected patient who acquires HDV has more active necroinflammation and develops cirrhosis more rapidly than chronic hepatitis of other viral aetiologies. In addition, the risk of mortality in patients with HDV cirrhosis was twice, and the risk of hepatocellular carcinoma was three times that of patients with ordinary

HBV cirrhosis.[177] Fortunately, the incidence of hepatitis D is decreasing worldwide.

## Hepatitis E

Infection with hepatitis E virus (HEV) accounts for sporadic and major epidemics of viral hepatitis in developing countries. It is endemic in the Indian subcontinent and in south-eastern and central Asia. The incidence in other parts of the world is much lower, and the disease appears to be restricted predominantly to individuals who have travelled to areas where it is endemic.[178] HEV infection is enterically transmitted, usually by sewage-contaminated water, and the viral genome has been found in the stools of infected patients.[179] Person-to-person transmission is uncommon and vertical transmission is rare. Lower socio-economic status and drinking well water are both significant risk factors for infection.[180] In contrast to HAV, HEV affects young adults and is rare in children.[181] The incubation period ranges from 2 to 10 weeks. The illness is usually insidious in onset. The prodromal phase lasts about 1–4 days and is characterized by influenza-like symptoms, fever, anorexia and abdominal discomfort, with occasional vomiting and diarrhoea. Arthralgia and macular skin rash may occur. These symptoms last for a few days and are followed by the appearance of jaundice, with a subsequent symptomatic improvement.[182] HEV infection is associated with fulminant hepatitis and acute liver failure in endemic regions.[183] The course may be cholestatic. Chronicity does not develop. The mortality rate is very high (about 25%) in women in the last trimester of pregnancy. The severe picture in pregnancy is more common in epidemics than in sporadic cases. Fulminant HEV infection may be confused with acute fatty liver of pregnancy.[184] Antibodies to HEV (IgG anti-HEV) are protective and probably provide a long-term immunity.[185] The diagnosis is made by antibody tests using recombinant proteins expressed from cloned HEV. These detect both IgG and IgM antibodies.[186] Antibody tests are not completely satisfactory.[187] HEV RNA can be determined by PCR.

# Chapter 4
# Diagnostic approach to viral hepatitis

Julie C Servoss, Lawrence S Friedman, Jules L Dienstag

Viral hepatitis enters into the differential diagnosis of both acute and chronic liver disease. Infection caused by all five currently identified hepatitis viruses (A–E) can present as acute viral hepatitis, whereas only hepatitis B (HBV), C (HCV) and D (HDV, delta) viruses are important causes of chronic liver disease. For most cases of viral hepatitis, diagnosis of the specific viral cause is based on routine serological tests (Table 4.1). In selected cases, the application of molecular biological techniques, including polymerase chain reaction (PCR) amplification, can enhance the sensitivity and sophistication of diagnostic testing in viral hepatitis. Specific serological and virological identification of each of the five types of viral hepatitis must be guided by both an appreciation of the clinical setting and a recognition of the limitations of currently available diagnostic tests.

## Hepatitis A

Hepatitis A virus (HAV), which causes acute but not chronic hepatitis, is spread almost exclusively by the faecal-oral route. In clinical practice, a diagnosis of acute hepatitis A is made by serological detection of specific viral antibodies. Although HAV antigen and HAV RNA can be detected with research techniques,[1] by the time a patient presents with symptoms of acute hepatitis, virus levels in stool and blood are markedly diminished or undetectable by conventional serological/virological detection methods.

Antibody to HAV of the IgM class (IgM anti-HAV) is usually detectable in serum with the onset of symptoms and is a reliable marker of acute or recent HAV infection (Fig. 4.1). Typically, IgM anti-HAV persists for about 3–6 months after acute illness, very rarely up to 18 months.[2] False-negative IgM anti-HAV results are uncommon, but occasionally the duration of IgM anti-HAV positivity is as short as several days.[3] False-positive IgM anti-HAV results have been described and are attributable to confounding binding in the immunoassay, as may occur in the presence in serum of rheumatoid factor or hyperglobulinaemia.[4] In a small proportion of cases, hepatitis A relapses several weeks to several months after apparent recovery. Such relapses may be associated with recurrent faecal excretion of HAV[5] and, theoretically, infectivity. In patients with relapsing hepatitis A, IgM anti-HAV may reappear in serum after its initial disappearance. However, in most cases, relapses occur during the period of IgM anti-HAV positivity associated with the initial expression of hepatitis.[6]

The primary immune response to HAV is of the IgM class. However, antibody to HAV of the IgG class (IgG anti-HAV) also appears in serum following HAV infection, but its concentration rises more gradually than does that of IgM anti-HAV. After HAV infection, IgG anti-HAV persists indefinitely and confers permanent protection against reinfection.

Both radioimmunoassays (RIAs) and enzyme-linked immunoassays (EIAs) are available for detecting total and IgM anti-HAV antibodies,[7] but EIAs have supplanted RIAs in clinical practice. Microparticle-based, automated fluorescence immunoassays are available as well. The presence of IgG anti-HAV, which signifies HAV infection in the recent or remote past, is reflected by the

*Low levels ($10^1$–$10^2$ genome equivalents/mL) may be detected in serum up to 21 years after recovery from acute HBV infection.
†Low levels may also be detected.

detection of total anti-HAV in the absence of IgM anti-HAV, whereas the presence of IgM anti-HAV, characterized by the presence of both total and IgM anti-HAV, is indicative of acute or recent hepatitis A.

Generally, the diagnosis of acute hepatitis A is not particularly difficult or challenging, except in the rare patient with rheumatoid factor activity and a false-positive IgM anti-HAV result. Persons who have received prophylactic immune globulin (passive immunization) may have low levels of IgG anti-HAV in serum for several weeks, although protection against infection tends to last for several months and outlasts detectable anti-HAV in serum. Active immunization with HAV vaccines induces an antibody response only to structural proteins (initially IgM anti-HAV and later IgG anti-HAV). By contrast, during natural infection, antibodies are produced against both structural and non-structural proteins. Although not available routinely, an EIA specific for antibody to the non-structural 3C proteinase of HAV can be used to distinguish natural infection from a vaccine response.[8] Patients immunized against HAV will not have detectable antibody against the 3C proteinase.

As noted above, HAV antigen can be detected in stool by RIA during the incubation period and early symptomatic phase of the illness. In addition, HAV RNA can be detected in stool, serum and body fluids by PCR techniques.[9] However, these sophisticated techniques are not needed in routine clinical practice.

## Hepatitis B

The complexity of the genomic organization and replicative cycle of HBV,[10] a DNA virus, is reflected in the complexity of the antigenic expression of, and associated antibody responses to, the virus. Hepatitis B virus accounts for a sizable proportion of all cases of both acute and chronic viral hepatitis. Currently, routine serological diagnosis relies on the detection of three pairs of antigens and antibodies: hepatitis B surface antigen (HBsAg) and its corresponding antibody (anti-HBs); hepatitis B e antigen (HBeAg) and its corresponding antibody (anti-HBe); and antibody to hepatitis B core antigen (anti-HBc) (hepatitis B core antigen [HBcAg], against which anti-HBc is directed, does not circulate freely in the serum). Assays to detect HBV DNA by molecular hybridization were introduced in the 1980s as commercially available kits, none of which was approved for routine use (Table 4.2). Such hybridization

**Table 4.2** Commercially available HBV DNA quantification assays

| Assay | Manufacturer | Method | Lower detection cut-off | Dynamic range of quantification |

RT-PCR, reverse transcription polymerase chain reaction. Adapted from Pawlotsky J. Hepatitis B virus (HBV) DNA assays (methods and practical use) and viral kinetics. *J Hepatol* 2003;**39**:S31–S35, with permission.

assays, with sensitivity thresholds of $10^5$–$10^6$ HBV DNA copies/mL, have now been supplanted by PCR methodology, with sensitivities generally as low as $10^2$–$10^3$ viral copies/mL, some with a sensitivity of $10^1$ copies/mL (see below). Molecular amplification assays for HBV DNA can identify evidence of HBV replication that cannot be detected by molecular hybridization (slot, dot-blot, liquid-capture, etc.) assays, and, technically PCR assays can demonstrate HBV infection in the absence of serological markers of infection, such as HBsAg.[11] Practically, however, current immunoassays for HBV antigens are so sensitive that reliance on PCR amplification of HBV DNA to establish a diagnosis of acute or chronic hepatitis B is almost never required in routine clinical practice. Additional viral markers that circulate in serum during HBV infection, e.g. HBV DNA polymerase, as well as pre-S1 and pre-S2 viral envelope antigens and their respective antibodies (anti-pre-S1 and anti-pre-S2), can be detected by experimental techniques that have no routine clinical applications.

## Serological tests

During HBV infection, HBsAg, the product of the S gene of HBV, circulates at high serum concentrations (up to $10^{13}$ particles per mL).[12] This viral protein comprises the outer coat, or envelope, of the virion. In addition, HBsAg is produced in excess as non-virion 22-nm spheres and tubules, which outnumber intact virions by several orders of magnitude. Intact virion-associated HBsAg differs from smaller, non-virion-associated spherical forms in containing more pre-S gene product. Circulating HBsAg can be detected readily in serum by commercial immunoassays (formerly RIA, now EIA) 1–10 weeks after infection with HBV and 2–8 weeks before the onset of clinical hepatitis (Fig 4.2). In very rare cases of acute hepatitis B, HBsAg may be undetectable at the time of presentation, either because levels of HBsAg never reach, or have already declined below, the detection threshold of the assay. Typically, false-positive HBsAg results are borderline or only weakly positive and rarely encountered.

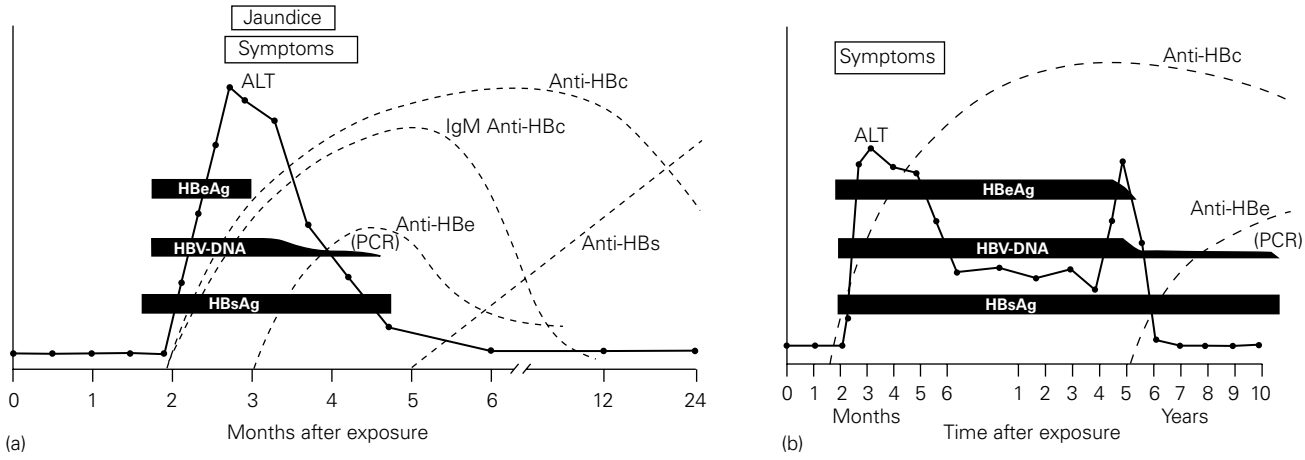

**Figure 4.2** Sequence of events after acute hepatitis B infection. (a) Acute HBV infection with resolution. (b) Acute HBV infection progressing to chronic HBV infection. ALT, alanine aminotransferase; HBeAg, hepatitis B e antigen; HBsAg, hepatitis B surface antigen; anti-HBe, antibody to hepatitis B e antigen; anti-HBc, antibody to hepatitis B core antigen; anti-HBs, antibody to hepatitis B surface antigen; IgM anti-HBc, antibody to hepatitis B core antigen of the IgM class. (From Hoofnagle JH, DiBisceglie AM. Serologic diagnosis of acute and chronic viral hepatitis. *Semin Liver Dis* 1991;11:73–83, with permission.)

Although anti-HBs is produced early during acute HBV infection, marked HBsAg excess prevents routine detection of anti-HBs until HBsAg levels decline. Typically, with the resolution of acute hepatitis B, HBsAg becomes undetectable as anti-HBs becomes detectable.[13] Because of the sensitivity of current assays, the previously described 'window period' between the disappearance of HBsAg and the appearance of anti-HBs in serum is rarely, if ever, observed nowadays. Antibody to HBsAg is a neutralizing antibody, which, when present, is associated with life-long immunity. In addition, anti-HBs is the antibody produced in response to hepatitis B vaccination with current vaccines composed entirely of HBsAg.[14] Anti-HBs levels of at least 10 milli-international units are regarded as protective. Failure of acute HBV infection to resolve, with evolution to chronic HBV infection, is suggested by persistence of circulating HBsAg and absence of detectable anti-HBs.

Hepatitis B core antigen (HBcAg), a component of the viral nucleocapsid, is associated with the intact virion and does not circulate freely in the serum. Therefore, HBcAg is not detectable routinely in serum. During acute HBV infection, IgM anti-HBc appears shortly after HBsAg and persists for approximately 6 months (rarely longer but almost never beyond 12 months) after the onset of acute HBV infection. During the course of acute HBV infection, levels of IgG anti-HBc rise more slowly, and eventually IgG anti-HBc replaces IgM anti-HBc. The presence of IgG anti-HBc signifies either resolved HBV infection (when detected with anti-HBs after clearance of HBsAg) or chronic HBV infection (when detected in patients with persistent HBsAg). Commercially available EIAs for total anti-HBc and IgM anti-HBc are available. The presence of IgG anti-HBc is inferred when total anti-HBc is present but IgM anti-HBc is undetectable. Antibody to HBcAg has not been felt to be a neutralizing antibody. However, chimpanzees immunized with HBcAg have been protected against HBV challenge, and the T-cell immune response to HBcAg has been shown to provide help in promoting the humoral immune response to HBsAg. Therefore, testing for anti-HBc is an alternative screening test for immunity to HBV that can be used to determine the need for hepatitis B vaccination. The presence of IgM anti-HBc is a helpful diagnostic adjunct when the time of onset of HBV infection is not known (for example, in a blood donor found to harbour HBsAg).

Occasional persons are found to have an isolated anti-HBc in the absence of HBsAg or anti-HBs. For example, before the introduction of contemporary blood donor screening approaches, up to 5% of healthy blood donors had isolated anti-HBc in the serum. Among human immunodeficiency virus (HIV)-infected persons, the rate of isolated anti-HBc in serum has been reported to be as high as 42%.[15] Isolated anti-HBc can occur in four settings: 1) during the now rare window period of acute HBV infection (see earlier); 2) during chronic HBV infection as levels of HBsAg become undetectable; 3) after resolved HBV infection in the remote past as anti-HBs levels fall below the limits of detection; and 4) as a false-positive result. Among populations with a high prior probability of HBV infection, i.e. in HBV-endemic areas, up to 20% of persons with isolated anti-HBc in serum have circulating HBV DNA, signifying chronic HBV infection.[16–18] In contrast, among persons with chronic hepatitis C, isolated anti-HBc is common but is almost never associated with detectable HBV DNA. In the absence of HBV DNA, isolated anti-HBc usually represents a false-positive result or HBV infection in the remote past. Therefore, in persons with isolated anti-HBc who are at

high risk of HBV infection (e.g. have high-risk behaviour or are members of an HBV-endemic population), testing for HBV DNA by a molecular assay is helpful to exclude or establish occult chronic HBV infection.

Hepatitis B e antigen (HBeAg) is a product of the nucleocapsid (core) gene of HBV but, unlike HBcAg, is a soluble, non-particulate protein that is secreted in serum.[19] For HBeAg to be expressed, the precore region of the C gene must be intact and translated. Detectable by commercial immunoassay (formerly RIA, now EIA), HBeAg is a convenient marker of high virus replicative activity, which in turn is associated with infectivity and liver injury. HBeAg is invariably detectable early in the course of acute hepatitis B, coincident with or immediately after the appearance of HBsAg, and generally disappears within several weeks in acute, resolving cases. Persistence of HBeAg in serum beyond the first 3–4 months predicts protracted (chronic) HBV infection. In patients with chronic hepatitis B, HBeAg tends to persist for months to years and signifies the active replicative phase of chronic HBV infection. HBeAg disappears at a rate of approximately 10% (range 9–19%) per year in patients with chronic hepatitis B, coincident with a dramatic decline in viral replication to undetectable or nearly undetectable levels.[20] Testing for HBeAg is not necessary in most cases of acute hepatitis B but plays an important role in the assessment of patients with chronic hepatitis B.

Chronic HBV infection can be divided into HBeAg-positive and HBeAg-negative categories. Early in the course of chronic HBV infection, both HBsAg and HBeAg are typically detected in serum, reflecting active viral replication, infectivity and hepatic inflammation. Most patients will ultimately undergo seroconversion with loss of HBeAg and appearance of anti-HBe, coincident with a sustained decline in viral replication, return of serum aminotransferase levels to normal, and decline in serum HBV DNA to low ($<10^3$–$10^4$copies/mL) levels that are generally undetectable with standard molecular assays (see later) (although HBsAg persists in serum). These persons are known as *inactive carriers*.

Some persons who are HBeAg-negative and anti-HBe-positive do have active chronic HBV infection with detectable HBV DNA (usually $>10^5$ copies/mL but at levels one to several $\log_{10}$ lower than in HBeAg-reactive chronic hepatitis B) and elevated or fluctuating serum aminotransferase levels.[21] Absence of HBeAg in serum in these patients is the result of a mutation in the precore or core promoter region of HBV DNA that halts production of HBeAg. The most commonly seen precore mutation is a substitution of adenosine (A) for guanine (G) at codon 1896 (G1896A) that results in a premature stop codon, which prevents production of HBeAg.[22] This HBV mutant is found in up to 27% of persons with chronic HBV infection in the USA but 50% and 92% of persons with chronic HBV infection in Asia and the Mediterranean, respectively.[23,24] When compared with the clinical course of persons with HBeAg-positive chronic HBV infection, the course of HBeAg-negative chronic HBV infection is typically characterized by lower serum HBV DNA levels, as mentioned above, and intermittent, rather than sustained, periods of necroinflammatory activity in the liver. In addition, long-term (rather than short-term) antiviral therapy is generally required to maintain suppression of HBV replication.

## Molecular tests

Qualitative (PCR-based) and quantitative molecular assays for HBV DNA in serum are commercially available. Suppression of HBV DNA in serum by antiviral therapy is generally monitored with quantitative HBV DNA assays.

Quantification of HBV DNA in serum is performed with either signal or target amplification techniques (Table 4.2). Signal amplification techniques require the use of a specific 'capture' oligonucleotide probe that hybridizes denatured DNA.[25] The signal (radioisotope, chemiluminescence, etc.) from the probe-DNA hybrid is then amplified for detection and quantitation.[25] Target amplification requires amplification of the viral genome (amplicons). The amplicons are then detected and quantified.

Assays that rely on signal amplification include the Hybrid Capture System (Digene Hybrid-Capture II HBV DNA Test, Digene Corp., Gaithersburg, MD, USA) and a branched DNA (bDNA) assay (Bayer, Emeryville, CA, USA). In the Hybrid-Capture System,[25–27] specific RNA probes are hybridized to the target HBV DNA to create RNA-DNA hybrids. Then, multiple RNA-DNA hybrids are captured onto microplate wells by universal capture antibodies specific for the hybrids. The captured RNA-DNA hybrids are then detected with the use of multiple antibodies (creating signal amplification) conjugated to alkaline phosphatase. The bound alkaline phosphatase is detected with a chemiluminescent dioxetane substrate that produces light, which is then measured spectrophotometrically. The signal can be amplified 3000-fold. The lower limit of detection of the Hybrid-Capture System is 4700 copies/mL, i.e. approximately $5 \times 10^3$ IU/mL.[25]

The bDNA technique[25,28] involves the use of specific oligonucleotide probes to hybridize HBV DNA to plastic microwells. Signal amplification occurs when bDNA amplifier molecules are hybridized to the target HBV DNA hybrids in the microwell. Multiple repeat sequences within the bDNA amplifier molecule are then conjugated with an alkaline phosphatase-catalyzed chemiluminescence probe similar to that used in the Hybrid-Capture System. The lower limit of detection of the bDNA assay is $7 \times 10^5$ DNA equivalents/mL.[25]

Although signal amplification techniques offer highly specific assays to detect HBV DNA, these assays are too insensitive to detect low levels of HBV DNA ($<5 \times 10^3$ copies/mL). Target amplification techniques such as PCR-based assays are highly sensitive and are capable of detecting as few as 10 copies/mL of HBV DNA (TaqMan-based PCR).[29] PCR assays rely on the use of specific primers that attach to each strand of target DNA. Then, new DNA strands are synthesized and amplified behind the primer. This cycle of DNA denaturing, primer annealing and strand synthesis is repeated multiple times, thereby resulting in amplification of the target HBV DNA. The most common primers used in HBV DNA PCR assays are complementary to the precore or core region.[9] Commercially available assays include the Amplicor HBV Monitor Test, v2.0 (Roche Molecular Systems, Pleasanton, CA, USA) and the Cobas Amplicor HBV Monitor Test, v2.0 (Roche Molecular Systems). The ranges of HBV DNA detection with these assays are 1000–40 000 000 copies/mL and 200–200 000 copies/mL, respectively. The Cobas Amplicor system is the more sensitive of the two assays and uses an Amplicor analyser that automates the amplification and detection process.

Recent advances in PCR technology include the development of 'real-time' PCR techniques to increase the sensitivity of the assay. Real-time PCR refers to the simultaneous amplification and quantification of viral genomes, thereby obviating the need for post-PCR manipulations.[30,31] Real-time PCR can detect a wide range of HBV DNA levels and offers a more rapid assay than conventional PCR techniques. In a recent study, LightCycler (LC)-PCR (Roche Diagnostics), a real-time PCR technique, was compared to the Hybrid-Capture II HBV DNA test (Digene Corp., Gaithersburg, MD, USA),[31] and LC-PCR was found to be rapid (~2.5 h) and 500 times more sensitive than Hybrid-Capture II, with an HBV DNA detection range of 250 to $2.5 \times 10^9$ copies/mL.

Currently, real-time PCR using the TaqMan probe is the most sensitive quantitative HBV DNA assay, capable of detecting as few as 10 copies/mL.[29] TaqMan technology relies on a fluorescent probe annealed to target DNA sequences for quantitation of DNA.[32,33]

Until recently, the HBV DNA quantitative units reported by the various assays listed in Table 4.2 did not represent the same actual amount of DNA in a given patient sample. Therefore, the World Health Organization (WHO) established an international standard for HBV DNA in international units (IU).[34] Ultimately, all commercial HBV DNA quantitative assays will adopt this new calibration standard and express HBV DNA levels in IU/mL. One IU/mL is equivalent to approximately 5 copies/mL.

## Serological and molecular testing in practice

Quantitative tests for HBV DNA in serum are useful to distinguish replicative from non-replicative chronic HBV infection and to monitor a patient's response to antiviral therapy. With the use of conventional serological markers plus molecular assays for HBV DNA, we can distinguish between two phases of chronic HBV infection.[35] The early 'replicative' phase is characterized by the presence of circulating HBeAg and high levels of serum HBV DNA (usually $>10^5$–$10^6$ copies/mL) and infectious virions. Clinically, patients are often symptomatic, have elevated serum aminotransferase levels, demonstrate histological evidence of liver necroinflammatory injury, and are highly infectious for their contacts. Eventually, patients may experience transition to the relatively 'non-replicative' phase, characterized by loss of HBeAg, appearance of anti-HBe in serum, and a marked decrease in serum levels of HBV DNA, which may remain detectable only by PCR (generally $<10^3$ copies/mL). An improvement in symptoms and in biochemical and histological indicators of necroinflammatory activity as well as a marked reduction in infectivity follow. Often the transition from the replicative to the non-replicative phase is accompanied by a clinical exacerbation of chronic hepatitis (postulated to represent cytolytic T-cell clearance of HBV-infected hepatocytes), with a transient, marked elevation in serum aminotransferase levels and perhaps an exacerbation of symptoms. Rarely, primarily in patients with marginally compensated chronic liver disease, this clinical exacerbation can resemble fulminant hepatitis and result in hepatic failure.

Once the infection has entered a non-replicative phase, liver injury is unlikely. However, subsequent spontaneous or immunosuppression-induced reactivation of HBV replication remains possible. Reactivation of replicative HBV is accompanied by high levels of HBV DNA in serum and may occur with or without the reappearance of HBeAg.[36]

The threshold that distinguishes the replicative from the non-replicative state has been defined as an HBV DNA level of $10^5$ copies/mL, although $10^3$–$10^4$ may be more accurate. Patients are classified as having replicative, non-replicative or reactivation HBV infection. Because the reappearance of IgM anti-HBc during reactivations is variable, occurring in some cases but not others, the absence of IgM anti-HBc does not distinguish reliably between reactivation of chronic hepatitis B and acute hepatitis B.[37]

During the course of chronic HBV infection, transition to the non-replicative phase is associated with a shift from primarily episomal HBV DNA to HBV DNA that is primarily integrated into the host genome of infected

hepatocytes, a process that may set the stage (i.e. is necessary but not sufficient) for the later development of primary hepatocellular carcinoma.[38] However, viral integration and development of hepatocellular carcinoma are probably not causally linked. Instead, both events probably result independently from HBV infection of long duration. In fact, development of hepatocellular carcinoma is also associated with the ongoing hepatic necroinflammatory activity that characterizes the replicative phase of chronic HBV infection.[39]

In addition to characterizing the status of viral replication in patients with chronic HBV infection, quantitative HBV DNA assays are useful in monitoring response to antiviral treatment. Recently, the National Institute of Diabetes and Digestive and Kidney Diseases and the American Gastroenterological Association proposed criteria to classify responses to antiviral therapy based on biochemical, histological and virological criteria.[21] A biochemical response is signified by a decrease in the serum ALT level to the normal range, and a histological response is signified by a decrease from baseline in histological activity index of at least two points. A critical component of the virological response is a reduction in serum HBV DNA to $<10^5$ copies/mL and loss of HBeAg in patients who were initially HBeAg-positive. For patients with HBeAg-negative chronic HBV infection, however, the only measure of virological response is loss of detectable serum HBV DNA. Assays to detect precore and core-promoter HBV mutations are also available. However, for routine clinical purposes, the presence of HBV DNA and elevated aminotransferase activity is usually sufficient for the detection of HBeAg-negative chronic hepatitis B.

For patients with HBV infection who are treated with the antiviral nucleoside analogue lamivudine, the emergence of a lamivudine-resistant mutant is characterized by the reappearance of HBV DNA in serum after an initial decline in level or disappearance. Although assays to detect specific YMDD (tyrosine-methionine-aspartate-aspartate) lamivudine-resistant mutations are available, reversal of virological and biochemical responses is usually sufficient to infer emergence of this mutation.

## Hepatitis D (delta agent)

Hepatitis D virus (HDV), or the delta agent, is an RNA virus that requires the helper function of HBV to complete its replicative cycle. Therefore, HDV infection is not encountered in the absence of HBV infection. Infection caused by HDV can occur either simultaneously with acute HBV infection (co-infection), superimposed on chronic HBV infection (superinfection),[40] or prior to overt reinfection of a liver allograft with HBV (subclinical or latent HDV).[41] HDV infection, especially superinfection, may result in more severe liver disease than does HBV infection alone. Whereas patients co-infected with HDV and HBV often have acute resolving hepatitis no more severe than, and indistinguishable from, that caused by HBV alone (with occasional exceptions),[42] persons with HDV superinfection are more likely to have severe hepatitis with more rapid progression to cirrhosis, and even more likely to have fulminant hepatitis, than are persons with chronic hepatitis B alone.[43] Persons with long-standing chronic hepatitis D and B often have inactive cirrhosis.

The diagnosis of HDV infection in clinical practice rests on the detection of antibody to HDV antigen (anti-HDV) by commercial immunoassay (formerly RIA, now primarily EIA). The titre of total anti-HDV is generally low (<1:100) and undetectable in over 90% of cases in acute HDV infection.[44] However, the time to first appearance of anti-HDV is variable, and repeated testing may be necessary to confirm the diagnosis. Anti-HDV tends to persist for only a short time beyond the resolution of acute hepatitis D and may disappear subsequently, leaving no marker of previous infection. Anti-HDV of the IgM class appears during acute HDV infection, but the presence of IgM anti-HDV does not distinguish acute from chronic HDV infection. IgM anti-HDV persists in chronic infection, and high titres are often found in patients with severe liver inflammation.[4] In persons with chronic hepatitis B who become superinfected with HDV, anti-HDV appears early, reaches high titres, and persists indefinitely. Serodiagnosis of HDV infection in this setting is quite reliable.

Routine diagnosis of acute HDV-HBV co-infection is based on the detection of anti-HDV in serum in association with IgM anti-HBc (Fig. 4.3). Because HDV suppresses HBV replication, loss of HBsAg from serum may be accelerated in HDV-HBV co-infection and, occasionally, IgM anti-HBc may be the only marker of acute HBV infection in this setting.[4] A diagnosis of HDV superinfection in a patient with chronic hepatitis B is supported serologically by the presence of anti-HDV in a patient who harbours HBsAg and IgG anti-HBc. Persistence of high titre anti-HDV for more than 6 months also supports a diagnosis of chronic HDV infection.

Immunoassay methods (RIA and EIA) have been developed but are not widely available to detect HDV antigen (HDAg) in serum. These immunoassays permit detection of HDAg in many patients with early acute HDV infection but rarely in patients with chronic HDV infection.[4] In contrast, HDAg can be detected by Western blot in over 70% of cases of chronic HDV infection.[45] Western blotting for HDAg, however, is technically difficult, cumbersome, not readily adaptable for routine diagnostic purposes, and remains a research tool confined to a small number of specialized laboratories.

Other research tools have been applied to the evaluation of HDV infection. Hepatitis D RNA (HDV RNA)

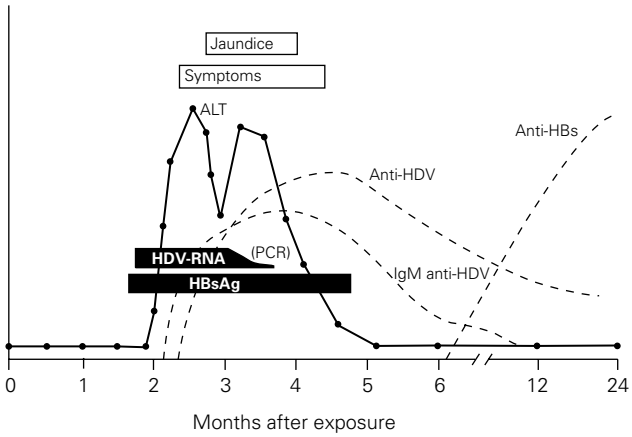

**Figure 4.3** Typical course of hepatitis B and hepatitis D (delta) virus co-infection. ALT, alanine aminotransferase; anti-HBs, antibody to hepatitis B surface antigen; anti-HDV, antibody to hepatitis D virus; HBsAg, hepatitis B surface antigen; HDV, hepatitis D virus. (From Berenguer M, Wright TL. Viral hepatitis. In: Feldman M, Friedman LS, Sleisenger MH, eds. *Sleisenger and Fordtran's Gastrointestinal and Liver Disease: Pathophysiology Diagnosis Management*, 7th edn. Philadelphia: WB Saunders, 2002: 1278–341, with permission.)

can be detected in serum by molecular hybridization transiently during acute HDV infection and persistently in chronic HDV infection.[46] Although testing for HDV RNA is now a research tool with limited availability, in the future, measurement of serum HDV RNA levels is likely to be used to monitor response to antiviral therapy in patients with chronic hepatitis D.[47] Research techniques for detection of intrahepatic HDV include demonstration of HDV RNA by *in situ* hybridization[48] and of HDAg by immunofluorescence and immunoperoxidase staining in frozen sections and formalin-fixed sections, respectively.[4] These techniques have limited utility because staining for HDAg becomes less accurate as specimens age. Only 50% of biopsy specimens obtained more than 10 years previously from patients with chronic HDV infection will stain positively.[9]

## Hepatitis C

Hepatitis C is characterized by an 85% rate of progression to chronicity following acute infection, a propensity for progression to cirrhosis, and an associated risk after protracted infection of primary hepatocellular carcinoma. Although HCV transmission has been most commonly the result of injection drug use and has been characterized most thoroughly following blood transfusion, non-percutaneous spread of HCV is thought to account for some sporadic cases of hepatitis C. Perinatal and sexual transmission of HCV are uncommon, however, and covert spread remains unexplained in many cases.[49,50] Even among persons who cannot recall a specific percutaneous exposure, however, blood-borne acquisition, often in the remote past, is the most likely source of infection.

### Serological tests

The identification of HCV,[51,52] an RNA virus responsible for most, if not all, cases of post-transfusion and sporadic (non-epidemic) 'non-A, non-B hepatitis', was followed by the rapid development of serological tests. Currently, anti-HCV is detected with a third-generation EIA. The first-generation RIA and then EIA (EIA-1) detected antibody directed against c100-3, a recombinant polypeptide derived from non-structural region NS4 of the viral genome. The value of this assay was limited, because anti-HCV was detectable no earlier than several weeks, and usually several months, after the onset of acute hepatitis and was not detectable at all in 30–40% of patients with acute, self-limited hepatitis C.[53] Even in patients with chronic transfusion-related non-A, non-B hepatitis shown by other techniques (see below) to be caused by HCV, anti-HCV was undetectable by first-generation EIA in approximately 20% of cases.

Because of the relative insensitivity of the first-generation anti-HCV assays, second-generation assays (EIA-2) were developed to detect antibodies to additional recombinant antigens: c22-3 derived from the core region and c33c from non-structural region NS4 of the HCV genome.[9] Second-generation assays detected anti-HCV earlier in the course of acute HCV infection and were much more sensitive, detectable in 95% of patients with chronic hepatitis C. Third-generation EIAs (EIA-3), designed to detect antibodies to an additional recombinant antigen from the NS5 region, have even higher sensitivities than those of EIA-1 or EIA-2 and can detect anti-HCV as early as 7–8 weeks after acquisition of HCV infection.[9]

Despite the improved sensitivity of second- and third-generation EIAs for anti-HCV, the specificities of the assays vary widely depending on the risk profile of the population being tested. For example, EIA-3 has a sensitivity of 95–98% when compared to HCV RNA testing, but the positive predictive value of EIA-3 in low-risk populations is only 25% (Table 4.3), confounded by many false-positive results.[9] False-positive EIA results have also been described in patients with autoimmune disorders such as autoimmune hepatitis.[54] The finding of an apparently biological false-positive anti-HCV result under these circumstances has been shown to correlate with hypergammaglobulinemia. In such cases, anti-HCV may become undetectable following therapy with corticosteroids, presumably because of a decrease in gamma globulin levels.[49,54,55] For persons from low-risk populations (i.e. with a low prior probability of in-

**Table 4.3** Enzyme immunoassays (EIAs) for the diagnosis of HCV infection

| Assay | Sensitivity (%)* | PPV in low-risk groups (%)† | PPV in high-risk groups (%)† | Window period (weeks)‡ |
|---|---|---|---|---|
| EIA-1 | 70–80 | 30–50 | 70–85 | 15 |
| EIA-2 | 90–95 | 50–60 | 90–95 | 9–10 |

PPV, positive predictive value. (From Berenguer M, Wright TL. Viral hepatitis. In: Feldman M, Friedman LS, Sleisenger MH, eds. *Sleisenger and Fordtran's Gastrointestinal and Liver Disease: Pathophysiology Diagnosis Management*, 7th edn. Philadelphia: WB Saunders, 2002: 1278–341, with permission.)

*Compared with HCV RNA testing.

†High-risk patients are considered those with a definitive risk factor for HCV acquisition and elevated serum aminotransferase levels. Low-risk patients include blood donors, patients with normal aminotransferase levels, and those with no risk factor for HCV acquisition.

‡Window period: time between acquisition of infection and first positive result.

fection) or with autoimmune disorders and a positive EIA for anti-HCV, confirmatory testing for HCV infection should be performed (see below).

The specificity of EIA testing for anti-HCV can be improved by supplemental testing with a recombinant immunoblot assay (RIBA). The major use of RIBA testing has been to confirm (technically speaking to 'supplement') EIA reactivity in low-risk populations, such as asymptomatic blood donors with normal serum aminotransferase levels, of whom one-half to three-quarters may have false-positive EIA anti-HCV reactivity.[56] A positive RIBA result confirms that the positive EIA result is a true positive. Currently RIBA testing is rarely required but, for historical reasons, the application and evolution of this assay are reviewed. Three generations of RIBA assays, RIBA-1, -2, and -3 were developed successively. RIBA-2 has replaced RIBA-1 as the most commonly used assay in the clinical setting, while RIBA-3 has only been approved for use by blood banks.[9] The first-generation RIBA assay consisted of a nitrocellulose strip with separate bands containing the polypeptides c100-3 (recombinant yeast-derived) and 5-1-1 (recombinant bacteria-derived), which are the products of overlapping non-structural segments of the HCV genome, as well as superoxide dismutase, a fusion protein with which c100-3 is expressed in its yeast vector and which may account for some false-positive EIA reactivity.[57] RIBA-2 (RIBA HCV 2.0 Strip Immunoassay, Chiron Corporation, Emeryville, CA, USA) contains a larger panel of HCV antigens, incorporating both first- and second-generation EIA proteins (c100-3, 5-1-1, c33c from the non-structural region, c22-3 from the HCV core-associated region, and superoxide dismutase). A specimen is considered positive if ≥2 detectable bands derived from at least two different HCV gene products are detected. Seventy-two to 100% of persons with a positive RIBA-2 result will have detectable HCV RNA by PCR techniques.[58] Specimens are considered indeterminate if detectable bands from only one HCV gene region appear or if the specimen reacts with the superoxide dismutase band and two or more HCV gene products.[9] For persons with an indeterminate RIBA-2 result or a positive EIA-3 and undetectable HCV RNA, additional testing with RIBA-3 can be considered. RIBA-3 includes two recombinant antigens, c33c and NS5, and two synthetic peptides, one from the nucleocapsid (c22) and c100-3 from the NS4 region.[9] In practice, however, testing for HCV RNA has supplanted RIBA testing in most instances.

## Molecular tests

The advent of molecular assays for HCV RNA, such as PCR amplification, has enhanced the sensitivity of testing for HCV infection. The ability to perform molecular assays for HCV RNA is useful in several settings: 1) diagnosis of acute hepatitis C; 2) confirmation of chronic hepatitis C; 3) demonstration of perinatal transmission of HCV; 4) detection of occupational exposure to HCV; and 5) monitoring the response to antiviral therapy.[25] In a small proportion of persons with acute, symptomatic HCV infection, anti-HCV is undetectable during the early weeks of infection (Fig. 4.4).[25] In addition, HCV RNA becomes detectable before anti-HCV in all cases and may be the only marker of infection during early infection, before the infection becomes apparent clinically. In these instances, if clinical suspicion of acute HCV infection is high, assays for HCV RNA can be used to confirm or exclude the presence of viraemia. HCV RNA assays are also used routinely to confirm a diagnosis of chronic hepatitis C. In almost all patients with chronic hepatitis and anti-HCV in serum, HCV RNA is present in serum continuously, but occasionally HCV RNA levels decline transiently and become undetectable.[59] Thus, a single negative HCV RNA result does not exclude viraemia, and a follow-up HCV RNA assay should be performed.

Assays for HCV RNA may also be used to determine the infection status of infants born to mothers with HCV infection. Because anti-HCV can be transferred passively

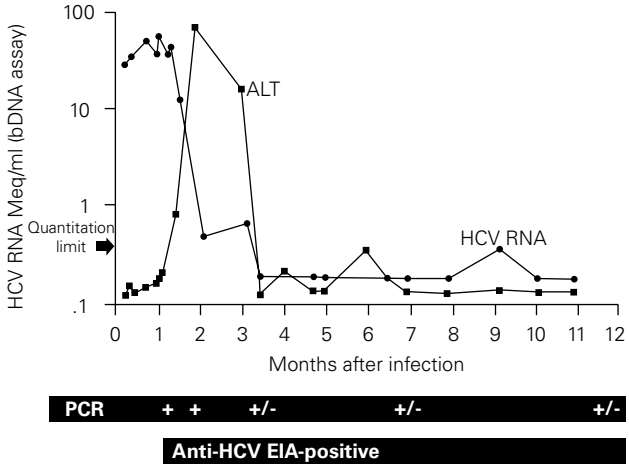

**Figure 4.4** Typical course of acute hepatitis C infection. Changes in hepatitis C virus (HCV) RNA and serum alanine aminotransferase levels (ALT) after acute post-transfusion hepatitis C. Note that viral RNA is detectable for several weeks before anti-HCV seroconversion. EIA, enzyme immunoassay; PCR, polymerase chain reaction. (From Chiron Corporation, Emeryville, CA, USA, with permission.)

from mother to infant and persist in the infant's serum for several months to 1 year, the diagnosis of HCV infection in the infant requires detection of HCV RNA.[60–64]

For blood-borne, occupational exposures to hepatitis C, HCV RNA can be detected before anti-HCV seroconversion, elevation of serum aminotransferase levels and symptoms of acute hepatitis. Thus, molecular assays are used frequently to determine whether transmission has occurred.

Finally, HCV RNA assays are also used to follow a patient's response to antiviral therapy. All treated patients are tested routinely for quantitative HCV RNA by PCR; an early virologic response (EVR) is defined as a ≥2-$\log_{10}$ reduction in HCV RNA at week 12; an end-treatment virologic response (ETR) is defined as undetectable HCV RNA at the completion of therapy; and a sustained virologic response (SVR) is defined as undetectable HCV RNA 6 months after completion of therapy. Absence of an EVR or a decline in serum HCV RNA levels (as determined by a quantitative assay) by <2-$\log_{10}$ at week 12 is predictive of a non-sustained virologic response (negative predictive value 98%).[65] Because qualitative assays are more sensitive than quantitative assays, the former are better indicators of ETR and SVR.

Both qualitative and quantitative HCV RNA assays are available (Table 4.4). The qualitative assays consist of transcription-mediated amplification (TMA) or PCR techniques and have lower limits of detection (50 IU/mL, or approximately 100 viral genomes/mL) than do the quantitative assays ($10^2$–$10^3$ IU/mL).[66] The TMA-based HCV RNA assay uses two enzymes, a reverse transcriptase and a T7 RNA polymerase. First, the reverse transcriptase synthesizes a double-stranded (dsDNA) template from single-stranded HCV RNA. Target amplification of the HCV RNA strand occurs when the T7 RNA polymerase transcribes new HCV RNA from the dsDNA template. Then, the new HCV RNA serves as a template for the reverse transcriptase inhibitor, and the cycle continues.[25] Recently, a TMA-based HCV RNA assay (VERSANT HCV RNA, Bayer Corp, Berkeley, CA, USA), yet to be approved by the US Food and Drug Administration (FDA), has been shown to have a lower limit of detection of 2.4 IU/mL.[67] PCR techniques can also be applied to HCV RNA. In contrast to PCR testing for HBV DNA, a reverse transcription step of HCV RNA is necessary to synthesize dsDNA, which then acts as a template for the PCR reactions. Once the HCV dsDNA is synthesized, specific primers attach to each strand of DNA. Then, new DNA strands are synthesized and amplified behind the primer. This cycle of DNA denaturing, primer annealing and strand synthesis is repeated multiple times, resulting in amplification of target DNA. This process is called reverse transcriptase-PCR (RT-PCR). Currently, Roche Molecular Systems has three RT-PCR assays with lower limits of detection ≤50 IU/mL (Table 4.4).

Quantitative HCV RNA assays have also been developed. Quantitative assays use target or signal amplification techniques such as RT-PCR or branched DNA (bDNA), respectively. The HCV quantitative assays are less sensitive than the qualitative assays, and their clinical use is limited to monitoring response to antiviral therapy. Two commercial RT-PCR quantitative assays are also available for HCV RNA (Roche Molecular Systems) with dynamic ranges of quantification of 600–850 000 IU/mL (Table 4.4). The bDNA technique[25] involves use of specific 'capture probes' to hybridize HCV RNA to microtitre plate wells. Signal amplification occurs when bDNA preamplifier molecules, which hybridize bDNA molecules, are in turn hybridized to the target HCV RNA in the well. Multiple repeat sequences within the bDNA amplifier molecule are then conjugated with an alkaline phosphatase-catalyzed chemiluminescence probe, and the chemiluminescence emission is measured. The newest generation of bDNA assays is the VERSANT HCV RNA 3.0 assay with a range of quantification of 615–7 690 000 IU/mL (1 IU = 5.2 copies) (Table 4.4).

Until recently, the HCV RNA quantitative units reported by the various assays did not represent the same actual amount of RNA in a given patient sample. Therefore, WHO established an international standard for HCV RNA quantification in international units (IU).[68] All commercial HCV RNA quantitative assays rely on this new standard and are calibrated to express the level of HCV RNA in IU/mL. For most assays, one IU/mL is equivalent to approximately 2.7 copies/mL.

**Table 4.4** Commercially available HCV RNA quantification assays

| Assay | Manufacturer | Method | Lower detection cut-off | Dynamic range of quantification |
|---|---|---|---|---|
| Qualitative assay | | | | |
| Versant HCV RNA | Bayer Corporation, Berkeley, CA, USA | Manual transcription-mediated amplification | 2.4 IU/mL | None |
| Amplicor HCV v2.0 | Roche Molecular Systems, Pleasanton, CA, USA | Manual RT-PCR | 50 IU/mL | None |
| Cobas Amplicor v2.0 | Roche Molecular Systems, Pleasanton, CA | Semi-automated RT-PCR | 50 IU/mL | None |
| Ampliscreen HCV | Roche Molecular Systems, Pleasanton, CA, USA | Semi-automated RT-PCR | <50 IU/mL | None |
| Quantitative assay | | | | |
| Signal amplification | | | | |
| Versant HCV RNA 2.0 Assay (bDNA) | Bayer Corporation Diagnostics, Tarrytown, NY, USA | Manual branched DNA (bDNA) | 200 000 genome equivalents/mL | 200 000–120 000 000 genome equivalents/mL |
| Versant HCV RNA 3.0 Assay (bDNA) | Bayer Corporation Diagnostics, Tarrytown, NY, USA | Semi-automated bDNA | 615 IU/mL | 615–7 690 000 IU/mL (1 IU = 5.2 copies) |
| Target amplification | | | | |
| Amplicor HCV Monitor v2.0 | Roche Molecular Systems, Pleasanton, CA, USA | Manual RT-PCR | 600 IU/mL | 600–850 000 IU/mL |
| Cobas Amplicor HCV Monitor v2.0 | Roche Molecular Systems, Pleasanton, CA, USA | Semi-automated RT-PCR | 600 IU/mL | 600–850 000 IU/mL |

In addition to the detection and quantification of HCV RNA, molecular techniques are available to determine the HCV genotype. The HCV genotype is now determined routinely in candidates for therapy of HCV infection. For patients with HCV genotype 2 or 3, 6 months of therapy with weekly pegylated interferon and 800 mg of daily ribavirin suffices to yield an SVR in approximately 80%.[25,69] For patients with other genotypes, a full year of combination therapy involving high-dose ribavirin (1000 to 1200 mg/day based on weight < or ≥75 kg) is required. Achievement of SVR occurs in 42–51% of patients with these more refractory genotypes.

Two methods of HCV genotyping are commercially available, including a reverse hybridization assay and direct nucleic acid sequence analysis of the 5′ non-coding region of the HCV genome. The reverse hybridization line probe assay (VERSANT HCV Genotyping Assay (LiPA), Bayer Diagnostics, Tarrytown, NY, USA)[70,71] relies on 19 type-specific oligonucleotide probes attached to nitrocellulose strips to detect sequence variation in the 5′ non-coding region of the HCV genome. Initially, biotin-labelled HCV DNA PCR fragments are hybridized to the oligonucleotide probes on the strip. Next, the biotin group of the hybridization complex is revealed by incubation with a streptavidin-alkaline phosphatase complex and a chromagen resulting in a purple-brown precipitate when a match occurs between the probe and the biotinylated PCR product. Alternatively, direct nucleic acid sequencing of the 5′ non-coding region of the HCV genome can be performed with a commercial kit (Trugene HCV 5′ NC Genotyping Kit, Visible Genetics Inc., Toronto, ON, Canada), and both methods are reliable. A recent comparison of the Versant HCV Genotyping Assay (LiPA) (previously marketed as Inno-LiPA HCV II) and the Trugene HCV 5′ NC Genotyping Kit demonstrated 100% concordance between the two assays in determining HCV genotype.[72]

## Hepatitis E

Hepatitis E virus (HEV) is an RNA virus classified as a calicivirus. Hepatitis E virus causes acute, but not chronic, hepatitis. Similar in some ways to HAV,[4] HEV is spread by the faecal-oral route and is an important cause of sporadic, endemic and epidemic hepatitis in certain developing countries.[73,74] Hepatitis E virus is not indigenous to the USA, but 'imported' cases have been reported in travellers returning from endemic areas, including Pakistan and Mexico. For unknown reasons, acute hepatitis E has a particularly high mortality rate (up to 20%) in pregnant women during the third trimester of pregnancy.

Routine serological testing for HEV is not available at present. However, immunoassays (Western blot and EIAs) with reported sensitivity rates of 80–90% have been developed in research laboratories for the detection

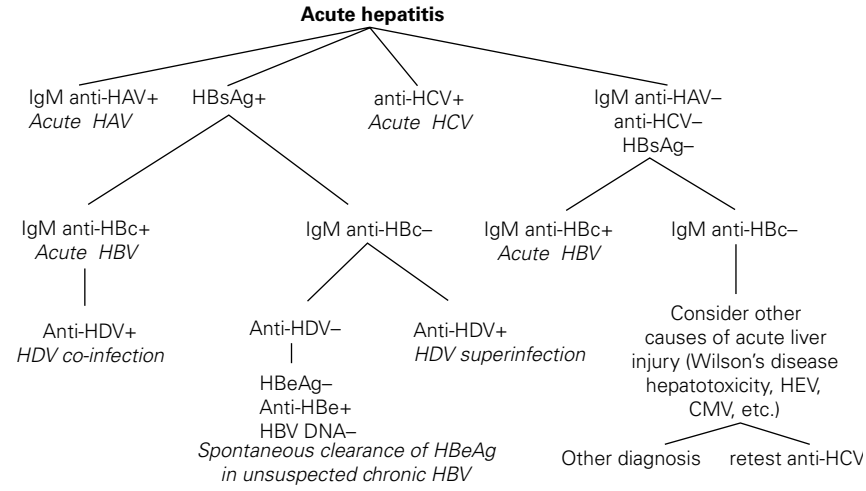

**Figure 4.5** Diagnostic algorithm for acute hepatitis.

of anti-HEV in serum based on recombinant proteins derived from the structural regions of the HEV genome (open reading frames 2 and 3).[9] Immunofluorescence assays can be used as research tools to detect HEV antigen in the liver and sensitive amplification assays (RT-PCR assays) available in research laboratories have been developed to detect HEV RNA. HEV antigen can be identified in stool, bile and liver during the incubation and symptomatic phases of acute HEV infection.[75] Antibody to HEV (anti-HEV) can also be detected in serum during acute hepatitis E.[73]

In practice, the diagnosis of HEV infection is currently made on the basis of compatible travel history and exclusion of other specific causes of acute viral hepatitis.

## Diagnostic application of serological tests

All five major hepatitis viruses can cause acute hepatitis, but only three – HBV, HDV and HCV – also cause chronic hepatitis. Therefore, serological diagnosis of viral hepatitis should be tailored to the particular clinical circumstances. As noted above, diagnostic testing for HEV is available on a research basis only. Infection with HDV does not occur in the absence of HBV infection, and testing for HDV should generally not be part of a first-line panel of clinical assays.

In suspected cases of acute viral hepatitis, appropriate initial tests should be directed towards detection of acute hepatitis A, B, or C (Fig. 4.5), with an initial diagnostic panel consisting of IgM anti-HAV, HBsAg, IgM anti-HBc and anti-HCV. The diagnosis of acute hepatitis A is established by detection of IgM anti-HAV. The diagnosis of acute hepatitis B is based on detection of HBsAg and IgM anti-HBc. The presence of IgM anti-HBc suggests that, if HBsAg is present, HBV infection is acute or that, if HBsAg is absent, the patient has acute resolving hepatitis B or acute hepatitis B with a level of HBsAg beneath the detection threshold of the immunoassay. Routine testing for HBeAg or HBV DNA during acute hepatitis B is not indicated, although both markers are present. If epidemiological or clinical features suggest HDV infection, such as an unusually severe episode of acute hepatitis or a risk factor such as injection drug use, testing for anti-HDV should be done. Finally, testing for anti-HCV should be done, especially in a patient with a history of injection drug use or with (now rare) post-transfusion hepatitis. Because of the low sensitivity of anti-HCV testing during acute hepatitis C, repeated testing for anti-HCV and testing for HCV RNA are appropriate if no other cause for acute hepatitis has been identified. If this initial battery of serological tests is negative, the diagnosis of acute viral hepatitis should be reconsidered. Other possible causes of acute liver injury, such as drug hepatotoxicity, biliary tract disease, metabolic disorders, autoimmune liver disease, cardiac failure, or involvement of the liver in a multisystem disease, such as infectious mononucleosis or metastatic malignancy, should be considered.

In cases of chronic liver disease, neither HAV nor HEV is included in the differential diagnosis. Testing for HBV

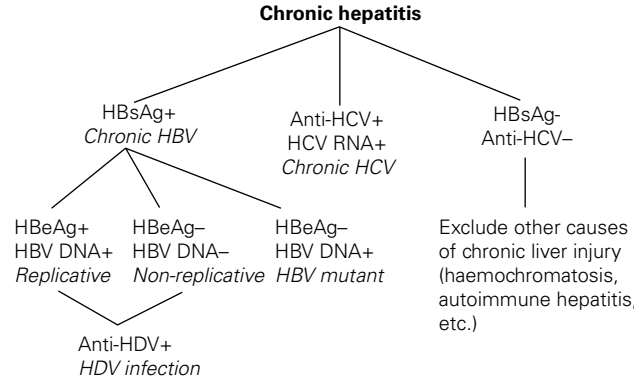

**Figure 4.6** Diagnostic algorithm for chronic hepatitis.

and HCV infection should be accomplished initially by immunoassays for HBsAg and anti-HCV, respectively (Fig. 4.6). If HBsAg is present, detection of IgG anti-HBc in the absence of IgM anti-HBc excludes acute hepatitis B and confirms the chronicity of hepatitis B. Additional information about HBV infection may be obtained by testing for HBeAg and HBV DNA in serum to document the presence of active viral replication. In addition, in patients with hepatitis B, anti-HDV testing is indicated to establish the presence of associated HDV infection, particularly if the clinical features of liver disease are severe or risk factors such as injection drug use exist. In a patient with a high risk of percutaneous exposure to HCV, the detection of anti-HCV by EIA usually confirms a diagnosis of chronic HCV infection. If doubt exists about the interpretation of the anti-HCV result (either falsely negative or falsely positive), testing for serum HCV RNA should be performed. Although liver biopsy is generally not indicated purely for diagnosis in chronic viral hepatitis, histological assessment is a routine component of pretreatment staging. Demonstration of viral antigens in liver tissue provides additional confirmation of a specific viral infection. However, apart from immunohistochemical detection of intrahepatic HBV antigens, techniques to detect intrahepatic viral markers are not widely available.

Common serological patterns and their interpretations are illustrated in Table 4.1 and diagnostic algorithms for acute and chronic hepatitis are illustrated in Figs 4.5 and 4.6.

# Chapter 5
# Evolution of hepatitis viruses

Peter Simmonds

The origins and evolution of the major viral pathogens affecting humans remain poorly understood, even though such information can provide important perspectives on the spread of viruses and mechanisms underlying the diseases they cause.

For some of the viruses causing hepatitis in humans there is extensive and wide-ranging information on their transmission, geographical ranges and genetic variability that combined provides some clues about their origins and tempo of evolutionary change. This chapter attempts to synthesize some of the available information for hepatitis C virus (HCV) and related viruses, and for hepatitis B virus (HBV), now known to be widely distributed in a range of ape species as well as humans. Although not in any way conclusive at present, these attempts to reconstruct the evolution of the two virus groups provide an interesting and useful alternative paradigm for ongoing studies of pathogenicity, future transmission and prevention.

## General principles of virus evolution

The evolution of viruses resembles that of all organisms, and is a process that is ultimately dependent on mutations in their genetic material. In many ways, however, viruses differ from commonly studied organisms such as the geneticist's mouse or fruit fly, particularly in their speed of sequence change, large population sizes and in the nature of the selection pressures they encounter. For example, of major importance for the persistence of HCV and HBV infections in humans is the ability of these viruses to mutate rapidly to evade host immune defences.

To understand the evolution of viruses and other organisms, a little background information on natural selection is needed. In popular use, the word 'evolution' describes the process of adaptive change, whereby organisms change in their phenotype (such as body shape or behaviour) in response to external, sometimes changing, selection pressures, and by competition with other organisms for limited resources in a shared environment. In this process, a random mutation in the genome associated with copying errors or chromosomal damage occasionally (and entirely by chance) might improve the fitness of an organism, allowing the mutated gene to spread and eventually predominate in the population where the advantage it provides to the organism, in terms of reproductive success, is significant. In this model of evolution, the appearance of distinct species of animals, plants and bacteria is the net result of large numbers of incremental changes in phenotype associated with adaptation to the wide range of separate contemporary and previous environments.

Surprisingly, this 'Darwinian' type of evolution makes very little contribution to the genetic diversity of organisms, measured at the level of DNA or RNA sequences. As one of the most hotly contested hypotheses of evolution change when originally proposed,[1,2] neutral theory demonstrates that the majority of sequence change that occurs over time in and between species is 'neutral'.[3] In this revised evolutionary model, nucleotide changes in gene and non-coding sequences that have little or no effect on organism fitness are tolerated and frequently become fixed in the population by chance. Thus, geographically isolated members of species can become genetically very different, even though morphologically and behaviourally they remain similar over long periods in stable environments. The frequency of fixation of neutral changes can be predicted to be relatively constant over time, and indeed there is a remarkably close correlation between sequence divergence of certain genes such as haemoglobin with known chronological times of splitting of different mammalian species and orders over the past 150 million years.

Evidence for both 'Darwinian' and neutral evolution can be found in human hepatitis viruses. Examples of adaptive changes include a specific amino acid substitution in the polymerase protein of HBV in patients receiving lamivudine therapy that confers antiviral resistance (see Chapters 20 and 21), and changes to a major B cell epitope in the HBV surface antigen (HBsAg) in individuals infected with HBV after immunization (Chapter 14). In these cases, single nucleotide mutations emerge that cause dramatic changes to the phenotype of the virus,

conferring major fitness advantages to the virus under new selection pressures (such as antiviral treatment and immunoglobulin immunotherapy).

In contrast to these adaptive changes, 'neutral' sequence drift undoubtedly accounts for much of the genetic diversity observed between geographically or epidemiologically separated populations of hepatitis viruses, such as the genotypes of HCV and HBV infecting humans and other ape species. In such cases, the process of divergence associated with the fixation of neutral changes does not greatly alter the phenotype of the viruses. For example, despite the greater than 30% sequence differences observed between genotypes of HCV, each retains a similar tendency for persistence in humans, to cause similar inflammatory liver damage and a slow progression to cirrhosis and hepatocellular carcinoma (HCC). Putting this viral diversity into context, coding sequences of (morphologically and behaviourally very different) humans and ostriches are also approximately 30% divergent, a comparison that highlights the contrasting highly conservative nature of HCV evolution over the period in which the major genotypes emerged. Indeed, this lack of phenotypic innovation demonstrates, perhaps, how the evolution of HCV (and HBV) is entirely shaped and constrained by their close adaptation to the particular ecological niche they inhabit, the human liver, and their requirement for efficient transmission between individuals.

## Hepatitis C virus

The genetic diversity of HCV exists at several different levels. Most obvious is the great genetic divergence of the currently classified six major genotypes of HCV. These frequently show specific geographical ranges in the human population and associations with particular risk groups for infection (see next section). At a lower level is the variability observed between different HCV strains within a genotype. Much of the sequence diversity observed between such HCV strains (such as the 5–8% divergence observed between variants in epidemiologically unlinked HCV genotype 1a, 1b and 3a infections) reflects processes of neutral sequence drift over time after the introduction of HCV into new risk groups in the 20th Century. It is also possible that some of the sequence divergence may be phenotypically selected changes associated with adaptation for replication in different individuals with different immune responses to infection. Finally, HCV diversifies measurably within an infected individual over time, forming what has been described as a 'quasispecies'. This pre-existing genetic variability, combined with an extremely large replicating population size of HCV in a chronically infected individual, provides a large pool of genetic variants that can readily adapt to new selection pressures such as antiviral treatment.

### HCV genotypes

HCV shows quite extensive genetic diversity, a feature shared with many other RNA viruses that infect humans and other mammals. Comparison of the nucleotide sequences of HCV variants recovered from infected individuals in different risk groups for infection, and from different geographical regions has revealed the existence of at least six major genetic groups (Fig. 5.1). As an average over the complete genome, these differ in sequence by 30–35% of nucleotide sites, with more variability concentrated in regions such as the E1 and E2 glycoproteins, while sequences of the core gene and some of the non-structural protein genes such as NS5 are more conserved. Least sequence variability between genotypes is found in the 5′ and the terminal region of the 3′ untranslated regions, where sequence conservation is thought to be essential for their replication and translation functions (see Chapter 24). In broad terms, the sequence differences between HCV genotypes are comparable to those observed between serotypes of other viruses, such as dengue virus 1–4 in the *Flaviviridae*, and between those of poliovirus serotypes (member of the *Picornaviridae*). It is therefore likely that the genotypes of HCV are antigenically distinct, representing a potential problem with the future development of broadly effective vaccines against HCV (Chapter 35).

Each of the six major genetic groups of HCV contains a series of more closely related subtypes, typically different from each other by 20% in nucleotide sequences compared with the >30% between genotypes (Fig. 5.1).[4] Some, such as genotypes 1a, 1b and 3a, have become very widely distributed as a result of transmission through blood transfusion and needle sharing between injecting drug users (IDUs) over the past 30–70 years (Chapter 25) and now represent the vast majority of HCV infections in western countries. These are the genotypes most commonly encountered clinically, and for which most information has been collected on response to interferon and other antiviral treatments (see Chapter 33).

A different pattern of HCV sequence diversity is observed in parts of Africa and south-east (SE) Asia. Here, there are close associations between HCV genotypes and specific geographical regions (Fig. 5.2). For example, HCV infections in Western Africa are almost invariably by genotype 2,[5–9] while those in Central Africa, such as the Democratic Republic of Congo (DRC) and Gabon are by genotype 1 and 4.[7,10–15] In both regions, there is a remarkable diversity of subtypes. For example, 20 of 23 HCV-seropositive blood donors in Ghana (West Africa) were infected by genotype 2, but each corresponded to

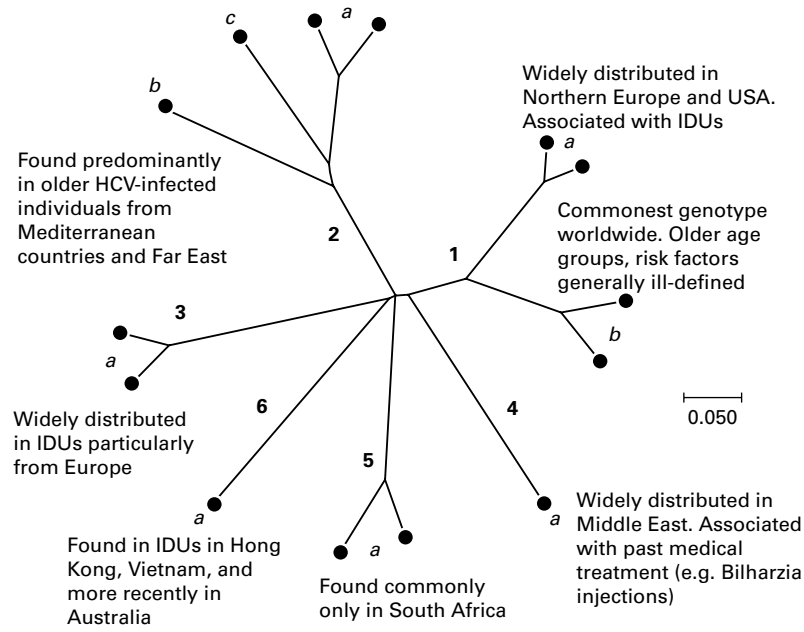

**Figure 5.1** Evolutionary tree of the principal genotypes of HCV found in industrialized countries, and their main epidemiological associations with specific risk groups. These genotypes of HCV are believed to have become prevalent over the course of the 20th century. The tree was constructed using the phylogeny programme Neighbour-Joining implemented in the MEGA package, using Jukes-Cantor corrected distances between complete genome sequences. IDU, injecting drug user.

different and previously undescribed subtypes.[5] This diversity is reproduced in Guinea-Bissau (West Central Africa), where 18 different subtypes of HCV genotypes 1 and 2 were found in samples from 41 HCV-infected individuals.[6] These field observations reflect both the huge genetic diversity of HCV genotypes 1, 2 and 4, and also its likely long-term presence in human populations in these parts of Africa. Taking this geographical mapping further, genotypes 3 and 6 show similar genetic diversity in south and eastern Asia.[7,16–18]

The model suggested by these genotype distributions is that HCV has been endemic in sub-Saharan Africa and SE Asia for a considerable time, and the occurrence of HCV infection in western and other non-tropical countries represents a relatively recent emergence of infection in new risk groups for infection.[13,19] In the 20th Century, parenteral exposure to blood-borne viruses became frequent through the widespread adoption of blood transfusion since the 1940s, the medical use of often unsterilized needles for injections and vaccinations (a practice that continues in many developing counties) and most specifically to industrialized countries, injecting drug use and the sharing of injection equipment. These new routes for transmission plausibly account for the epidemiological and genetic evidence for recent epidemic spread of HCV over the past 50 years in Europe, Egypt and elsewhere.[13,20–22]

However, one of the puzzles about the origins of HCV is the absence of obvious transmission routes for HCV in human populations of Africa and SE Asia, where the greatest genetic diversity is observed. Transmission by either sexual contact or from mother to child is uncommon (see Chapter 25), and there is little evidence historically for the type of widespread parenteral exposure that fuelled the HCV epidemic in western countries. However, recent field investigations in southern Burkino Faso (Central/Western Africa), where HCV genotypes 1 and 2 are prevalent and highly diverse in sequence, have shown associations between HCV infection with previous sexually transmitted diseases (STDs), circumcision

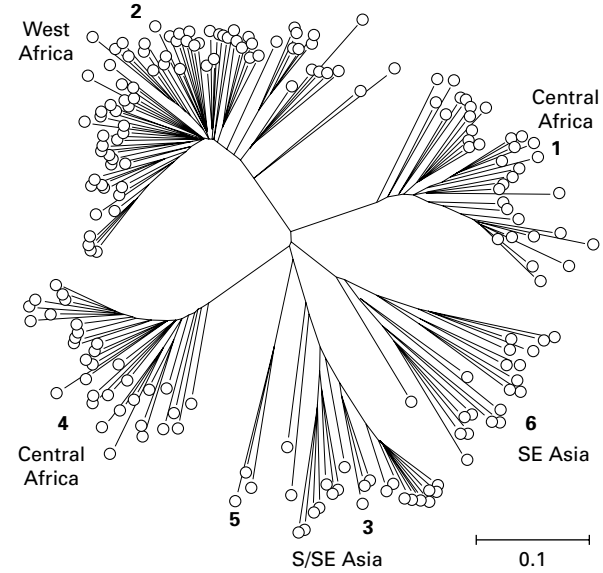

**Figure 5.2** Evolutionary tree of all available NS5B sequences of subtypes and genotypes of HCV, including those found in high diversity areas of of genotypes 1, 2 and 4 (sub-Saharan Africa), and 3 and 6 (south-east Asia). HCV variants still fall into six distinct clades, but with far greater numbers of genetic variants corresponding to subtypes in industrialized countries. The tree was constructed using the phylogeny programme Neighbour-Joining implemented in the MEGA package, using Jukes-Cantor corrected distances between partial NS5B sequences (320 bases).

and scarification practices.[23] Although the association with STDs has not been documented in studies carried out in western countries (see Chapter 25), it is possible that lack of mucosal integrity associated with long-term untreated infections may facilitate the entry of HCV into the genital tract. Determining how long HCV has been in these 'endemically' infected populations would clearly be of value in understanding the epidemiology of HCV in these regions (see below).

Even less is known about the earlier divergence of the six major genotypes of HCV, the origins of HCV infection in humans, and the underlying basis for the current geographic distribution of HCV genotypes. Strangely, those areas where HCV is endemic and highly diverse are precisely those where HBV is prevalent (see below), and also represent regions where human and ape population ranges overlap. However, in contrast to HBV, there is currently no evidence that HCV or HCV-like variants infect Old World ape or monkey species.[24] Therefore, despite the tempting analogies with the introduction and spread of human immunodeficiency virus (HIV)-1 and -2 infections in humans through cross-species transmission of simian viruses from chimpanzees and mangabeys,[25,26] it would be highly speculative and currently unjustified to imagine that HCV originated in these human populations as a result of similar cross-species transmissions. On the other hand, it has been discovered that a very distantly related HCV-like virus, GB virus B,[27] infects tamarins and/or other New World primates. The existence of this homologue in such a distantly related primate species certainly allows the possibility that HCV or HCV-like viruses may indeed be more widely distributed in primates than previously thought. Larger-scale serological and PCR-based surveys of a much larger range of primates in Africa, Asia and South America are required to resolve this issue.

## Sequence variability within genotypes

Several studies have described the rapid sequence drift of HCV over time, a process of diversification that leads to the existence of identifiably separate HCV strains or isolates within human populations. By comparing HCV sequences from sequential samples from chronically infected individuals, or from those infected from a common source, rates of sequence change of HCV were measured to be $1.44 \times 10^{-3}$ nucleotide changes per site per year over the whole genome, or 4 4.1 and $7.1 \times 10^{-4}$ changes per site per year in the NS5 and E1 regions.[28,29] In coding regions of the genome, these changes occur predominantly at synonymous sites (sites that do not alter the encoded amino acid), and are therefore likely to represent the accumulation of phenotypically neutral changes. The expectation from neutral theory that such diversification should occur at a constant rate over time is implicit in attempts to use this rate to estimate times of spread of HCV in specific transmission networks such as IDUs,[20–22] and indeed extrapolation to calculating times of introduction of specific HCV genotypes such as 1a, 1b, 3a and 4a into new risk groups for infection in western countries.[29] For example, the current sequence diversity and phylogenetic tree structure of genotype 4a in Egypt is compatible with the introduction of HCV into that population through parenteral treatment for schistosomiasis (tragically with non-disposable and poorly sterilized needles) in the 1950s and 1960s.[21,30,31] The increasing sequence diversity within genotypes 3a, 1a, 1b, 2a and 2b, respectively, suggests times of introduction of these viruses at increasingly earlier times in the 20th Century associated with other parenteral risk factors for infection such as injecting drug use, blood transfusion, large-scale immunizations and syphilis treatment.[32]

While regions of the genome such as NS5B have frequently been used for epidemiological reconstruction, other parts of the genome such as the 'hypervariable' regions (HVRs) of E2 and NS5A show much greater variability and much more rapid amino acid sequence change over time. This variability may arise through specific selection (Darwinian) mechanisms operating on the virus associated with immune escape. For example, the HVR in E2 may be a target for neutralizing antibody, and HCV persistence may therefore require continuous virus sequence change to evade B-cell responses.[33–36] For HIV-1, it is known that initial infection is accompanied by a number of amino acid changes in class I binding motifs in potential T-cell epitopes, such as the Arg → Lys or Gly change in the immunodominant epitope in $p24^{gag}$ recognized by the B27 allele.[37] These mutations occur with some fitness cost and revert to wild type on the development of severe immunodeficiency, and probably on further transmission to other individuals with different HLA types. It is therefore possible that many of the amino acid polymorphisms observed in HCV are also driven sequentially by selection from different major histocompatibility complex (MHC) class I or II alleles encountered during a virus's passage through human populations, comparable to the observed immune-selected changes in cytotoxic T-lymphocyte (CTL) epitopes in experimentally infected chimpanzees.[38] Supporting this hypothesis is the observation that HCV sequence change was slower in individuals with defects in T- or B-cell immunity,[39] interpreted as indicating reduced immune selection on CTL or B-cell epitopes. Indeed, recovery from HCV infection is associated with strong and sustained CTL responses around the time of primary infection,[40–42] a time where there was evidence for specific changes in CTL epitopes, and accelerated sequence change in the HCV coding sequence was observed in those who became chronic carriers.[43,44]

The high degree of sequence variability observed within genotypes in the NS5A region is puzzling, because it has been demonstrated that, at least in some human populations, certain sequences in the 'interferon sensitivity determining region' (ISDR) of genotypes 1b, 2a and 2b (described as 'prototype') are associated with resistance to interferon (IFN) treatment[45] (see Chapter 33). NS5A is a multifunctional protein with a number of activities, such as binding to protein kinase (PKR), that contribute to the evasion of host cell antiviral mechanisms[46,47] (Fig. 5.3). As the 'prototype' ISDR sequence of NS5A is specifically found in individuals who resist IFN therapy, it is difficult to imagine why there should not be selection and the acquisition of resistance to treatment in those with non-'prototype' sequences. However, NS5A is known to contain a high concentration of T- and B-cell epitopes,[48–51] and it is possible that immune selection drives the ISDR or neighbouring sequence away from the optimal functioning protein (corresponding to the prototype sequence) in individuals with certain human leukocyte antigen (HLA) types, analogously to the changes in p24$^{gag}$ of HIV-1 selected by the B27 class I allele. A poorly functioning NS5A protein may make the infecting virus more sensitive to intracellular antiviral responses and thus to a greater likelihood of spontaneous viral clearance, as well as increased susceptibility to IFN therapy in those who remain viraemic.

The balance in this 'trade-off' between NS5A function and immunological recognition may differ between genotypes of HCV. For example, the reason why genotypes 2 and 3 infections are generally much more responsive to IFN treatment (see Chapter 33) may be because a far greater proportion of individuals immunologically recognize the prototype NS5A protein. Subsequent evolution of the infecting virus with a functionally impaired NS5A protein makes it less able to resist the further assault of exogenously administered IFN used for therapy. Human population-specific differences in the frequencies of HLA types in different study groups may also go some way to explaining why the association of 'prototype' ISDR sequences with treatment resistance varies so much between studies in Japan and Europe (Chapter 33).

## HCV 'quasi-species'

The processes of neutral and adaptive evolution of HCV operate during the course of chronic HCV infection within an individual, leading to both continued fixation of nucleotide changes over time, and the development of variable degrees of sequence diversity within the HCV replicating population at a given time point. Sequence diversity is generated continuously during virus replication because RNA copying by the virally encoded RNA polymerase (NS5B) is error-prone, and because the replicating population of HCV is so large. For example, ongoing error rates ranging from 1 in 10 000 to 100 000 bases copied typically found in RNA polymerases,[52,53] combined with a rate of virus production of up to $10^{12}$ virions per day,[54] would produce a genetically diverse population of variants. It could be predicted statistically that the 'quasi-species' would include mutants differing at every nucleotide position and every combination of paired nucleotide substitutions from the population average or consensus.

Even though the consensus sequence may be optimal in fitness at any one time, the existence of a large and diverse population would allow very rapid adaptive (Darwinian) changes associated with changes in the replication environment. This might take the form of evolving immune responses that select against viruses with specific T- or B-cell epitopes. It might also confer resistance to antiviral agents. The rapid and reproducible independent appearance of specific amino acid changes associated with the acquisition of HIV-1 resistance to reverse transcriptase and protease inhibitors is a dramatic demonstration of 'quasi-species' evolution. This may be

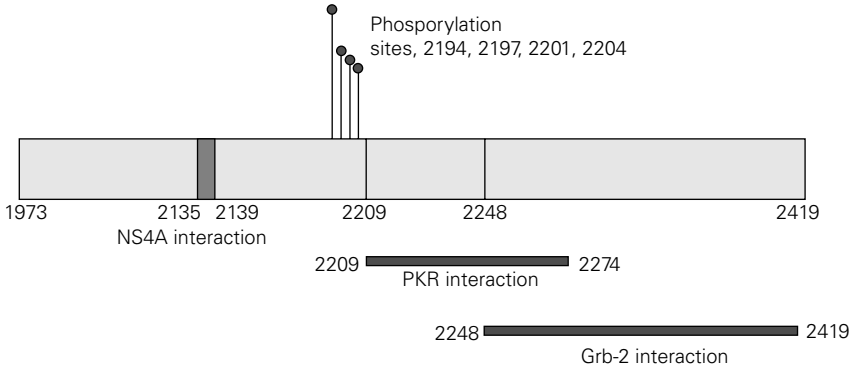

**Figure 5.3** Diagram of the NS5A gene, showing the interferon-sensitivity determining region (ISDR), and regions of the protein known to interact with protein kinase (PKR) and other cellular pathways associated with innate cell defences against viruses. Sequence changes in the ISDR correlate with sensitivity of the virus to interferon therapy, potentially representing a trade-off between functional activity and immune selection.

reproduced in HCV infections treated with the new generation of antiviral agents, such as BILN2061 and other protease inhibitors (Chapter 34).[55–57]

### Origin of HCV genotypes

How long HCV has been present in human populations is difficult to estimate. As described above, the diversity of HCV variants within genotypes 1, 2 and 4 in sub-Saharan Africa and of genotypes 3 and 6 in SE Asia suggests that HCV may have been endemic in these populations for considerably longer than in western countries. As the evolutionary process of HCV sequence divergence that led to the diversity of subtypes in these regions is likely to have been predominantly neutral in mechanism, it may therefore be possible to calculate the times of splitting of HCV subtypes, and possibly also the time of divergence of the six main clades of HCV through use of published rates of HCV sequence change over time.[28,29]

Extrapolation of these rates to time the 20% and 30% sequence divergence observed between HCV subtypes and genotypes produces relatively recent times of origin that in many ways are difficult to reconcile with the epidemiology of HCV and its global distribution. For example, the diversity of HCV variants observed in West African genotype 2 sequences predicts a time of origin for this endemic pattern of infection approximately 200–250 years ago, while the HCV genotypes 1–6 would have diverged about 100 years earlier. Even using complex methods for correction for multiple substitutions and allowing rate variation between sites, the current diversity of HCV genotypes predicts an origin no earlier than 1000 years ago.[29] This seems recent for such a widely distributed virus infecting often relatively isolated human populations in equatorial Africa and SE Asia.

We have argued that hidden constraints of HCV sequence change, such as the extensive RNA secondary structure in coding regions of the genome,[58,59] may severely limit the number of 'neutral' sites in the genome. In the case of HCV, such constraints would operate on base positions where sequence changes would disrupt internal base-pairing of RNA structured elements.[19,58] Given the complexity and large scale of these HCV RNA secondary structures, truly 'neutral' sites not involved in base-pairing may be rare indeed. Although neutral drift evidently still occurs in HCV, reconstructing the timescale of diversification is hampered by not knowing how many and at which sites sequence changes can be fixed without fitness cost. Until these issues are better understood, there remain major problems in making adequate correction for multiple substitutions in the calculation of evolutionary distances. In making the estimates above for 350–1000 years for the time of divergence of HCV genotypes, we are in danger of telescoping a much longer period of virus evolution into an unrealistically short time-frame.

## Hepatitis B virus

The tempo and mode of HBV evolution show many similarities with those of HCV. Several genotypes of HBV exist, many with specific geographical locations overlapping those of HCV. Similarly, much of the sequence change observed on chronic infection shows evidence for adaptive selection, with evidence for amino acid changes in response to immune pressure and antiviral treatment. There are, however, important differences, most strikingly the existence of widespread infection of non-human apes with HBV variants that show a complex evolutionary relationship with human genotypes. Furthermore, there is frequent recombination between HBV genotypes infecting humans, whereas this is extremely uncommon in HCV. Persistence of HBV infection *in vivo* is also characterized by modulation of gene expression, including the appearance of mutations in the precore region that prevent translation of the HBV e antigen (HBeAg), probably originating through some kind of immunological selection.

### HBV genotypes

Variants of HBV can be currently classified into a total of approximately seven or eight genotypes.[60,61] The genotypes designated A–E and G differ from each other by around 9% in nucleotide sequence (Fig. 5.4). However, genotype F and the related genotype H, are outliers and more divergent in sequence (approximately 13%). Certain genotypes show specific geographical distributions: B and C in East and SE Asia; E in West, sub-Saharan Africa; A predominantly in Central Africa; and genotypes H and F largely confined to aboriginal Indian populations in Central and South America. There is currently insufficient information for genotype G to allow its geographical distribution to be defined. Genotype D appears to be globally distributed (Europe, Africa, Asia) without evidence for a specific geographical origin as found for other genotypes. Regions where certain genotypes can be localized correspond generally to where HBV in human populations is endemic and highly prevalent (sub-Saharan Africa [A, E], east/SE Asia [B, C] and South America [F]). As described above, the first two areas are also those characterized by HCV endemicity and genetic variability.

Recombination between different genotypes frequently leads to the appearance of viable hybrid viruses with highly variable and frequently complex combinations of genetic elements derived from the parental viruses.[62] Although many recombinant viruses have been observed only sporadically, others may be widely distributed,

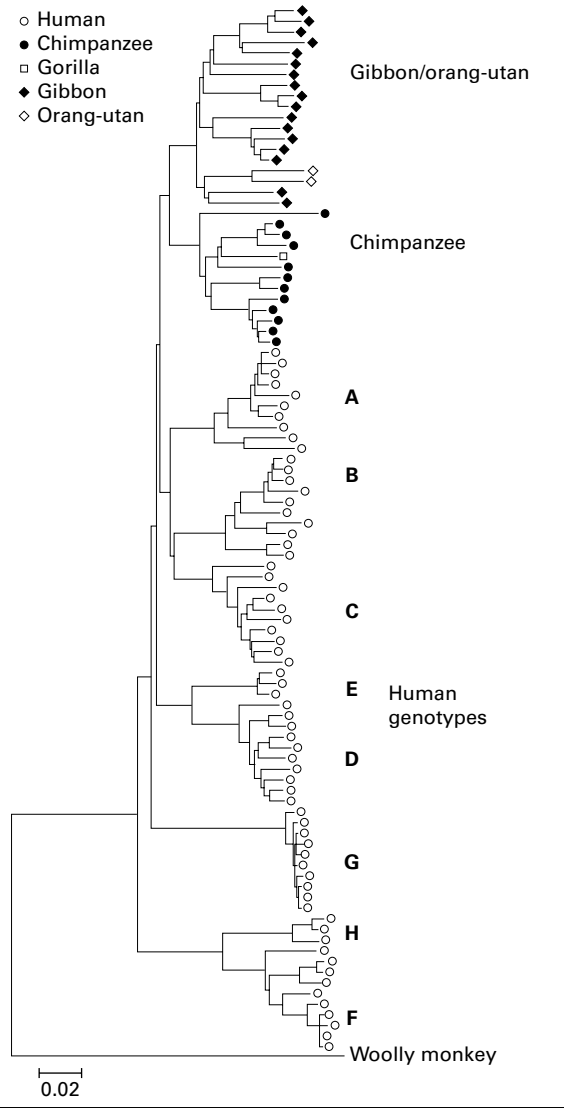

**Figure 5.4** Genotypes of HBV infecting humans (A–H), and relationship with those infecting chimpanzees, gibbons, other ape species and the woolly monkey. Human genotypes A–E and G are approximately equally divergent from each other and from the two clades of HBV variants infecting predominantly chimpanzees and gibbons (9% sequence divergence). These latter sequences are more similar to these human genotypes than those found in human populations in Central and South America (F and H), and the highly divergent HBV variant recovered from a captive woolly monkey (of uncertain origin). The tree was constructed using the phylogeny programme Neighbour-Joining implemented in the MEGA package, using Jukes-Cantor corrected distances between complete genome sequences.

such as a C/D recombinant virus in Tibet,[63] A/C in Vietnam[64] and B/C recombinant frequently found in eastern Asia.[65] Infection with the latter is more frequently associated with HBeAg expression than the non-recombinant form of genotype B, and it may therefore differ in long-term pathogenicity, transmissibility and treatment response from non-recombinant forms.[66]

HBV infection is also highly prevalent in chimpanzees and gorillas in sub-Saharan Africa, and in gibbons and orang-utans in SE Asia, each species showing frequencies of HBsAg carriage ranging from 10% to 30%.[24,67] In general, these different ape species are infected with genotypes of HBV distinct from each other, with suggestions that ape-derived HBV variants can be classified into chimpanzee, gibbon and orang-utan-specific genotypes.[67–74] This may be an oversimplification, as further analysis of HBV variants in SE Asian primates showed that phylogenetic grouping correlated better with geographical range than host species.[67] For example, variants from orangutans more closely resembled those from gibbon species at the southern end of their geographical range, a result of an overlap in their natural habitat, rather than forming a separate species-specific phylogenetic group (Fig. 5.4). Similarly, from the minimal data available at present, HBV variants infecting gorillas appear most similar to HBV variants recovered from central African chimpanzees,[68] rather than forming a separate species-associated lineage.

What are the origins of HBV infection in humans? Despite the existence of widespread infection of ape species in areas where human HBV infection is endemic and highly prevalent, there is no evidence for direct cross-species transmission, as human- and primate-derived HBV genotypes are invariably distinct and non-overlapping. Thus, despite large surveys, there is no evidence for infection in human populations in Central or West Africa with HBV variants resembling those found in chimpanzees, nor have the human genotypes from this region (A and E) been detected in chimpanzees (with the exception of one genotype E-infected chimpanzee, although in this case, iatrogenic transmission of HBV in captivity cannot be ruled out[72]). There is similarly no overlap between human genotypes B and C with gibbon- or orang-utan-derived HBV variants. There is therefore no support for the type of cross-species transmission model proposed for the origins of HIV-1 or -2 infection in humans.[25,26]

The inter-relationships of human- and non-human ape-derived HBV genotypes are indeed complex, and difficult to reconcile with any straightforward evolutionary hypothesis for human HBV origins.[19] Ape-derived genotypes of HBV are interspersed with human genotypes A–E and G, differing from each other and from these human genotypes by the same 9% level of divergence found between most human genotypes. Although the chimpanzee and gibbon/orang-utan groups are internally relatively diverse, this does not reproduce the multiple genotype diversity observed in human populations, and the outlier genotype F/H from South America. It could be argued that humans acquired HBV

infection through cross-species transmission of HBV variants infecting a different set of non-human primate species in Africa and Asia. However, several serological and PCR-based surveys concur that HBV infection in the wild is confined to the four species of ape described above.[24,67]

## HBV sequence variability within genotypes

The phylogenetic tree of human and ape HBV variants (Fig. 5.4) includes a selection of published sequences from each genotype. From this it is apparent that variable degrees of sequence divergence exist within each genotype, with genotype E sequences being perhaps the least variable, and the gibbon/orang-utan clade being the most diverse. Just as the human and other ape genotypes show different geographic distributions, sequence variability within genotypes may also correlate with geographical origin. For example, while both genotype C and D variants are widely distributed in SE Asia, those from mainland Asia are genetically distinct from HBV variants found in the aboriginal population in Papua New Guinea and from those in Australia.[75,76] Variants of genotype A (but not E) are similarly segregated between Central and West Africa, while Central American variants designated as genotype H[77] could perhaps be more consistently classified as geographical variants of genotype F found in South America. These observations are consistent with long-standing endemic infections in what are frequently aboriginal and highly isolated human populations, implying extremely slow long-term sequence change over time. How this can be reconciled with observation for rapid sequence change over short periods is discussed in the next section.

The previous evolutionary history of HBV in humans and non-human ape populations therefore remains difficult to reconstruct, and the current distribution of HBV infection and association of certain genotypes with specific geographical areas and/or host species cannot be easily explained by any of the currently discussed theories for HBV origins. As for HCV, attempting this type of reconstruction would be assisted by knowledge of the rate of sequence change of HBV, providing some kind of estimate of the times of divergence of the human and ape genotypes. Although short-term rates of sequence change of HBV have been measured (see next section), extrapolating these to longer periods leads to the same intractable problems encountered for HCV (see above).

## Mechanisms of HBV sequence change

For HCV, neutral sequence drift undoubtedly accounts for much of the genetic variability observed between different genotypes, as well as between isolates of the same genotype found in different infected individuals. For HBV the situation is much less certain. The rate of fixation of sequence changes of HBV has been calculated by sequence comparisons of HBV variants recovered from sequential samples from chronically infected individuals,[78] averaged at $2.1 \times 10^{-5}$ substitutions per site per year for those who were HBeAg-positive. Remarkably, however, sequence change was more than 10 times faster in those who were HBeAg-negative. The continued production of HBeAg during chronic infections reflects partial immune tolerance to HBV, and is typically the outcome of perinatal infection (see Chapter 11). The much higher rate observed in those who have cleared HBeAg therefore suggests that the majority of sequence changes in HBV are immunologically driven. This might take the form of changes to class I or II epitopes presented to T cells (as described for HIV-1), or alterations to linear or conformational epitopes recognized by immunoglobulins.

Understanding the relative contributions of neutral and adaptive mechanisms of sequence change of HBV is complicated by a number of factors peculiar to HBV. Most of the genome of HBV is configured to contain not one but two or in some regions three coding sequences in different reading frames (Chapter 10). Given that the remaining single coding and non-coding regions of the genome are packed with RNA structural elements and transcriptional and translational regulatory sequences (Chapter 10), it is doubtful whether there are any sites where sequence change has no significant effect on phenotype as demanded by neutral theory.[3] Combined with the evidence for intense immune system-mediated selection for sequence change, a large part of the sequence diversification over time observed in chronically infected individuals and on transmission must represent the evolution of HBV mutants changing under intense Darwinian selection for immune evasion. As already described for HIV-1 epitopes, such sequence changes incur fitness costs and may revert on transmission of infection to individuals with different HLA types. Thus, the apparent relatively rapid sequence change observed in chronic infection, rather than being accumulative, may simply involve flip-flopping of certain key amino acid residues that are most immunogenic. There may therefore be no net sequence evolution over longer periods, each genotype gravitating towards a particular phenotypically optimized master sequence constrained in a relatively rugged fitness landscape. As described earlier for HCV and related viruses, this restriction of neutral sites suggests that while only 10–13% divergent, times of divergence of genotypes of HBV infecting human and primates are not only incalculable but also potentially ancient in the absence of sustained neutral drift. Indeed, the apparently simple and largely unstructured branching of human and ape genotypes may well conceal a complex evolutionary history that is now obscured by

large numbers of selected, convergent sequence changes. These may defeat attempts to construct a true phylogeny for HBV by nucleotide sequence comparisons alone.

Further evidence for the genetic plasticity of HBV under selection pressure is provided by observation of the rapid and stereotyped amino acid changes in the *pol* gene that confer resistance to lamivudine[79] and other antiviral agents targeting the HBV reverse transcriptase (see Chapter 20). As for HIV-1 and HCV, this is the likely outcome of a large 'quasi-species' population present in infected individuals, in which mutants with the required resistance change may be present by chance at the start of antiviral therapy, and expand under drug-induced selection pressure to become the dominant variant over the initial weeks of therapy. Comparable is the observation that treatment of immunosuppressed transplant recipients with anti-HBsAg antibodies frequently generates HBV mutants with mutations in the immunodominant 'a' determinant that escape from antibody binding.[80,81] Less certain are the selection pressures that drive sequence change in the precore region, and which inhibit the expression of HBeAg.[82] These nucleotide changes include a stop codon in the coding sequence, and substitutions in the core promoter region that decrease transcription of the HBeAg/core mRNA. The regularity with which pre-core mutants emerge during the course of chronic infection, particularly in HBV genotypes B, C, D and E suggests that such changes have a selective advantage over wild-type HBV variants. At present, however, the functional significance of this change, and indeed of HBeAg expression itself, remain unclear.

## Summary

The evolution of HCV and HBV comprises highly dynamic processes, occurring both through multiple processes of adaptive selection that drive sequence change (such as those resulting from the host immune response and from antiviral treatment) and through drift in which phenotypically neutral sequence changes accumulate over time without altering the phenotype or behaviour of the virus. However, despite their potential to evolve rapidly, the longer-term evolution of both viruses appears remarkably conservative. Little fundamental change in the relationship with their human hosts in terms of persistence and transmission has developed between genetic variants of HBV and HCV, despite the probably extremely long periods over which this viral diversity has developed. HCV and HBV thus appear to have successfully filled very specific, different ecological niches in human populations. The intimate host/parasite relationships in which these viruses thrive are therefore likely to have a degree of complexity that we are only just beginning to understand in current studies of their pathogenesis.

# Section III
# Hepatitis A Virus

# Chapter 6
# Structure and molecular virology

Stanley M Lemon, Annette Martin

## Introduction

Hepatitis A virus (HAV), the causative agent of acute, infectious type A hepatitis, is a positive-strand RNA virus classified within the family *Picornaviridae*. While both its structure and the organization of its genome share features in common with other picornaviruses, such as poliovirus or encephalomyocarditis virus, several important features of HAV distinguish it from other human and animal members of this large virus family. These unique features of HAV include its relatively high level of resistance to thermal denaturation, its remarkable stability under low pH conditions, and the composition and details of the assembly of the viral capsid structure (in as much as it is understood). Coupled with the fact that HAV shares only very limited nucleotide homology with other picornaviruses,[1] these features have contributed to the classification of HAV within a novel genus of the family *Picornaviridae*, the genus *Hepatovirus*.[2] One other distinct species of picornavirus, avian encephalomyelitis virus, has been placed within this genus on the basis of a remarkably close phylogenetic relationship to HAV.[3]

## Overview of HAV structure and the viral life-cycle

As with other picornaviruses, the infectious HAV particle is small, non-enveloped, and approximately 27 nm in diameter.[4] It comprises a highly stable, icosahedral protein capsid containing an RNA genome consisting of a single, messenger-sense molecule approximately 7.5 kb in length.[1] The HAV genome generally resembles that of other picornaviruses in terms of its overall organization and, quite likely, the mechanisms by which it replicates (Figs 6.1 and 6.2). There is a small viral protein (VPg) linked to the 5′ terminus of the genomic RNA,[5] and a lengthy, templated poly-A tract at the 3′ end. Like the genomic RNAs of other positive-strand viruses, this positive-sense RNA acts as messenger RNA, directing the translation of viral proteins upon its release into the cytoplasm following the entry of virus particles into the hepatocyte, the major cell type infected by the virus. Viral RNA replication takes place exclusively within the cytoplasm of the infected cell. A single open reading frame (ORF) extends through much of the length of the genomic RNA and encodes a large viral polyprotein that is co-translationally processed into individual structural and non-structural proteins, in large part by a single, virally encoded proteinase. This results in the production of three to four mature structural proteins (encoded by the 5′ third of the ORF) that assemble into the capsids required for production of progeny virus, as well as at least seven non-structural proteins (encoded by the remainder of the ORF) that function to support replication of the genome. The organization of the viral genome and the proteins it encodes is depicted in Fig. 6.1.

A recent detailed review of the viral replication cycle is available elsewhere,[6] but key steps in the life-cycle of HAV include (1) the attachment of the virus to a cellular receptor and its penetration into the hepatocyte, (2) uncoating of the viral RNA with its release into the cytosol, (3) translation of the RNA genome by a process involving internal ribosome entry and resulting in the production of the viral polyprotein, (4) co- and post-translational proteolytic processing of the polyprotein into both structural and non-structural proteins, (5) assembly of an RNA replicase complex at the 3′ end of the viral RNA and initiation of viral negative-strand (intermediate) RNA synthesis, (6) non-conservative synthesis of multiple copies of positive-strand RNA molecules produced from single negative-strand RNA intermediates, which are then directed to further polyprotein translation and RNA replication cycles, or (7) packaged into immature viral particles, followed by (8) maturation of the viral particles and their transport out of the cell. These events are depicted in Fig. 6.2.

Although many of these steps in the viral life-cycle have been studied in detail with other picornaviruses, relatively few particulars are known of these events for

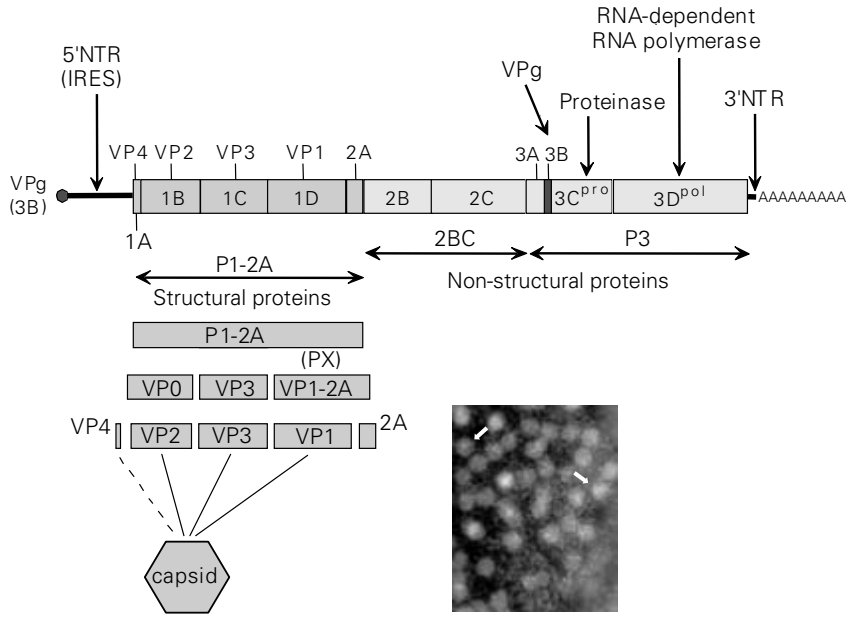

**Figure 6.1** Organization of the HAV genome and processing of the structural protein precursors. The virion RNA is 7.5 kb in length, positive-sense, and has 5′ and 3′ non-translated regions (5′NTR and 3′NTR) flanking a single large open reading frame encoding the viral polyprotein (shown as the large rectangular box). The 5′ terminal uridine residue is covalently linked to a small viral protein (3B, otherwise known as VPg). The 5′NTR contains substantial RNA secondary structures which comprise both replicase-recognition signals and the viral internal ribosomal entry site (IRES) that directs the cap-independent translation of the viral polyprotein (see also Fig. 6.3). The 3′NTR terminates in a poly(A) tract. The polyprotein is composed of three functionally distinct domains (P1–2A, 2BC and P3): each of these domains is proteolytically processed to yield smaller precursors as well as the mature viral proteins (1A, 1B, 1C, etc.). The structural proteins (shown in mid-grey), VP1 (1D), VP2 (1B), VP3 (1C), and possibly VP4 (1A), are encoded by the P1 region. 2A can also be considered a structural protein, as it functions in particle assembly and is not required for RNA replication. However, it is not a component of the mature virus particle. The non-structural proteins (shown in pale grey, except for 3B, shown in dark grey) have functions related to RNA replication, and are encoded by the 2BC and P3 regions. These proteins include an NTPase (2C) with possible helicase activity, VPg (3B) which functions in protein priming of RNA synthesis, the viral specific cysteine proteinase ($3C^{pro}$), and an RNA-dependent RNA polymerase ($3D^{pol}$). Primary proteolytic cleavage occurs between the 2A and 2B proteins and is directed by $3C^{pro}$, which also has RNA-binding activity and has functions related to RNA replication. Other processing events are also mediated by this protease, except for two cleavages within the structural protein precursors (the 1A/1B and 1D/2A cleavages) that occur during particle morphogenesis. The inset shows an electron microscopic image of 27 nm diameter virus particles with shape suggesting icosahedral symmetry (arrows).

HAV. The viral RNA replicase is an assembled structure comprising several different non-structural proteins that are associated with membranous vesicles that appear to be formed by redirection of membranes from the endoplasmic reticulum.[7,8] The association of the viral replicase with intracellular membranes is typical of positive-strand viruses, and is also observed with hepatitis C virus (HCV).[9]

## Growth of HAV in cultured cells

Unlike other human hepatitis viruses, HAV can be propagated in a variety of different types of mammalian cells, although most often cells of primate origin are used. Interestingly, and in contrast to the invariably transient nature of HAV infections in infected humans, infection of cultured cells is typically not associated with any dramatic cellular injury and commonly leads to long-term persistence of the virus. These observations are consistent with the fact that HAV replication does not interfere specifically with cellular macromolecular synthetic processes, and does not induce the shutdown of cellular protein or nucleic acid synthesis as observed with poliovirus in cultured cells.[10] Variants of HAV that are cytopathic for cultured cells have been described, however (see below).

HAV was first isolated in marmoset liver explant cultures and was subsequently propagated in continuous fetal rhesus monkey kidney cells.[11,12] However, the virus may be directly isolated from clinical materials in primary African green monkey kidney (AGMK) cells, or, with somewhat greater difficulty, in continuous cell lines including BS-C-1 cells, MRC-5, FRhK-4, PLC/PRF-5 (human hepatoma cells), and others.[13–15] HAV is also

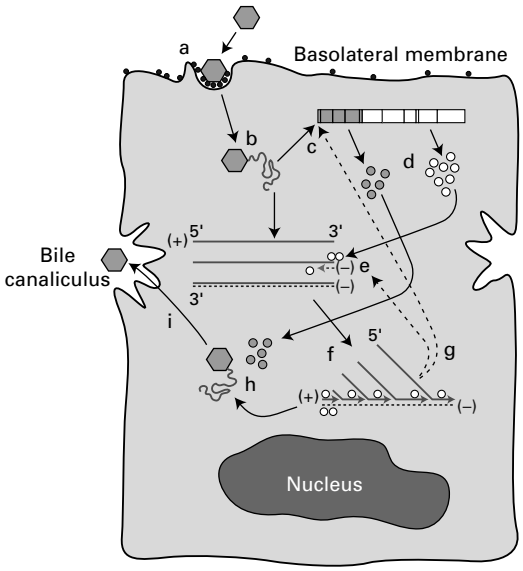

**Figure 6.2** Schematic showing major features of the replication cycle of HAV. (a) Virus attachment occurs at a specific cellular receptor on the basolateral surface of the hepatoctye, within the space of Disse, and is followed by (b) penetration and uncoating of the virus particle. Subsequent events take place exclusively within the cytoplasm of the cell, and do not disrupt cellular homeostasis. These include (c) translation of the polyprotein by a 5′ cap-independent mechanism under control of the viral IRES, (d) co-translational processing of the polyprotein by the $3C^{pro}$ proteinase into structural and non-structural proteins, (e) assembly of a membrane-bound viral replicase complex at the 3′ end of the positive-strand genomic RNA (dark grey) resulting in the synthesis of a negative-strand intermediate RNA molecule (dotted line), (f) synthesis of new positive-strand progeny RNA (dark grey), which can either (g) reinitiate the cycle by undergoing translation or replication (dashed lines) or (h) be packaged into new virus particles. Finally, (i) newly formed virus particles are transported to the apical surface of the cell and exported into the biliary canaliculus.

capable of replicating in a broader diversity of mammalian-derived cell types, including cells of guinea pig or dolphin origin.[16]

Wild-type virus usually replicates very slowly and to relatively low titres in cultured cells. Thus, there is no utility to virus isolation as a diagnostic modality. Low passage virus typically requires several days to weeks to reach maximal titres in cell cultures, and usually requires immunological or nucleic acid hybridization techniques to be detected because of the lack of virus-induced cytopathic effects. Immunohistochemistry typically shows viral antigens confined to the cytoplasm, and present in a fine, speckled pattern (Fig. 6.3). With continued *in vitro* passage, however, the virus becomes progressively adapted to growth in cell culture, replicating more rapidly and achieving higher titres.[13,17] Well-adapted variants of the virus that replicate rapidly (i.e. with a replication cycle about 24 h in length) and to higher than usual titres in cultured cells may lead to cytoplasmic vacuolar changes and cell death.[18] Cellular injury appears to arise from the induction of apoptotic pathways leading to programmed cell death.[8,19] These viruses allow the use of conventional plaque assays for viral quantitation. Interestingly, continuous passage of the virus in cell culture frequently results in a reduction in the ability of the virus to replicate and cause disease in primates.[20]

*In vitro* replication is blocked by guanidine and brefeldin A,[21–23] which are both known to inhibit the replication of other picornaviruses.

## Structure of the HAV genome

The positive-strand RNA genome is a single-stranded 35S RNA molecule, approximately 7.5 kb in length, possessing structured 5′ and 3′ termini and a 3′ poly-(A) tail (Fig. 6.1).[1,24] As with other positive-strand viruses, purified genomic RNA is itself infectious and, whether extracted from virions or produced synthetically from cloned cDNA, will produce virus when transfected into permissive cultured cells or inoculated into the liver of susceptible primates.[25,26] However, the recovery of virus from synthetic wild-type RNA is very difficult in transfected cell cultures, and usually requires primate inoculation.

The small VPg protein that is covalently linked to the 5′ end of the genomic RNA is not required for infectivity, and its presence is probably vestigial, reflecting its

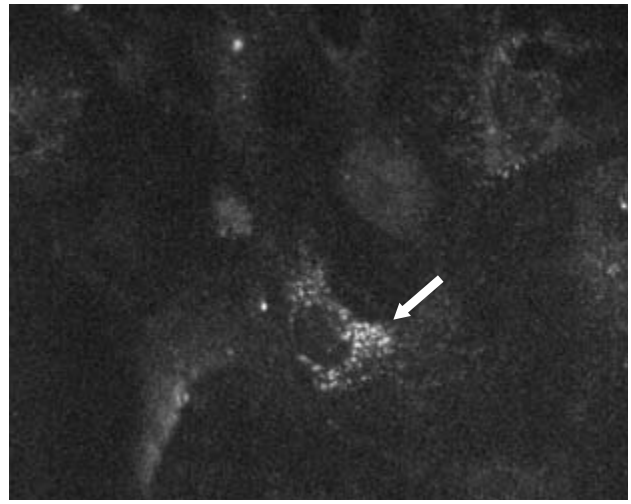

**Figure 6.3** Immunofluorescence staining of viral antigen in African green monkey kidney cells infected with a cell culture-adapted variant of HAV. Convalescent human antiserum was used as the source of antibody. Replication of the virus is evidenced by speckled cytoplasmic fluorescence within infected cells.

role as the protein primer for nucleic acid synthesis (see below).

## 5′ Non-translated RNA segment

The RNA genome contains a relatively lengthy 5′ non-translated region (5′NTR), ~730 bases long, with substantial secondary RNA structure and comprising series of several complex stem-loop structures.[27] RNA secondary structure within this segment of the genome has been mapped by a combination of phylogenetic comparative sequence analyses, functional genetic studies, and direct biophysical and nuclease mapping techniques[27] (Fig. 6.4). Structured elements within the 5′NTR have also been visualized at low resolution by transmission electron microscopy.[28]

The 5′NTR sequence contains several functional domains. These include a 5′ terminal hairpin followed by two RNA pseudoknots that are likely to function in recognition of the viral RNA by the replicase during initiation of RNA synthesis. Although apparently essential for replication,[29] it is not known whether these structures function in the positive-sense molecule, or in the negative-sense RNA intermediate (as replication signals at the 3′ end of this molecule). Both pseudoknots (Fig. 6.4) contain exclusively canonical Watson-Crick base-pairs, and are devoid of non-canonical G:U pairs that are commonly found in other structured RNAs. Thus, they may exist within either sense RNA. Surprisingly, the analogous segment of the poliovirus genome contains a cloverleaf RNA structure that has been shown to be required for initiation of negative-strand RNA synthesis,[30] and not positive-strand RNA synthesis as might be anticipated by the normal direction of RNA synthesis.

The two pseudoknots are followed by a pyrimidine-rich tract of about 44 nts (Fig. 6.4). This segment of the 5′NTR is not essential for either replication or pathogenicity, and has no recognized function.[31] It appears to assume a unique structural conformation,[32] nonetheless, and is likely to provide the virus with some selective survival advantage, given the efficient utilization of the genome that is generally evident among picornaviruses. Analogous and lengthier single-stranded, pyrimidine-rich RNA segments are found in the 5′NTR of other picornaviruses where they contribute to pathogenesis,[33] as well as within the 3′NTR of HCV, where it is essential for RNA replication.[34]

The pyrimidine-rich tract is followed by a highly structured RNA segment that functions as an 'internal ribosomal binding site' (IRES). The IRES facilitates the initiation of viral translation in a 5′ cap-independent fashion, as alluded to above, directing an interaction of the 40S ribosome with the viral RNA at a point close to the initiator AUG for viral protein translation.[35,36] Although IRES elements are found in all picornaviruses (as well as in some other virus families), the HAV IRES

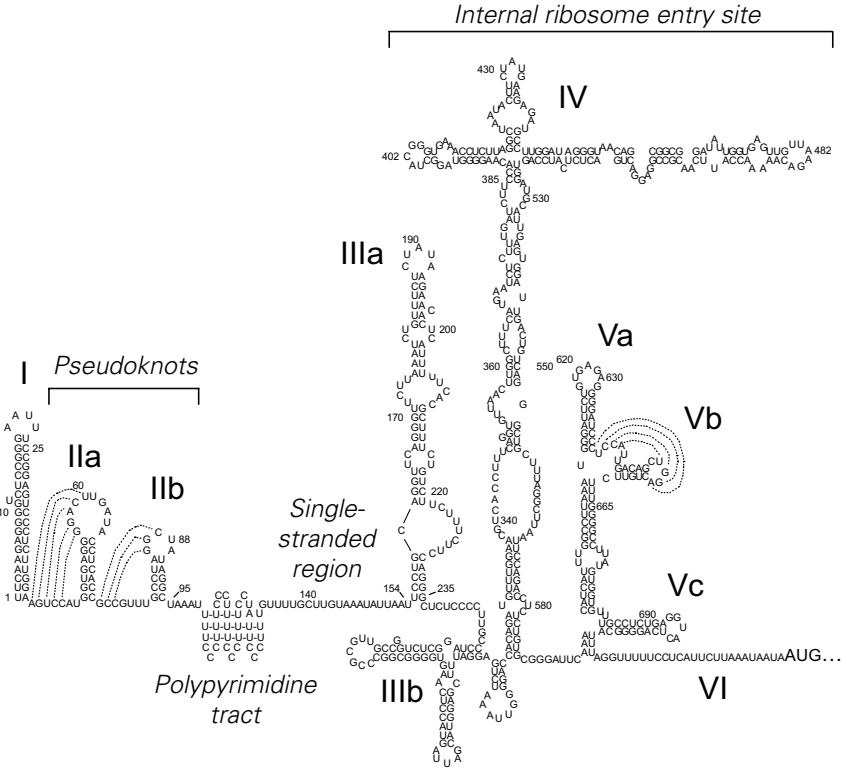

**Figure 6.4** Putative secondary structure of the 5′NTR of the HAV genome.[27,32] The 5′ terminal hairpin (domain I) and pseudoknots (domain II) are likely to function in recognition of the genome by the viral RNA replicase, while the IRES (domains III–VI) control the cap-independent translation of the viral polyprotein. The polypyrimidine tract that is present between these structural elements is not necessary either for replication or translation and is of unknown function. The initiator AUG is large font at the 3′ end of the displayed sequence.

differs from other viral IRES elements in its stringent requirement for cellular translation initation factors. Other picornaviral IRES elements require only a cleavage fragment of eukaryotic initiation factor eIF-4G, but the HAV IRES requires the intact protein for efficient translation initiation.[37,38] It also utilizes one or more cell-specific translation initiation factors,[39–41] and the affinity of the 5′NTR for these and other cellular proteins may play a role in defining cellular tropisms of the virus.[42–45] The strongest evidence relates to the cellular polypyrimidine tract-binding protein (PTB), which stimulates IRES directed translation both *in vitro* and in cultured cells.[40]

Most studies suggest that the IRES of HAV is less active than IRES elements of other picornaviruses, resulting in relatively inefficient translation of the viral message and possibly contributing to the slow growth of the virus.[37,42] The requirement for intact eIF-4G also means that HAV protein translation must compete for initiation factors in cells that are actively supporting ongoing translation of cellular mRNAs. Cellular protein translation shut-off is accomplished by several other picornaviruses (including poliovirus) through the proteolytic cleavage of eIF-4G by a viral proteinase. This does not occur in HAV-infected cells, as discussed above, and it is likely that the need to compete with cellular protein translation further compromises the efficiency with which the viral proteins are translated from the genomic RNA. From an evolutionary viewpoint, the resulting down-modulation of viral RNA replication may provide the virus with a survival advantage. It is likely to facilitate replication at relatively low levels within hepatocytes, such that the infection may fail to induce an active immune response for several weeks before the occurrence of disease, a period during which the virus may be shed and transmitted to other persons.

## Other structured RNA elements

Limited information is available concerning the 3′NTR of HAV, but it is likely to contain conserved secondary and tertiary RNA structure. Studies with other picornaviruses suggest that the 3′NTR is not absolutely required for viral replication,[46] but it nonetheless plays an important role in RNA replication by facilitating recognition of the positive-strand RNA by the viral replicase complex.[46,47]

Small stem-loop structures that function as *cis*-acting RNA replication elements (*cre*s) have been recognized within the genomes of many other picornaviral RNAs. The *cre* is likely to be a universal feature of picornaviruses, as it appears to template the addition of uridyl residues to the viral VPg molecule in a viral polymerase-driven reaction required for protein-priming of viral RNA synthesis.[48–50] HAV is likely to possess a *cre* as well, although it has yet to be specifically identified. The HAV

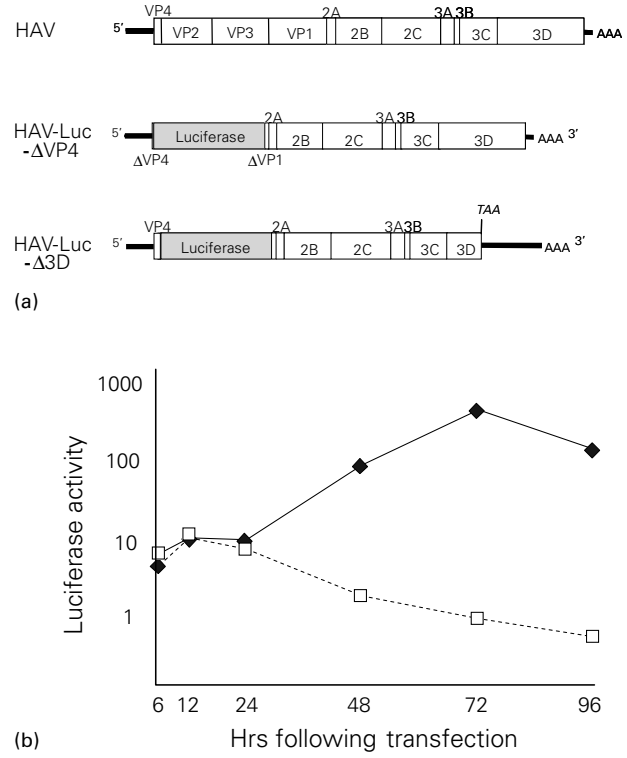

**Figure 6.5** Replication of HAV RNA is not dependent upon capsid protein coding sequence. (a) Genomic organization of HAV and the HAV-LucΔVP4 replicon encoding firefly luciferase (lightly shaded region) inserted in frame, replacing all but the 5′ 12 nts (ΔVP4) and 3′ 39 nts (ΔVP1) of the P1 segment, in an infectious cDNA clone derived from the rapidly replicating, cytopathic HM175/18f virus.[22] Although it contains sequence encoding VP4, HAV-LucΔ3D is otherwise similar to HAV-LucΔVP4 except for a single, lethal nucleotide change resulting in premature termination of translation within the $3D^{pol}$ coding sequence. (b) Luciferase activity (light units) present in lysates of Huh-7 cells transfected with HAV-LucΔVP4 (♦) or HAV-LucΔ3D (□) transcript RNA. Luciferase activity present 24 hours after transfection reflects translation of input T7 transcript RNA, while subsequent increases in luciferase activity (logarithmic scale) are produced from newly replicated subgenomic RNAs.

*cre* does not reside within the RNA segment encoding the capsid proteins, however, as this segment of the genome can be deleted without impairing the ability of the viral RNA to undergo autonomous replication in permissive cell cultures (see Fig. 6.5).[22]

## The polyprotein coding region

As indicated above, the non-coding regions flank a single large ORF encoding a polyprotein that is proteolytically processed into both structural (P1–2A) and non-structural (2BC and P3) viral proteins (Fig. 6.1). The primary cleavage of the polyprotein occurs between these two segments of the polyprotein, under the direction of the

only proteinase encoded by the virus, the $3C^{pro}$ protein.[51–53] The P1 segment encodes four polypeptides (1A–1D or, in order, VP4, VP2, VP3 and VP1) that assemble to form the viral capsid. The 2A protein of HAV lacks homology with any other picornaviral 2A proteins, and does not possess the *cis*-active proteinase activity found in the 2A proteins of other picornaviral genera. As discussed below, it remains attached to some otherwise fully formed virions and is likely to function in viral assembly, most likely as a precursor fusion with 1D (VP1).[54,55] These proteins are discussed in greater detail in the section below concerning viral capsid assembly.

The remaining non-structural proteins probably all contribute directly to the assembly of the membrane-bound viral replicase complex. Proteins 2B and 2C (possibly also the precursor 2BC) are believed to have a role in RNA replication. Mutations in these proteins appear to contribute to attenuation.[56–58] They also appear to be involved in directing the rearrangements of cellular membranes required for replicase assembly.[7] The 2B protein is very hydrophobic, and has been suggested to anchor the replicase complexes to intracellular membranes.[8] 2C, on the other hand, has NTPase activity and contains a helicase sequence motif. The P3 non-structural proteins include a putative RNA-dependent RNA polymerase ($3D^{pol}$), a cysteine proteinase ($3C^{pro}$),[59] which is responsible for most cleavages in the processing of the viral polyprotein,[60] and VPg (3B) which is attached to the 5′ end of both positive- and negative-strand RNAs (see Fig. 6.1).

### Genetic diversity

The genetic diversity of HAV has been investigated by determining the partial genomic nucleotide sequences of large numbers of human HAV strains recovered from diverse sources.[61–63] These studies have shown that circulating human strains of HAV are relatively closely related genetically, especially when compared to the genetic diversity evident among other picornaviruses such as poliovirus. Two major human HAV 'genotypes' (genotypes I and III) have been documented, the sequences of which differ from each other at >15% of the bases studied near the VP1–2A junction. Other human minor genotypes have also been identified. As discussed below, these viruses all belong to a common serotype.

## The HAV virion

Current understanding of the physical structure of the HAV particle is based largely on analogy with other picornaviruses. There are no available high-resolution structural models such as those that exist for other picornaviral genera.[64,65] However, recent yet unpublished cryoelectron microscopy studies suggest that HAV has a structure resembling those of other members of this viral family, with the exception that depressions on the surface of the particle are much less evident than with other picornaviruses (Cheng, H; personal communication).[66]

### Biophysical characteristics

Approximating the physical characteristics of enteroviruses such as poliovirus, the majority of infectious HAV particles sediment at 156S and band at a density of 1.325 $g/cm^3$ in caesium chloride.[67] Also in common with the enteroviruses, hepatitis A is stable at low pH (less than pH 3.0).[68] However, the thermal stability of HAV is considerably greater than that of other picornaviruses.[18,69,70] This characteristic of the virus is likely to contribute significantly to its ability to be spread through the environment, and to cause common source outbreaks of hepatitis.

Incubation of the virus for 4 weeks at room temperature results in only a 100-fold decrease in infectivity. Over shorter periods of time (10 min), significant loss of infectivity does not occur until 60 ºC.[18] The virus capsid is significantly stabilized in the presence of 1 M $Mg^{2+}$, resulting in only a 100-fold decrease in infectivity upon heating to 80 ºC for 10 minutes.[69] However, infectivity is destroyed almost instantaneously by heating above 90 ºC. HAV is highly resistant to drying, and infectious virus has been recovered from acetone-fixed cell sheets. It is also highly resistant to detergents, surviving a 1% concentration of sodium dodecyl sulfate. Solvent-detergent inactivation procedures do not reduce the infectivity of HAV, explaining why hepatitis A transmission has occasionally been associated with the administration of high purity clotting factor concentrates.[71,72]

### Protein composition

Biochemical and genetic studies indicate that the highly stable capsid of HAV is composed of multiple copies of the three major structural proteins, VP1, VP2 and VP3. These designations are based on those of their homologues in the poliovirus capsid, named originally on the basis of relative molecular mass with VP1 being largest. An alternative, perhaps preferable, but less often utilized nomenclature, is based on the position of each within the amino terminal (P1) segment of the viral polyprotein: 1A (VP4), 1B (VP2), 1C (VP3) and 1D (VP1) (see Fig. 6.1).[73] The major proteins are approximately 273, 222 and 246 amino acids in length, respectively.[1,74] VP1, however, has a heterogeneous carboxy terminus,[75] reflecting a unique maturation mechanism (see below). Like other picornaviruses, the viral capsid probably contains 60 copies of each of these major proteins.

In addition to VP1, VP2 and VP3, the existence of a fourth structural protein, VP4 (1A), is predicted by the

genomic RNA sequence. This small polypeptide has a predicted length of either 21 or 23 amino acids depending on which of two possible AUG codons at the 5′ end of the OFR are utilized to initiate translation of the polyprotein.[76] The VP4 polypeptide is incorporated into nascent particles in the form of a VP2 precursor, VP0 (1AB). This precursor protein undergoes a maturation cleavage during the final assembly of the viral particle, leading to production of the mature VP2 and VP4 polypeptides. However, the resulting VP4 product of this cleavage has never been demonstrated directly in preparations of HAV particles,[24] and it is not clear that it remains associated with mature virions, as is the case with poliovirus and other well studied picornaviruses.

### Antigenic structure

Early comparisons of the complete nucleotide sequences of different strains of HAV demonstrated approximately 97% amino acid conservation in the sequences of the major viral capsid proteins.[1,77-80] While only limited information is available concerning the presence of antigenic differences among different strains of HAV, studies with human (HM175 strain) and owl monkey-derived (PA21) isolates of HAV demonstrated that these viruses, representing divergent viral genotypes, elicit antibodies with substantial cross-neutralizing activity and thus belong to a single serotype.[81,82] This appears to be the case for all strains of HAV. Some monoclonal antibodies are capable of distinguishing unique epitopes that are variably present in strains of HAV isolated from humans versus strains isolated from naturally infected cynomolgus and African green monkeys.[83,84] Nonetheless, even simian and human strains of HAV demonstrate substantial antigenic cross-reactivity.

The critical neutralization epitopes of HAV are assembled, conformationally derived structures rather than linear epitopes. Thus, neutralizing murine monoclonal antibodies do not recognize denatured capsid proteins that have been separated by electrophoresis in sodium dodecyl sulfate-polyacrylamide (SDS-PAGE) gels. Furthermore, antisera raised to purified capsid proteins or proteins expressed from recombinant DNA show only weak reactivity with native capsids and have very limited virus neutralization activity.[85] This explains why it has proven difficult to develop a vaccine based on recombinant DNA technology. Although individual capsid proteins expressed from recombinant cDNAs can assemble into antigenic particles *in vitro*, this approach has not achieved commercial success for vaccine production.

Antigenic variants of HAV have been selected in cell culture by continued passage of cell culture-adapted virus in the presence of neutralizing murine monoclonal antibodies. Sequencing of the genomic regions encoding the capsid proteins of these mutants indicated the presence of an array of closely spaced epitopes in polypeptide loops within VP3 and VP1, comprising an immunodominant, conformationally defined neutralization site on the capsid surface.[86,87] These studies suggest that the involved residues of VP1 and VP3 are more closely positioned on the surface of the HAV particle than the analogous residues within the poliovirus capsid,[64,88] but this awaits confirmation by an atomic-level resolution structural model.

Several HAV strains recovered from naturally infected non-human primates demonstrate subtle antigenic differences from human viruses, as discussed above.[83,84] They appear to constitute a biologically distinct group of viruses that are capable of causing liver disease in infected cynomolgus and African green monkeys, but not chimpanzees which, like New World owl monkeys and certain tamarin species, develop acute hepatitis following challenge with human strains of HAV.[89] Conversely, human strains of HAV generally do not cause disease in cynomolgus or African green monkeys. These differences in virus host range could be due, at least in part, to differences in the cellular receptors utilized by these viruses.[82,90]

## Molecular processes in viral replication

### Attachment and entry

Mature virus particles attach to cultured cells and undergo uncoating with release of viral RNA into the cytoplasm by about 4 hours post-infection.[91] However, few other details of cellular attachment, penetration and uncoating of HAV are known. A candidate cellular receptor (huHAVcr-1) has been identified and shown to be a mucin-like glycoprotein.[92,93] This putative receptor protein interacts with the virus particle leading to virus neutralization.[94] It is widely distributed in different tissues but its exact role in the attachment of virus to hepatocytes in humans is uncertain.

### Polyprotein translation and processing

The positive-sense virion RNA that is released by uncoating of the virion acts directly as messenger for the synthesis of the large polyprotein. This probably follows removal of the small virally encoded peptide (VPg) which is covalently linked to its 5′ end.[5] As indicated above, protein translation is initiated in a 5′ cap-independent fashion under the control of the IRES (Fig. 6.4).

The first processing event within the resulting polyprotein is likely to occur in a co-translational manner, is carried out by the virus-specified $3C^{pro}$ proteinase[59] and results in cleavage at the junction of the 2A and 2B proteins.[51–53,95] This results in the release of a large structural protein precursor P1–2A, which is further processed by

$3C^{pro}$ into three capsid protein precursors: VP0 (or 1AB, the precursor for VP2), VP3, and VP1–2A, the precursor for VP1. The non-structural 2BC and P3 polypeptides are co- and post-translationally processed by $3C^{pro}$ to generate all non-structural proteins (Fig. 6.1).[96–98]

## Replicase assembly and RNA replication

The polypeptides located downstream of 2A in the polyprotein play essential, although in many cases poorly defined, roles in RNA replication. Experience with other picornaviruses suggests that many if not all of these proteins may have multiple functions in viral replication. For example, in addition to its role as the viral proteinase responsible for proteolytic processing of the polyprotein, the 3C sequence is likely to play an important role in replicase assembly. In addition, viral precursor polypeptides may have unique functions as partially uncleaved processing intermediates (such as 3ABC) that differ significantly from their functions as fully cleaved, mature proteins.[6,99]

The $3D^{pol}$ RNA-dependent, RNA polymerase of HAV serves as the catalytic core of a large, membrane-bound macromolecular complex that acts as an RNA replicase.[8] The 3A protein is likely to play a role in anchoring this replicase complex to cellular membranes via a hydrophobic sequence located near its amino terminus.[100] Cellular proteins that were shown to bind to 5′ and 3′ NTRs may also play important roles in viral RNA translation and/or replication. Poly-rC binding protein 2 (PCBP2), which interacts with the 3CD protein and 5′NTR of poliovirus, also interacts with the HAV 5′NTR.[41] Surprisingly, glyceraldehyde-3′-phosphate dehydrogenase (GAPDH) has been shown to bind specifically to both the HAV 5′ and 3′NTR sequences, and in doing so may influence translation and/or replication of the viral RNA.[45,101,102] In addition, polypyrimidine-tract binding protein (PTB) and poly-A binding protein (PABP) appear to contribute to the efficiency of picornaviral translation and thus could also contribute in a significant manner to viral replication.

Within the replicase complex, the virion RNA serves as a template for negative-strand RNA synthesis (Fig. 6.2). This negative-strand intermediate then acts in turn as a template for synthesis of new positive-strand RNA molecules, that can either be translated into protein (reinitiating the replication cycle) or packaged into new virions. Studies with poliovirus suggest that 3B (VPg), the small genome-linked protein, is likely to function as a protein primer for viral RNA synthesis in these reactions, as it does in the case of poliovirus.[48] It first must undergo a uridylylation reaction that covalently adds two uridyl residues to VPg in a reaction catalyzed by the viral polymerase and templated by the *cre* stem-loop,[49] a putative RNA structure yet to be identified in HAV (see above). These uridine residues become the first two nucleotides of each nascent RNA strand, and VPg remains covalently coupled through them to the 5′ ends of both strands of RNA. However, although it is clear that the HAV genome is coupled to the 3B protein (VPg) as is the case with poliovirus,[5] there is some evidence that suggests that the priming of RNA synthesis may differ from events occurring during poliovirus replication. In contrast to poliovirus, the infectivity of synthetic HAV RNA is dependent upon the presence of the first two uridine residues in the genome.[103]

RNA amplification is non-conservative and asymmetric, with more of the positive-sense RNA being produced in infected cells than the negative-strand intermediate. The physical nature of the negative-strand RNA during the process of positive-strand RNA synthesis represents an ongoing controversy in the replication of positive-strand viruses. It seems likely that the template for new positive-strand RNA synthesis is actually a duplex molecule, as available evidence suggests that negative-strand RNAs do not exist in a single-stranded conformation and are not physically separated from the positive-strand template following their synthesis. Not much is known about the molecular determinants of RNA replication that probably reside within the 5′ and 3′NTRs of the genome.[104,105] The poly(A) tail following the 3′NTR appears to be elongated during RNA replication in cells transfected with RNA transcripts, indicating that its length may be important for genome replication.[106]

## Particle assembly

Substantial evidence suggests that the mechanisms of HAV particle assembly differ significantly from those operative with other, well-studied picornaviruses. Deletions in the amino-terminal part of 2A have been shown to abolish infectivity.[107] This appears to be due to a requirement for this domain of 2A to be present as a carboxy-terminal extension of P1 in order to facilitate the folding of the capsid protein precursor required for efficient $3C^{pro}$-mediated processing. These cleavages are followed by the assembly of pentamers containing five copies each of VP0, VP3 and VP1–2A. These pentamers subsequently assemble into complete capsids, after which cleavage at the VP1–2A junction releases the mature VP1 protein. This cleavage appears to be mediated by a cellular rather than a viral proteinase, resulting in a heterogeneous VP1 carboxy terminus.[74,75] The amino-terminal 2A extension thus appears to play a critical role in the assembly of the capsid, a feature that is unique to HAV among the picornaviruses.[54,107] Deletions within the carboxy-terminal half of the 2A protein have no appreciable effect on the kinetics of RNA replication, but do alter the VP1/2A cleavage, resulting in accumulation of

uncleaved VP1–2A precursor in virions and appearing to cause a delay in the appearance of infectious particles, as well as a fourfold decrease in specific infectivity of the virus particles.[107,108] A subpopulation of otherwise mature virions contains the VP1–2A precursor, which was referred to originally as the 'pX' protein.[109]

The VP4 proteins of other picornaviruses, such as poliovirus, are considerably larger than the VP4 sequence encoded within the HAV genome. They also are myristylated at their amino terminus, a feature relating to an essential role that they play in the capsid assembly process during replication of these viruses.[110] In contrast, available data suggest that the VP4 molecule of HAV is not myristylated, despite the presence of an internal consensus myristylation site.[76,111] This is surprising, but both the apparent absence of a myristylated VP4 and the functional role of the 2A extension on the VP1 molecule are very unusual features that set HAV apart from other human picornaviruses. They suggest that the structural organization of the HAV particle and its assembly process may be very different from what is known of better studied picornaviruses.

Only the positive-strand RNA is packaged into new virions. Newly assembled HAV particles appear to be transported to the apical plasma membrane of the hepatocytes, where they are released into the hepatic canaliculi, resulting ultimately in the secretion of virus into the biliary system.[23] VP0 (1AB, Fig. 6.1) is cleaved into its two constituent polypeptides following the assembly of the virus particle and packaging of the viral RNA. It occurs by an as yet undetermined mechanism. This is called the 'maturation cleavage', and probably results in increased stability of the virus particle. There is some evidence that this cleavage occurs more slowly with HAV than with other picornaviruses.[112] It has been suggested that this slow maturation of the particle may prevent reinfection of gastrointestinal tract epithelial cells during excretion of the virus. Cells lining the crypts of the small intestine are presumably the very first cells to be infected by the virus following an oral exposure.[113]

## Regulation of viral replication

Replication of the virus is probably regulated at several key steps, including a switch from translation to replication that converts genomic RNA from the support of protein synthesis to the templating of negative-strand RNA synthesis, and a later switch that diverts newly synthesized RNAs from protein production and RNA replication to packaging into progeny viral particles (Fig. 6.2). Although linear in its organization (Fig. 6.1), the genomic RNA of HAV may well assume a circular conformation during active replication. This is supported by studies of other positive-strand RNA viruses,[114] as well as cellular RNAs. Circularization could be achieved by the interaction of cellular and viral proteins with the terminal sequences of the viral RNA, as described above, leading in effect to a protein bridge. Such a conformation would provide unique opportunities for controlling protein synthesis by facilitating re-entry of ribosomes after completion of a cycle of translation, or for controlling the switch from translation to replication.

## Molecular basis of adaptation of HAV replication to cultured cells

The progressive increase in the replication capacity of the virus that occurs upon continued cell culture passage appears to be due to changes in the 2BC sequence and within the viral IRES element.[42,43,56,57,115–117] The molecular basis for these changes remain unknown, but presumably they reflect differences in the cellular proteins available to support replication in cultured cells compared with cells *in vivo*. Mutations within 2BC appear to be particularly important for efficient replication of the virus in cultured cells.[56,57] These mutations directly enhance the efficiency of RNA replication, and not other steps in the virus life-cycle.[22] Mutations within the IRES sequence in the 5′NTR enhance its translational activity in cultured cells, and cause more subtle changes that are cell type-specific.[42,43,118]

Highly cell culture-adapted viruses are often attenuated (or no longer even infectious) when used to challenge susceptible primates and have been studied as candidate attenuated vaccines.[119–121] The attenuation properties of these viruses are closely related to the mutations conferring cell culture adaptation, and have been mapped recently to the VP1–2A and 2C proteins.[58]

# Chapter 7
# Epidemiology

Mike G Catton, Stephen A Locarnini

The epidemiology of hepatitis A virus (HAV) may be understood in terms of the natural history of the virus and its physical properties. HAV consists of an unenveloped, 27-nm, spherical particle (Fig. 7.1), containing a linear, single-stranded, positive-sense RNA genome, and is classified in the family Picornaviridae genus Hepatovirus.[1] The virus is more robust than other picornaviruses and may remain infectious on surfaces, in the environment and in uncooked foods for significant periods.[2–4]

Infectious HAV has been shown to persist in a variety of experimentally contaminated waters and soils and in sediment after 3 months at 25 °C, when dried onto inert surfaces after 30 days at 25 °C, and in experimentally contaminated cookies after 30 days at 21 °C.[4] Significant quantities of HAV persisted in a faecal suspension on the hands of volunteers after 4 hours, and high levels of infectious HAV were transferred from fingers to fomites over the same period.[5] HAV is relatively heat-stable but generally inactivated by cooking temperatures.[6–8] Significant infectivity of purified virions remained after heating at 60 °C for 60 minutes,[7] and may persist after as long as 12 hours at 60 °C.[6] Infectivity of HAV diluted in phosphate-buffered saline (PBS) was lost after heating at 70 °C for 4 minutes, 80 °C for 5 seconds, and immediately at 85 °C.[8] HAV has also been shown to be relatively resistant to many commonly available hard-surface disinfectants.[9]

Acutely infected human beings are the only significant natural reservoir of HAV, although a number of other primate species may be infected.[10] HAV is secreted from the liver into the bile and is shed in high titres in the faeces.[11] No state of chronic infection with HAV has been identified, and immunity after infection is life-long. Transmission is primarily by the faecal-oral route,[12] most frequently person-to-person, or via contamination of uncooked foods or water. Standards of human hygiene and sanitation, therefore, have an important role in mediating transmission of HAV and are reflected in the variation in hepatitis A epidemiology observed in different populations, and in the changing epidemiology of hepatitis A in many populations over recent decades.

Children experience subclinical infection with HAV much more frequently than adults and may excrete virus for prolonged periods.[13,14] Together with children's generally lower standards of hygiene compared with adults, these factors give children a prominent role in the epidemiology of HAV. For instance, transmission associated with childcare centres is a particularly important feature of the epidemiology of hepatitis A in developed countries such as the United States[15–18] (reviewed by Hadler and McFarland[19]). In many parts of the developing world, asymptomatic seroconversion to hepatitis A in childhood is widespread,[20] and as a consequence morbidity due to hepatitis A in these populations is very low.

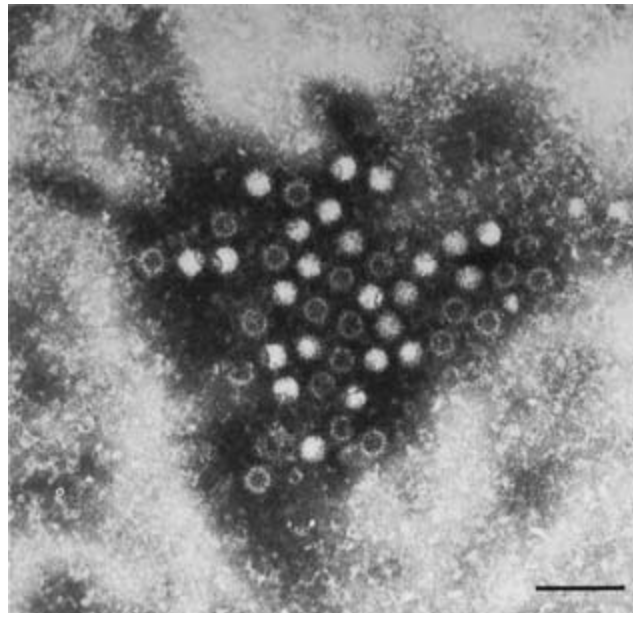

**Figure 7.1** Hepatitis A virus. Bar represents 100 nm. (Electron micrograph provided by Dr John Marshall, Victorian Infectious Diseases Reference Laboratory, Melbourne, Australia.)

A transient viraemia of moderate titre is associated with acute HAV infection,[11] and blood-borne transmission of hepatitis A has been described, both experimentally[12] and in isolated instances after blood transfusion.[21] Recent outbreaks of apparently parenterally transmitted hepatitis A among haemophiliacs[22–26] (reviewed by Vermylen and Peerlinck[27]) have increased awareness of the potential for transmission of HAV by this route.

Normal immunoglobulin was first reported to be effective in the pre-exposure and post-exposure prophylaxis of hepatitis A in 1945.[28,29] Administered within 2 weeks of exposure to hepatitis A, immunoglobulin is 80–90% effective in preventing disease and continues to be the mainstay of post-exposure prevention of hepatitis A[30] (reviewed by Winokur and Stapleton[31]). Immunoglobulin (Ig) has also provided effective pre-exposure prophylaxis of hepatitis A among visitors to endemic areas. More recently, inactivated hepatitis A vaccines have been shown to be safe and effective[32,33] and are replacing immunoglobulin for all but the most short-term pre-exposure prophylaxis among groups at risk of infection with HAV.

## Transmission

### Faecal-oral and person-to-person transmission

Direct person-to-person spread by the faecal-oral route is the most important means of transmission of hepatitis A. High titres of virus are present in the faeces from late in the incubation period, when the patient is maximally infectious, until the first week of clinical illness. Duration of faecal shedding is relatively well characterized, with data available from early studies of human transmission, animal model and laboratory studies[12,34–36] (reviewed by Gust and Feinstone[37]).

During studies at Willowbrook State School,[12] infectivity for humans was demonstrated in pooled faeces obtained from patients with infectious hepatitis 14–21 days before jaundice and was retained until 1–8 days after the onset of jaundice. Faecal samples collected during convalescence have been shown consistently not to be infectious for humans. [38,39] Epidemiological investigations of HAV outbreaks have identified the period of approximately 1 week before onset of clinical symptoms as the period of maximal infectivity.[40,41] Pooling of specimens and the relatively large inocula used in human transmission studies probably explain the slightly greater duration of infectivity observed in these studies than that implied by epidemiological analysis of hepatitis A outbreaks.[42]

The natural history of hepatitis A has been studied extensively in non-human primate models including chimpanzees (*Pan troglodites*), tamarins (*Saguinus mystax*) and owl monkeys (*Aotus trivirgatus*). In experimentally infected tamarins, HAV particles or hepatitis A antigen (HAAg) appears in the faeces several days to a week before the onset of biochemical hepatitis, peaking at about the time of histological evidence of liver damage and quickly declining over several days.[43] More prolonged shedding is evident when viral RNA is measured. HAV RNA reappeared in the faeces of tamarins experimentally infected with the MS-1 strain of HAV on day 4 after inoculation, peaking on day 15, and declining after day 25, roughly coincident with the alanine aminotransferase (ALT) peak, to become undetectable by day 34.[44] In the same faecal samples, HAV antigen was detected between day 7 and 22 after inoculation. The duration of faecal shedding of HAV RNA in this study is consistent with data obtained by virus isolation from experimentally infected owl monkeys using the HM-175 strain[34] and the HM-175/S18 variant.[45] HAV reappeared in stools 4–7 days after inoculation, reached peak concentrations on day 17–26, and declined to undetectable levels by day 39.[34]

Using immune electron microscopy (IEM), HAV-like particles have been shown to be present in human faeces from at least 5 days before the onset of biochemical hepatitis[46,47] until the second week of illness.[35,48] Duration of faecal shedding of HAV was positively related to the presence of icteric hepatitis.[46,47] HAV particles were not detected by IEM or radioimmunoassay (RIA) >14 days after onset of dark urine in 200 consecutive patients with hepatitis A;[34] 45% of faecal specimens collected in the first week after onset of dark urine contained HAV compared with 11% collected in the second week. The estimated concentration of viral particles in faeces was shown to peak within 5 days of onset of dark urine and decline rapidly thereafter.[35] At the peak of shedding, faeces may contain $>10^8$ infectious particles/mL.[11]

The use of nucleic acid hybridization has demonstrated the presence of HAV RNA in the faeces of some patients infected with hepatitis A into the convalescent phase of illness.[14] More recently, polymerase chain reaction (PCR) has been used to demonstrate HAV RNA in faeces of several patients >1 month after clinical onset.[49–51] Few direct data are available regarding the potential infectivity of these patients. However, the weight of human transmission data and epidemiological data from outbreaks suggest that prolonged infectivity in the faeces is unlikely to be common. One study has recently demonstrated intravenous infectivity for two tamarin monkeys of stools collected from a hepatitis A patient 27 days after the ALT peak, and positive for HAV antigen and HAV nucleic acid.[50] Nucleic acid-positive, EIA-negative stools collected days later from the same patient were not infectious for tamarins. This study used virus immunocapture followed by PCR targeting the VPI amino terminus and detection

by gel electrophoresis or nucleic acid hybridization, together with an EIA employing polyclonal animal sera to examine specimens from an institutional hepatitis A outbreak. HAV was detected in the faeces of seven hepatitis A patients and 11 of their contacts who developed hepatitis A despite immunoglobulin prophylaxis. Four of the 11 infected contacts shed HAV nucleic acid for prolonged periods ranging from 25 to 52 days after peak ALT. The patient described above was the only one of these in whom convalescent shedding of HAV antigen was demonstrated, probably reflecting high titre shedding. Convalescent shedding of HAV could not be demonstrated among the seven patients who did not receive IgG prophylaxis. As the intravenous route has recently been shown to be orders of magnitude more infectious for primates than oral inoculation of HAV,[52] further study is still warranted to better define the potential for faecal-oral transmission from patients shedding HAV nucleic acid in the faeces during convalescence.

Shedding of virus in the faeces may also recur during uncommon clinical relapses of acute hepatitis A,[53] but chronic faecal shedding of HAV has not been described. The apparent disappearance of hepatitis A from isolated populations in Greenland and Alaska for long periods, as evidenced by studies of age-specific seroprevalence,[4] and high clinical attack rates during hepatitis A outbreaks among those not yet born at the time of previous outbreaks,[54,55] support the idea that chronic shedding of HAV occurs rarely if at all.

HAAg and HAV RNA may persist in the faeces of infants and young children for longer periods than in adults.[13,14] During the second week of illness, 46% of children had HAAg detected in faeces compared with 14% of adults.[14] During an outbreak of hepatitis A in a neonatal intensive care unit, three of five preterm infants for whom serial faecal specimens were obtained were shown to excrete HAAg for 1–4 months, and HAV RNA for between 4 and 7 months. One of the infants was implicated in transmission of hepatitis A to a staff member 5 months after the initial diagnosis of hepatitis A and coincident with a faecal specimen shown to contain HAV RNA but not HAAg.[13]

Twenty-two per cent of hepatitis A cases reported to the Viral Hepatitis Surveillance Program, Centers for Disease Control and Prevention in 1993 gave a history of personal contact with a case of hepatitis A, which was the most commonly identified risk factor[56] (Fig. 7.2). Other commonly identified risk factors were association with a day-care centre (15.5%), foreign travel (6.3%), homosexual activity (4.9%), injecting drug use (2.4%) and linkage with an outbreak (2.2%).[56] Transmission is usually limited to close contacts of cases,[18] especially to other family members. Attack rates among susceptible household contacts of cases vary between approximately 20% and 80%.[57–59] In one recent small study, 52% of susceptible household contacts were found to be hepatitis A-specific IgM-positive during follow-up. Their relationships to the index case were as follows: mother 40%, wife 57%, brother 60%, son 71% and daughter 80%. None of two susceptible fathers, one husband, two sisters, or three other friends or family acquired infection.[58] In contrast, similar attack rates were observed among susceptible siblings and parents of 96 children hospitalized in Athens with symptomatic hepatitis A, ranging from 20% among fathers to 30.8% among mothers.[60]

Outbreaks of hepatitis A attributable to direct person-to-person spread occur frequently in settings characterized by faecal contamination, close contact, and compromise of hygienic standards such as day-care centres[18,61] (reviewed by Hadler and McFar-

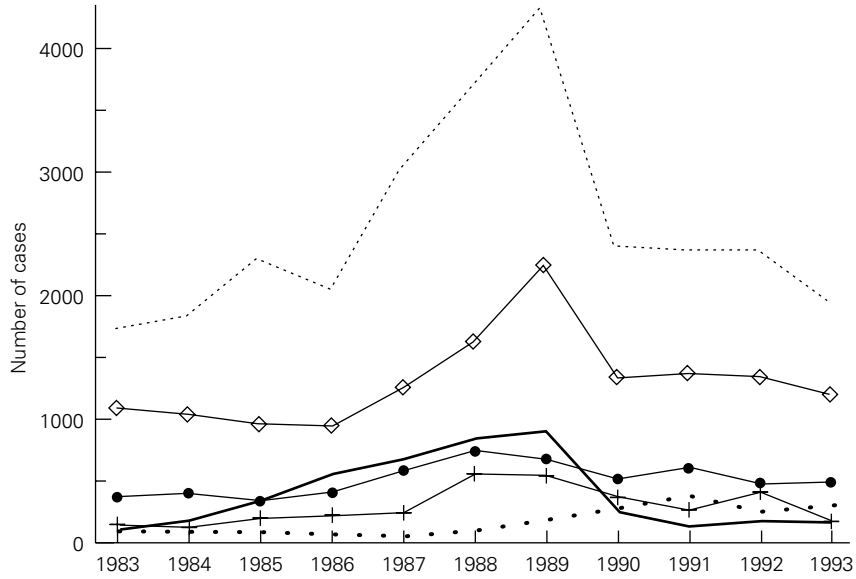

**Figure 7.2** Trends in selected risk factors associated with reported cases of hepatitis A by mutually exclusive groups, United States, 1983–1993. [black line] drug use; [dotted line], homosexual activity; [◊], day care; [dashed line] contact with HAV; [+], outbreak; [●] foreign travel. (From CDC, Viral Hepatitis Surveillance Program, 1993.[56])

land[19]), schools,[62] institutions for the mentally handicapped,[63–65] prisons,[66,67] and among military forces in the field.[68] Patients of institutions for the intellectually handicapped have a higher prevalence of anti-HAV than age-matched controls in the general community,[63,69,70] and prevalence of anti-HAV has been correlated with duration of institutionalization rather than with age.[69,70] Many outbreaks of infectious hepatitis have been reported in this setting,[40,64,65] and high rates of hepatitis have been reported among staff of these institutions.[65]

Young children have a prominent role in spread of HAV because of their relatively low hygiene standards and the frequency of subclinical infection in this age group.[17,19,59,71,72] Hepatitis A infection was asymptomatic in 84% of children 1 and 2 years of age, 50% of children 3 and 4 years of age, and 20% of children over 5 years of age in a large community-wide study of hepatitis A in day-care centres.[18] The importance of day-care centres in transmission of hepatitis A began to be appreciated in the 1970s.[61] Between 1980 and 1981 in the United States, 14% of all hepatitis A cases were found to be day-care-related in counties with large numbers of centres caring for very young children, compared with 1.5% in counties with fewer centres of this type.[15] A large 2-year study established that outbreaks were most associated with large centres operated for profit, centres open for >15 hours per day, and centres with more than 50 children in diapers.[17] Introduction of hepatitis A into the centre was related to the number of children attending the centre at a given time and the hours of operation, whereas the risk of disease spread was related to the presence of diapered children. Like other hepatitis A outbreaks in which children play a central role, those associated with day-care centres are often prolonged and not recognized until several adults have become ill. Parents were found to be most frequently represented among the clinically ill (70–80%), with caregivers (15%) next most often.[73]

Transmission to health-care professionals exposed to hospitalized hepatitis A cases has been relatively infrequent,[74,75] probably because of the rapid decline in faecal shedding after the onset of symptoms. In a prospective study of 248 patients with viral hepatitis hospitalized in Athens, no evidence of nosocomial transmission was obtained despite a lack of strict infection control procedures.[75] Cases of nosocomial hepatitis A transmission are well described, however,[76–80] usually in the context of either a patient incubating hepatitis A and hospitalized for other reasons, or of subclinical infection in a faecally incontinent patient. Several outbreaks in neonatal intensive care units have been characterized by largely subclinical and potentially unnoticed infection of infants brought to light by high rates of clinical disease among their adult contacts.[13,81,82]

Homosexual men have an increased prevalence of HAV-specific antibody and a relatively high incidence of new infection.[83] Many outbreaks of hepatitis A infection among homosexual men have been described since the early 1980s in developed countries,[84–86] including simultaneous outbreaks in 1991 in North America,[87] England,[88] the Netherlands[89] and Australia.[90] These may relate to increases in frequency of sexual activities considered at low risk of human immunodeficiency virus transmission but facilitating spread of other pathogens such as HAV. For example, oral-anal contact,[83,91] digital-rectal contact,[91] and possibly oral-genital sex and handling of condoms after anal intercourse[90] have been identified as risk factors for acquisition of HAV. However, it has not always been possible to link specific high-risk sexual practices to the majority of hepatitis A cases during outbreaks among homosexual men.[84] It is possible that risks for HAV transmission in this setting vary. Further study is warranted.

## Food-borne and waterborne transmission

Transmission of hepatitis A via faecally contaminated food or water is well described and may be associated with outbreaks of disease. Such outbreaks are frequently dramatic because of the explosive nature of spread but currently account for only 2.2% of reported hepatitis A cases in the United States.[56] Food-borne and waterborne transmissions continue to be important routes of transmission in developing countries and are particularly relevant to the susceptible traveller.

Food may be contaminated with HAV during preparation by an infected food handler or before handling, as is typically the case with shellfish. A great many outbreaks of hepatitis A have been reported in association with consumption of raw or partially cooked bivalve molluscs, such as mussels, oysters and clams.[92–95] The availability of specific serology allowed confirmation of the apparent epidemiological association between shellfish ingestion and hepatitis A following a well-characterized family outbreak of hepatitis A as a result of ingestion of contaminated mussels in Victoria, Australia.[93] A dramatic example of such a shellfish-associated HAV outbreak occurred in Shanghai in 1988.[95,96] More than 300 000 cases of hepatitis A were reported and epidemiological studies implicated consumption of raw clams in 90% of cases. HAV and HAV RNA were subsequently detected in clams.[96]

Bivalve molluscs are frequently eaten raw, or after steaming, which suffices to open the shell but does not produce internal temperatures sufficient to inactivate HAV.[97] Bivalves feed by filtering nutrients from large volumes of sea water. HAV present in faecally contaminated water is likewise filtered, and although no replication takes place within the mollusc, HAV may

be concentrated 100-fold relative to the surrounding water and persist for up to 7 days.[98] Shellfish may be grown commercially in shallow waters adjacent to populated areas with potential for contamination by sewage. Shellfish harvested from sewage-polluted waters may be purified for consumption by depuration, which relies on natural elimination of pathogens during a holding period of 2–3 days. However, >10% of input HAV HM175 has been shown to persist in Eastern oysters maintained for 5 days at 12–24 °C in clean flowing sea water.[4]

Food handlers acutely infected with hepatitis A may contaminate food during preparation if basic handwashing practices are not followed. Transmission usually occurs in the late incubation period when the person is asymptomatic and faecal shedding of virus is at its peak. A variety of foodstuffs and beverages have been implicated in transmission of hepatitis A in this manner, particularly sandwiches[87] and salad vegetables,[99] but also bread,[100] pastries,[101] fruit,[102] orange juice[103] and others. Usually the implicated foods are uncooked or have been handled after cooking, as hepatitis A is generally inactivated by normal cooking temperatures. Outbreaks may be sizable and explosive. In 1974, 133 cases of hepatitis A occurred in a single wave of illness among naval recruits in San Diego exposed to salad and grapefruit prepared by an infected food handler,[104] and in 1991, 230 cases of hepatitis A occurred among persons eating at two sandwich shops in Milwaukee staffed by the same infected food handler.[87]

Waterborne transmission is probably relatively important in maintaining endemicity of HAV in the developing world, where faecal contamination of drinking water is widespread. However, accurate data are limited, particularly in view of the potentially confounding effect of hepatitis E. In developed countries contamination of water occurs infrequently, and this route of transmission, although described,[105–107] is of minor importance. However, the large pool of susceptibles in developed countries means that waterborne transmission, when it occurs, has the potential to cause high attack rates.[108]

Contaminated water is probably the most important source of hepatitis A infection among travellers to developing countries, as a consequence of faecal contamination of drinking water, ice and water-based drinks, through swimming in polluted waters, and following consumption of foods prepared with contaminated water such as fruit and vegetables, reconstituted milk products, or shellfish originating from polluted waters.[109] Person-to-person spread, especially from young children, is another likely important source of hepatitis A acquisition by travellers. Adult food handlers in developing countries, on the other hand, are unlikely to be shedding HAV because of the high rates of adult seropositivity in these regions. Few data are available concerning the incidence of hepatitis A among short-term travellers to developing countries. Of hepatitis A cases reported to the Viral Hepatitis Surveillance Program, Centers for Disease Control and Prevention in 1993, 6.3% were associated with a history of international travel.[56] The rate of symptomatic hepatitis A among unprotected, non-immune Northern European travellers visiting developing countries was approximately three per 1000 per month[110] (reviewed by Steffen[111]), the majority of whom were tourists who had stayed in hotels. Among backpackers and others eating and drinking under non-hygienic conditions the incidence of hepatitis A may be sixfold higher.[111] Similarly, hepatitis A has been demonstrated to be a risk for all Canadian travellers to endemic areas, irrespective of the perception of risk.[112] Prolonged travel under poor living conditions was associated with more than a sevenfold greater adjusted risk of acquiring hepatitis A than trips of <2 weeks duration with accommodation in first-class hotels. However, high-risk trips accounted for only 7% of total hepatitis A cases among travellers, the majority of which were acquired during trips in the medium- and low-risk categories.

Long-term travel to developing countries carries a high risk of hepatitis A acquisition among unprotected susceptibles. Among American missionaries with >20 years of service in Africa >90% were hepatitis A seropositive.[113] The incidence of hepatitis A was highest in the first 1–2 years of service, during which 28% of susceptible persons were infected, and continued at a median of 5.4% per annum for the next decade thereafter. A 48% rate of seroconversion to HAV (19/1000/month) was seen among 108 susceptible unprotected French volunteers working in the field in Central or West Africa for 18–35 months.[114]

## Blood-borne transmission

The importance of blood-borne transmission in the epidemiology of hepatitis A remains to be definitively established. The potential infectivity of HAV by the blood-borne route is high. Experimental inoculation studies using tamarins and chimpanzees have recently demonstrated wild-type HAV to be $10^{4.5}$-fold more infectious intravenously than orally.[52] However, transmission of hepatitis A by blood or blood products, while

well described, is infrequent. Among injecting drug users (IDUs) hepatitis A is common and has been associated with large and prolonged outbreaks. Parenteral transmission has not been conclusively established as the major route of transmission between IDUs because of the confounding potential for faecal-oral transmission.

Characterization of the viraemia associated with acute hepatitis A infection has advanced considerably in recent years. Using sensitive PCR assays 73–100% of hepatitis A patients have been shown to be viraemic at presentation.[115–117] Data from patients with hepatitis A[115–120] and animal model studies[34,45,115,121] have shown that the viraemia is longer than previously understood, typically commencing an average of 17 days before the ALT peak, and persisting for between 18 and 79 days after this. An atypical minority of cases have either prolonged or relapsing viraemia and hepatitis.[115–117,122] Human immunodeficiency virus (HIV) co-infection appears to prolong viraemia.[123,124] Viraemia is able to persist even in the presence of high levels of specific anti-hepatitis A IgM antibody.[115,116,122] However, the highest viral loads, and presumably, therefore, the highest risk of blood-borne transmission, appear to occur prior to the ALT peak and the appearance of IgM, being 1000-fold higher than those after the ALT peak.[115] This accords with early transmission studies demonstrating infectivity of pools of serum collected as early as 16–24 days before and up to 3 days after the onset of jaundice.[12,125]

Several studies have used PCR amplification to study human sera collected after the onset of clinical symptoms of hepatitis A. Using nested PCR targeting the 5′-non-coding region (NCR), HAV nucleic acid was demonstrated in the serum of 73.7% of patients at admission. Among patients with typical self-limiting hepatitis, 55.5% were still viraemic between days 11 and 15, declining to zero after day 20.[117] A nested PCR targeting the VP1 region found HAV RNA to persist in the serum for a mean of 30 days (range 5–59) after hospital admission, correlating closely with the duration of abnormal ALT, but not peak ALT.[119] A real-time quantitative PCR targeting the 5′NCR was used to demonstrate HAV viraemia in 100% of 41 acute hepatitis A patients, and to demonstrate the persistence of viraemia in excess of 60 days after diagnosis in six other serially studied subjects.[118] An earlier study using nested PCR to target the 5′NCR had also found a high proportion of acutely infected patients to be viraemic (92% of 38 patients), but a mean persistence of viraemia for only 18 days in 25 serially sampled patients.[116]

Many studies describe subgroups of patients with atypical clinical courses characterized by either prolonged or relapsing biochemical abnormality and viraemia.[115–117,122] Continuous viraemia persisting for as long as 490 days after the onset of jaundice has been described.[122] Recurrence of viraemia and hepatitis for variable periods after resolution of the initial clinical episode is also well described.[115–117,122,126] One early study using slot blot hybridization detected intermittent viraemia persisting for approximately 15 months in a case of relapsing hepatitis A.[126]

A limited number of clinical studies have been able to demonstrate the onset of viraemia. Using PCR, HAV RNA was detected in the serum of two haemophiliacs for 6–7 weeks, from 11 days before ALT elevation in one of the pair.[127] More recently, the onset and persistence of HAV viraemia were studied using archived serum samples from a clinical trial.[115] Nested PCR assays targeting the VP3-VP1 junction, VP1-P2A junction and 5′NCR were used to study 13 subjects with an average of eight serum samples collected at approximately monthly intervals before and after their peak ALT. All subjects were viraemic in specimens collected 15–37 days before peak ALT, and none earlier than this. All subjects were viraemic in specimens collected 18–69 days after ALT peak, declining rapidly thereafter to give a mean persistence of HAV and a viraemia of 79 days.

Data are relatively limited concerning the concentration of HAV viraemia. Using chimpanzee inoculation as an end-point, the titre of HAV in blood has been shown to be moderate, containing between $10^3$ and $10^5$ chimpanzee-infecting doses (CID)/mL.[11] End-point dilution of PCR-positive samples in normal human serum and subsequent PCR has recently been used to estimate HAV virus load before and after the ALT peak, with calibration of the method using cell culture-derived HAV. At the ALT peak, virus load was estimated to be $7.9 \times 10^3$–$7.9 \times 10^5$ copies/mL serum, which correlated to $10^2$–$10^4$ plaque-forming units (pfu)/mL, while titres of $7.9 \times 10^5$–$7.9 \times 10^6$ copies/mL ($10^4$–$10^5$ pfu/mL) were demonstrated in the 20-day period prior to peak ALT, and $7.9 \times 10^2$–$7.9 \times 10^3$ copies/mL (10–100 pfu/mL) after the peak ALT (Fig. 7.3).[115] Before and after this 49-day period, titres in positive samples were estimated to be <400 copies/mL (5 pfu/mL).

Two more recent studies using quantitative RT-PCR assays to study HAV virus loads in hospitalized patients have shown good agreement in detecting peak virus loads after presentation respectively of between $1.8 \times 10^3$–$7.71 \times 10^6$ copies/mL[118] and between $2.0 \times 10^3$ and $3.1 \times 10^5$ copies/mL.[122]

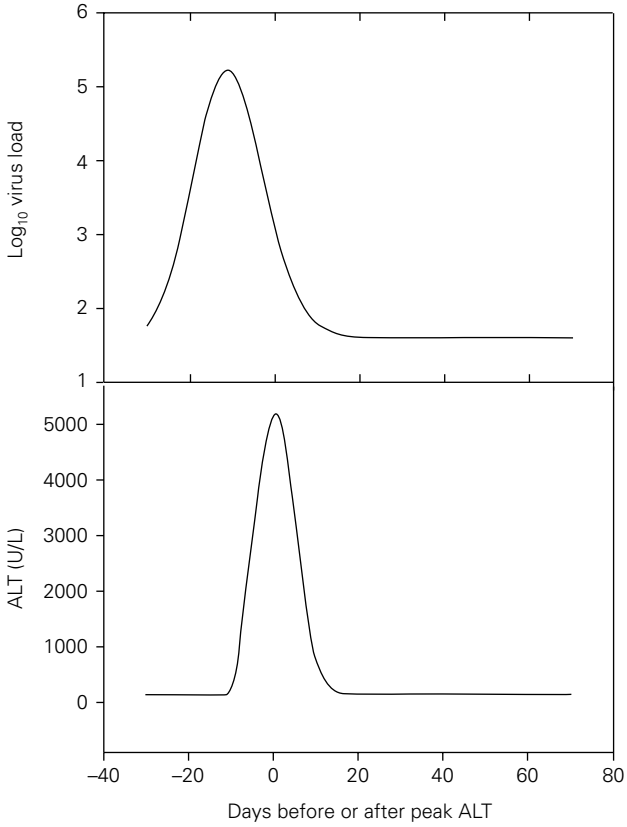

**Figure 7.3** A model of HAV serum viral load relative to peak ALT (based on data from Bower[115]).

Among HIV-infected individuals with acute hepatitis A, the duration of viraemia was significantly longer than in non-HIV-infected patients (median 53 days compared with 22 days), and virus loads estimated by titration were higher (median litre $1 \times 4^{-7}$ compared with $1 \times 4^{-3}$) but the peak ALT was less.[124] There was no correlation of HAV virus load with CD4 count, HIV virus load or HIV therapy. Another study demonstrated a prolonged viraemia of 256 days, and a peak load of $2.1 \times 10^7$ copies/mL in a single HIV-infected individual acutely infected with hepatitis A.[123]

Animal inoculation studies have generally suggested a viraemia of approximately 3 weeks' duration,[34,45,121] although a recent study using nested PCR found longer periods of viraemia ranging from 25 to 91 days.[115] HAV was isolated from the serum of experimentally infected owl monkeys within 11 days of inoculation, and this viraemia continued for a mean of 20.5 days thereafter, peaking a mean of 17.6 days after inoculation and 8.8 days before maximal ALT values.[45] Viraemia significantly diminished in titre but was detectable in the presence of serum-neutralizing antibody in five of six animals.[45] PCR demonstrated HAV RNA in the serum of an experimentally infected chimpanzee for 3 weeks, from 1 week before liver enzyme elevation to 1 week after peak elevation.[121] Nested PCR assays targeting the VP3-VP1 junction, VP1-P2A junction and 5'-untranslated region (UTR) demonstrated viraemias commencing 17–22 days before peak ALT, and persisting for 53–63 days after this in two chimpanzees inoculated with $10^6$ CID of hepatitis A intravenously.[115] Animals receiving lower inocula either orally or intravenously became viraemic 14–18 days before peak ALT, and this persisted for 11–26 days after the peak. Virus loads were also found to correlate with inoculum in this study. Animals receiving $10^6$ CID experienced virus loads of $7.9 \times 10^3$ particles/mL ($10^2$ pfu/mL) prior to the ALT peak, $7.9 \times 10^5$ particles/mL ($10^4$ pfu/mL) at the ALT peak, and 79–$7.9 \times 10^2$ (1–10 pfu/mL) over the following 35 days. Animals receiving 1 CID intravenously had peak viraemias of $10^3$ pfu/mL, and lower virus loads at all time points than chimps receiving larger inocula.

The likelihood of transfusing a unit of blood infectious for HAV appears to be low. Preliminary data obtained using PCR to screen 6000 randomly selected donations of plasma found none positive for HAV.[128] The potential co-transfusion of HAV-specific antibodies to the recipient of multiple blood units and the rising seroprevalence to HAV with age further diminish the risk of post-transfusion hepatitis A. A number of prospective studies have assessed the risk of transmission of hepatitis A by single-donor blood products.[129–132] HAV was not transmitted to any recipients in 15 such studies involving the transfusion of 44 612 units of blood or blood components. Nevertheless, isolated cases of post-transfusion hepatitis A have been described.[21,133] At present, blood donors are not screened for the presence of anti-HAV antibody.

Infrequent outbreaks of apparently parenterally spread hepatitis A have occurred where transmission by multiple-donor blood products has been implicated, albeit usually not conclusively proven. A number of outbreaks of hepatitis A have been described among haemophiliacs receiving factor VIII concentrates (reviewed by Vermylen and Peerlinck[27]), including outbreaks in Italy,[24] Germany,[22,134] Belgium,[27] Ireland[26] and South Africa.[23] Both local unpaid plasma donors[22,24] and products including plasma obtained from paid plasmapheresis donors in the United States[26,44,134] have been involved. In most outbreaks,[22,24] multiple batches of concentrate were implicated, each carrying a relatively low risk of HAV transmission, with severe haemophiliacs requiring intensive treatment most at risk of acquiring HAV. The Irish outbreak saw a higher attack rate and was subsequently attributed to a source plasma pool collected from Irish donors in an area experiencing an outbreak of hepatitis A.[25]

Both ion exchange chromatography and solvent detergent inactivated factor VIII concentrates as well as solvent detergent heparin precipitation purified concentrates have been associated with outbreaks.[23,27] Before

the introduction of solvent detergent inactivation, transmission of HAV by factor VIII concentrates had not been recognized.[135] While the method was highly validated as capable of completely inactivating enveloped viruses in blood products, it has been suggested that this technique may not be sufficient for complete inactivation of non-enveloped viruses such as HAV.[24,85] Furthermore, it has been suggested that the very low concentrations of neutralizing antibody to HAV in final concentrates prepared using ion exchange chromatography or heparin precipitation may diminish the opportunity for neutralization of any residual infectious virus.[23] Study of the Belgian outbreak has also raised the possibility that earlier less pure factor VIII preparations had provided passive immunity to HAV that is no longer present.[136] Significant levels of HAV-specific antibody were demonstrated in now discontinued intermediate purity factor VIII manufactured in Scotland, but were absent from high purity solvent detergent and ion exchange chromatography inactivated factor VIII.[71]

The strength of evidence implicating factor VIII concentrates as the source of hepatitis A among haemophiliacs varies between reports. Italian,[127] South African[23] and German[134] investigations have obtained molecular data in support of HAV-contaminated factor VIII concentrates, the Italian and South Africa investigations also obtaining epidemiological data. In Italy, 52 cases of HAV infection, 81% icteric, were documented between 1989 and 1991 in haemophiliacs receiving organic solvent- and detergent-treated factor VIII at 12 centres.[127] A case-control study showed acquisition of hepatitis A to be highly associated with receiving >2000 units of factor VIII and with receiving factor VIII from one manufacturer, while not associated with other potential routes of HAV acquisition. HAV sequences were subsequently detected by nested PCR in five of 12 implicated factor VIII lots, and sequence identity was shown with HAV RNA obtained from the serum of two recipients available for study.[127] In the recent German investigation, complete sequence identity was shown in the VP3C terminus and VPI/2A junction regions between HAV nucleic acid amplified from a plasma pool, two lots of the subsequent factor VIII preparation and the sera of six haemophilia patients who received it.[134] The virus titre in the infected plasma pool sourced from plasmaphoresis donations collected in the USA was consistent with a single viraemic donation with a titre of approximately $2 \times 10^6$ copies/mL in a pool of approximately 3000 donations. It is not clear why an anti-HAV titre of 6.11 IU/mL in the infected pool did not neutralize and remove HAV as virus–antibody complexes.

In contrast, HAV RNA could not be detected by PCR in several ion exchange chromatography and solvent detergent inactivated factor VIII concentrates manufactured in Scotland and the United States,[128,137] and epidemiological investigations in the United States,[138] France[139] and Brazil[140] failed to demonstrate transmission of HAV by solvent detergent and ion exchange chromatography purified concentrates manufactured in those countries.

Thus far, there have been no reports of successful demonstration of infectivity of factor VIII preparations implicated in HAV transmission.[127,134] This might be due to low virus load and the greater ease of detection of such titres by PCR than by infectivity in animals.

In an *in vitro* study, the HM 175/18f strain of HAV was added to plasma preparations containing varying quantities of HAV-specific antibody and subjected to cryoprecipitation, solvent and detergent inactivation, diethylaminoethyl (DEAE) anion exchange chromatography, and lyophilization.[141] If the reduction in infectivity attributable to each of the above steps was additive, this protocol was potentially able to inactivate 8.6–9.3 log of HAV. Although the magnitude of HAV viraemia and frequency with which viraemic plasma units might be included in plasma pools would be important determinants of the adequacy of such a reduction in infectivity, it was concluded that this preparation method does not provide a significant margin of safety, particularly if the original plasma pool is obtained from a population where HAV is not rare.[141]

A multicentre outbreak of hepatitis A has also been reported among cancer patients treated with interleukin-2 (IL-2) and lymphokine-activated killer (LAK) cells.[142] Pooled human blood group AB serum from paid donors used to supplement the LAK cell culture medium was subsequently implicated as the infectious source. The serum pools underwent complement inactivation (56 °C for 30 minutes) and sterile filtration (pore size 0.22 μm) before use. Attack rates of 85%, 62%, or 50%, respectively, occurred among those exposed to one or other, or both of two implicated pools compared with no cases among susceptibles exposed to other serum pools. Hepatitis A-specific IgM was detected in residual samples from the serum pools when tested at a dilution of 1/2000, but neither serum samples nor LAK cell pools induced evidence of hepatitis A when inoculated into marmosets.[142]

Injecting drug use has become increasingly important in the epidemiology of hepatitis A in many parts of the world. The prevalence of anti-HAV among IDUs was found to be 43% compared with 5% among the general population in Norway and, at 44% among Danish IDUs, was four times the prevalence in the general popula-

tion.[143] Outbreaks of hepatitis A among Scandinavian IDUs have also been reported.[144,145] Increasing numbers of outbreaks of hepatitis A among IDUs were reported in the United States during the 1980s.[146] Between 1983 and 1986, the percentage of hepatitis A cases with a history of injecting drug use rose from 4% to 19% against a background of relatively constant overall rates of hepatitis A. The number of hepatitis A cases associated with injecting drug use peaked in the United States in 1989 and subsequently declined relatively rapidly (Fig. 7.2).[56] Significant outbreaks of hepatitis A have been described among IDUs in England,[147–149] and in inner Sydney[150] and Queensland[151] in Australia. In England the epidemiology of hepatitis A is reported to have changed with most cases occurring in young males and the commonest risk factor being IDU.[147] Fourteen outbreaks were described in England in 2002 alone, all associated with IDUs. In Estonia genotyping of HAV viruses from initial cases among IDUs and other community cases during a 1998–1999 outbreak suggested transmission of the HAV outbreak strain from IDUs into the general population.[152] Needle sharing has not been clearly demonstrated as the mode of transmission in these outbreaks, which have frequently been attributed to poor hygienic conditions among IDUs.[143] Intravenous drug use, frequent injecting, intravenous heroin use and multiple drug use were found to be significantly associated with the acquisition of hepatitis A during a prolonged outbreak among IDUs in Suffolk, England commencing in 2001. While suggesting the potential importance of person-to-person transmission by the blood-borne route, it is equally possible that transmission was via faecal contamination of injecting paraphernalia among this most chaotic group of drug users. Definitive data are not available.

### Perinatal transmission

Isolated cases of apparent perinatal transmission of HAV have been described.[82,153] An infant was isolated from its mother and treated with immunoglobulin when the mother developed symptomatic hepatitis A immediately after delivery, subsequently infecting three other family members.[153] HAV RNA was detected in serum and faeces from the infant, who remained clinically well on days 17 and 32 after birth, but not on day 101. Cord blood did not contain HAV RNA. Hepatitis A-specific total antibody subsequently became positive 6 months after birth. It was concluded that transmission of HAV to the infant occurred via intrapartum exposure to contaminated maternal blood or faeces.[153]

### Primate-to-human transmission

Human HAV naturally infects chimpanzees (*Pan troglodites*) and may be experimentally transmitted to chimpanzees, tamarins (*S. mystax*, *S. labiatus*, *S. nicricollis*, *S. fuscicollis*), owl monkeys (*Atous trivirgatus*), and possibly a number of other non-human primates[46,47,92,154,155] (reviewed by Balayan[10]). Since the description of an outbreak of hepatitis A among chimpanzee handlers at a United States Air Force base in 1961,[156] more than 40 similar outbreaks involving more than 170 human cases have been reported.[10] The epidemiology of these outbreaks suggests that typically the animals were infected after capture from the wild and subsequently transmitted HAV to primate handlers.[37]

## Seroprevalence

### Major seroprevalence patterns

Hepatitis A has a worldwide but uneven distribution between geographical regions and population groups. In many regions, the epidemiology of hepatitis A has been changing as improved sanitation, housing and socioeconomic standards alter transmission patterns.[37,60,157] Our understanding of the comparative epidemiology of hepatitis A is based largely on seroprevalence data. Estimates of HAV disease incidence based on morbidity data are likely to be very inaccurate, although they may provide insight into trends in disease activity within a given region, as deficiencies in data quality will tend to be constant. Shortcomings of hepatitis A morbidity data are attributable to the high frequency of subclinical infection, lack of laboratory facilities to distinguish hepatitis viruses in many regions or the failure to differentiate them in recorded data, and physician underreporting.[71,72]

Comparison of measured seroprevalences in different population groups provides a more reliable picture of the epidemiology of HAV disease. Seroprevalences vary from as low as 13% in Scandinavian countries such as Sweden, to approaching 100% in areas of the developing world such as Ethiopia.[157–159] Three distinct patterns (A, B and C) of age-specific HAV seroprevalence have been described (Fig. 7.4).[13,71,160] These patterns may be descriptive of the epidemiology of HAV in different countries, or in different population groups within the same country. For instance, the pattern of age-specific hepatitis A seroprevalence seen among Aboriginals in the Northern Territory of Australia[161] contrasts with that observed among urban and provincial populations in Victoria.[162]

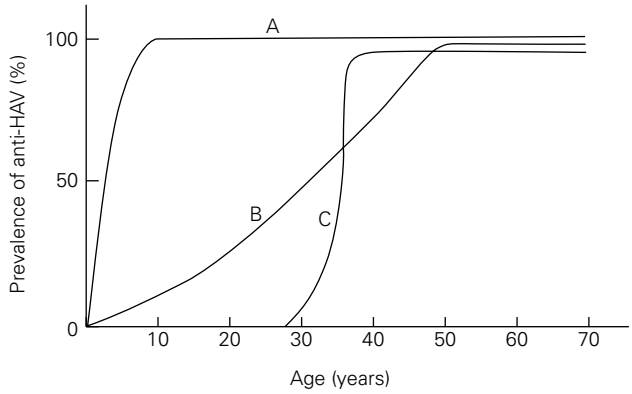

**Figure 7.4** The three major patterns of age-specific prevalence of anti-HAV. (From Gust,[155] with permission.)

Seroprevalence pattern A is typical of HAV epidemiology in developing countries, particularly tropical countries in which HAV may be hyperendemic, including most of Asia, the Pacific islands, Central and South America, and Africa.[159,163,164] Crowded living conditions, poor community sanitation and inadequate water supplies promote high levels of intrafamilial and foodborne and waterborne transmission of HAV within the community in these areas. Exposure to HAV before age 10 years is almost universal in these populations, and seroprevalence among adults approaches 100%.[159,163] Seroconversion among children is usually asymptomatic.[20] In these countries reported rates of hepatitis A are low and outbreaks rare, with most cases of HAV among visitors from lower prevalence areas such as tourists and voluntary workers. In one recent study of long-term American missionaries to Africa, the rate of acquisition of hepatitis A was 28% during the first 1–2 years of service and a median of 5.4% per annum for the next decade thereafter.[113]

Pattern B is typical of most developed countries including Scandinavia, North American, Japan and Western Europe. Exposure to HAV is infrequent among children in these countries, and seroprevalence increases slowly through early adulthood, reaching high or medium levels[162,165–167] among the older age group in a sigmoidal shaped curve (Fig. 7.4). The increase to quite high levels of seropositivity among older age groups is probably a cohort effect, reflecting high levels of HAV exposure present during childhood and subsequent gradual improvement in living standards over many decades. This explanation is suggested by the observed decline in the number of clinical cases of infectious hepatitis among children in the United States, Australia, Denmark, the former Czechoslovakia and Puerto Rico,[168–170] and a decrease in HAV-specific antibody prevalence in sera from the same age group collected many years apart in Australia, Germany, Japan, Italy and Finland.[168,171–174] For example, in Germany the HAV seroprevalence in the 20–29-year-old age group declined from 51% to 11% between 1965 and 1975.[171]

Epidemiological patterns intermediate between the above patterns A and B may occur as living standards improve in countries where HAV was formerly endemic, including eastern Europe, Mediterranean countries, the republics of the former Soviet Union, and parts of the Americas and Asia.[60,175–177] This situation is characterized by a decline in total infection rates and an increase in the mean age of exposure to HAV into older childhood or adolescence. A consequence of the increasing age of first exposure to HAV may be a paradoxical increase in the rate of symptomatic hepatitis A among this new pool of susceptibles. Sizable community outbreaks involving person-to-person spread of HAV may constitute a significant proportion of hepatitis A in such populations along with occasional foodborne outbreaks.[60]

The third seroprevalence pattern, pattern C, is typical of populations in which HAV is not endemic, but into which HAV is introduced from outside, abruptly infecting a large pool of susceptibles before disappearing. This results in an abrupt demarcation between high seroprevalence among those alive during the epidemic and minimal seropositivity among those born subsequently. This pattern has been well described in isolated populations in Greenland[55] and Alaska.[54]

## Demography

The differing age distribution of hepatitis A infection between developing and developed countries is largely a consequence of differing standards of hygiene and sanitation, as discussed previously. In the developing world, HAV infection is almost universal among children, reflecting early widespread exposure. In the developed world, clinical cases generally predominate among adults. Although a slightly greater incidence of cases may be seen among males in developed countries, there appears to be no gender association of HAV disease other than as a reflection of greater exposure risk through occupations, such as sewage workers, or participation in high-risk activities such as frequent oral-anal contact among male homosexuals.[90]

Socio-economic status has been shown to be inversely associated with prevalence of HAV-specific antibody.[167,178,179] Higher and lower HAV seroprevalences, respectively, were found in a lower socio-economic group[178] and in an upper socio-economic group[167] than in middle class populations in the United States. A similar association of HAV seroprevalence and socio-economic

status has been demonstrated in studies performed in Italy[74] and Ethiopia.[159] Other factors increasing the risk of HAV transmission in the Italian study were large families, crowded living conditions, and poor hygienic and sanitary conditions.[180] Higher hepatitis A seroprevalences have been observed in rural areas compared with urban areas in several countries,[175,181] and a higher incidence of hepatitis A infection has been observed among rural Thai children compared with children living in urban Bangkok.[175]

## Temporal patterns

Peaks of disease prevalence occurred every 5–10 years between the early 1950s and 1970s in some temperate developed countries including the United States, Canada, Australia and Denmark.[37] However, this cyclical pattern appears to have broken down as rates of HAV disease have declined in recent decades. The pattern has persisted in some population groups within the United States such as the Sioux Indians, among whom large hepatitis A outbreaks occur approximately every 7 years, predominantly affecting the 5–9-year-old age group.[177,182] A cyclical disease pattern is also seen in some countries currently of intermediate hepatitis A endemicity, such as Mauritius and Thailand, as improving sanitary conditions create a transition phase between endemic disease and sporadic self-limited epidemics.[175,177,183]

Similarly, seasonal peaks of HAV disease, which used to occur in autumn and winter in some temperate countries,[37] are no longer seen except as reflections of travel patterns to endemic areas. For instance, Germany, unlike the United States, retains a seasonal peak of hepatitis A in autumn, more pronounced in children than adults, which has been attributed to summer school holiday travel by children to Mediterranean countries where hepatitis A is still endemic.[158] In contrast, seasonality has never been a prominent feature of HAV epidemiology in tropical countries.

## Molecular epidemiology

Systematic study of HAV genetic variability was facilitated by the introduction of sequencing of HAV nucleic acid amplified directly from crude faecal suspensions by antigen-capture PCR.[184] Genetic analysis of 152 HAV strains obtained from multiple countries subsequently led to the proposal that HAV strains may be differentiated genetically into seven unique genotypes (I–VII). Viruses from four genotypes (I, II, III, VII) were recovered from human hepatitis A cases, and the remaining three genotypes (IV, V, VI) isolated only from cases of hepatitis A-like illness among captive simian species.[185] Nucleotide sequences of strains in the respective proposed genotypes were found to vary at 15–20% of base positions in a 168-bp section of the VP1/2A junction region, whereas within major genotypes, subgenotypes varying at approximately 7.5% of positions were described.[185]

As well as the VP1/2A junction,[184–191] genetic variability of HAV strains has also been studied by sequencing of short regions in the VP3 C terminus,[184] the VP3/VP1 junction region,[186,189,191] the VP1 N terminus[185,187,192–194] and the 5′NCR.[190]

Recently, phylogenetic studies were carried out using the full-length VP1 sequences from 81 HAV strains sourced from Europe and Central and South America between 1983 and 2001.[195] This approach reflects the recognition of the superiority of full-length VP1 over the VP1/2A junction for characterization of other picornaviruses, together with the importance of VP1 as an antigenic determinant both in HAV and other picornaviruses[196,197] (reviewed by Costa-Mattioli[198]). This study revealed five distinct lineages of HAV sequences well supported by high bootstrap values, yet suggested that the existing genotypes II and VII each only represented by a single strain, may in fact be subgenotypes of the same type.[195] Further phylogenetic analysis of the full-length VP2 and VP3 sequences of the genotype II strain 9F94, together with recombination analysis using recombination identification programme (RIP) software, suggests that genotype II may not be a distinct human genotype.[199]

The majority of human HAV infections are due to viruses from either genotype I or III, each of which has two subgenotypes denoted A and B.[198,200] Genotype I strains are the most widespread in the world.[184,185] Genotype IA strains have been identified originating from North, Central and South America, China, Thailand, Japan, the former USSR and South Africa, while genotype IB strains have come from South America, Europe, Australia, Japan, North and South Africa and Jordan[184,185,187–191] (reviewed by Costa-Mattioli[198]).

Genotype IIIA strains have been identified originating from Western Europe, USA, Malaysia, India, Nepal, Sri Lanka, and more recently from France, Italy and Spain.[184–186,198,201–204] In Estonia an outbreak associated with IDUs in 1998–1999 has seen genotype IIIA surplant genotype IA as the dominant HAV strain circulating in the community, the latter having predominated from 1994 to 2001.[152]

There is some evidence that geographically related strains from endemic areas appear to form distinct clusters distinguishable from other isolates of the same genotype from elsewhere.[152,184,185] There is also evidence for co-circulation of imported strains with endogenous strains.[185,186] Association of different HAV strains with shellfish of local and imported origin has been hypothesized to explain heterogeneous co-circulating HAV strains and the prominence of shellfish consumption as a risk factor in outbreaks in France and Italy.[186,201]

In the course of outbreak investigations molecular epidemiological studies provide essential support to traditional epidemiological investigations aimed at identifying chains of transmission and probable sources of infection. A high degree of relatedness has been shown between different viruses from the same outbreak,[152,186,190,201] and between viruses obtained from cases and shellfish identified as the infection source.[190]

Variation observed at the nucleic acid level should not compromise the protective efficacy of HAV vaccines based on genotype I strains (HM175 and CR326), as the close antigenic relationship between the majority, if not all, of human HAV strains is well established.[205] While naturally occurring antigenic variants of HAV have recently been described,[190,195,206] different serotypes have not.

## Conclusion

The general trend in the developed world is towards declining incidence of hepatitis A as standards of hygiene and sanitation continue to improve. In contrast, slow or minimal improvement in living conditions is likely in the foreseeable future in many developing countries, and hepatitis A will continue to be endemic in these areas. Within countries in transition towards hepatitis A eradication, some populations have slower rates of decline in incidence because of special risks, such as residents of institutions, some ethnic groups, IDUs and homosexual men. These will remain potential foci of hepatitis A persistence and may contribute to outbreaks in an increasingly susceptible general population, as may travellers returning from countries in which hepatitis A is endemic. In addition, children in day-care centres represent a large susceptible pool in which hepatitis A may be silently amplified and spread into the community.

With the availability of safe and effective vaccination for hepatitis A, the opportunity arises for intervention in HAV transmission on a population scale. Notably, vaccination could diminish the risk in low prevalence countries of hepatitis A outbreaks arising from persisting or external foci of infection. This might be achieved by targeted vaccination of risk groups, or it may require a broader approach including general childhood vaccination. In contrast, in hyperendemic areas, the morbidity caused by hepatitis A is minimal and competing public health priorities are many. Widespread uptake of hepatitis A vaccination is probably unlikely in such countries in the near future. If vaccine-acquired immunity is found to wane with time, vaccination may be of questionable value in areas where hepatitis A is endemic without improvements in hygiene and sanitation. Otherwise, morbidity attributable to hepatitis A may be increased through creation of a cohort of susceptible adults without altering high level transmission of HAV.

Improved hepatitis A surveillance and monitoring are currently required in both the developed and developing world, along with increased understanding of the duration of vaccine-induced immunity and implementation of public health measures aimed at improving sanitation and hygiene in the developing world. In the longer term, incorporation of hepatitis A vaccination into widespread childhood immunization protocols should facilitate eventual elimination of hepatitis A, as will soon be achieved with poliovirus.

# Chapter 8
# Natural history and experimental models

Robert H Purcell, Suzanne U Emerson

## Historical perspectives

Disease resembling hepatitis A was described in ancient times.[1] Outbreaks of hepatitis were reported among troops in military campaigns of the 17th through the mid-20th Centuries and the disease came to be known as 'campaign jaundice'. Outbreaks of hepatitis were also common among civilians, prompting Cockayne to designate such epidemics of jaundice as 'infective hepatitis'. By the 1940s, a second type of hepatitis, 'serum hepatitis', was recognized, and in 1947, McCollum introduced the terms 'hepatitis A' for infectious hepatitis and 'hepatitis B' for serum hepatitis. Epidemiologic and volunteer studies in adults and children from the 1950s through the 1970s demonstrated the predominantly faecal-oral route of transmission of hepatitis A, the bloodborne and sexual transmission of hepatitis B and the existence of a third hepatitis, designated non-A non-B hepatitis. The development of sensitive serological tests and animal models for each of these viruses during the 1970s and 1980s yielded much new information about the epidemiology and natural history of these agents and provided evidence for two additional hepatitis viruses: hepatitis D virus (HDV) and hepatitis E virus (HEV). Seroepidemiologic studies have shown that virtually everyone in developing countries has been infected with hepatitis A virus (HAV) by age 5–10 years and that this was also true for populations of industrialized countries until the mid-20th Century.[2] Such infections, occurring at an early age, are much more likely to be subclinical than when they occur in older children or adults. Thus, hepatitis A is an uncommon disease (but common infection) in developing countries and such was probably the case in industrialized countries until the early 20th Century. Ironically, the epidemics of hepatitis reported before the early 20th Century were probably not hepatitis A, but hepatitis E, as is still the case in developing countries.

## Clinical features of hepatitis A

The clinical presentation of viral hepatitis is similar, regardless of the aetiology, and the diagnosis must be made on the basis of serologic tests. However, each type of viral hepatitis has clinical features and a natural history that is more characteristic of that agent than of the other hepatitis viruses.

### Clinical spectrum

Infection with HAV may result in a wide spectrum of clinical outcomes, ranging from a completely inapparent infection detected serologically by evidence of a rising titre of anti-HAV, to subclinical disease characterized by limited symptoms and biochemical abnormalities of liver function tests to classical icteric hepatitis, to potentially fatal fulminant hepatitis with hepatic failure and coma. The most important factor determining outcome of HAV infection appears to be age. Clinical hepatitis A is more frequent with increasing age in almost all published reports.[2–12] Less than 5% of children below 3 years of age, 10% of children from 4–6 years of age and 80% of adults develop icteric clinical illness, regardless of the strain of infecting virus. Naturally attenuated and unusually virulent strains of HAV appear to be rare.[12–16] Fulminant hepatitis A occurs most commonly in patients over 50 years of age and death from hepatitis A is also most common in this age group.[8,11,17]

### Prodromal phase

The incubation period in viral hepatitis is often defined

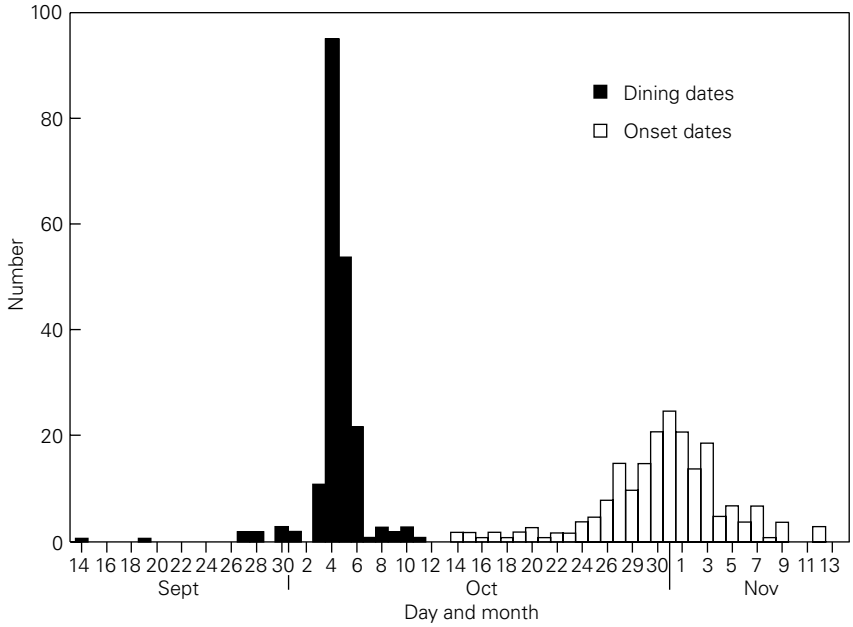

**Figure 8.1** Incubation period of hepatitis A. Number of hepatitis A cases, by date of eating contaminated food and by date of illness onset.[16]

as the time between exposure to the virus and the appearance of dark urine, the first sign usually noticed by the patient. The average incubation period in hepatitis A is approximately 4 weeks (range 2–7 weeks), based on experimental infections and analyses of common-source epidemics[16–20] (Fig. 8.1). Variations in the incubation period may be related to the infectious dose, differences in strain virulence or host factors.[21,22] Patients developing symptomatic disease usually experience a prodromal period beginning several days before onset of illness and characterized by malaise, flu-like symptoms, anorexia and fever.

## Acute disease

### *Major signs and symptoms*

Prodromal signs and symptoms (Table 8.1) may continue into the acute phase, followed by darkening of the urine and lightening of the faeces, but they usually decrease as jaundice, manifest by icterus of the sclera, skin and mucous membranes, develops.[23–26]

### *Laboratory tests*

Hepatitis A viraemia and faecal shedding, detected initially by volunteer studies but now by enzyme-linked immunosorbent assay (ELISA) or reverse transcriptase-polymerase chain reaction (RT-PCR), appears approximately 2–3 weeks after infection, during the incubation period, and peaks before onset of disease (Fig. 8.2).[27–34] As viral titres fall, biochemical markers of liver damage (see below) increase, paralleled shortly thereafter by the appearance of antibody to HAV (anti-HAV), first of the IgM class and then, shortly thereafter, of the IgG class. Anti-HAV of the IgM class can be detected for 3–4 months, but IgG anti-HEV persists, probably for life. Thus, patients with hepatitis A are usually positive for IgM anti-HAV when first seen by a physician and a positive test for IgM anti-HAV is diagnostic of recent infection. With the increasing use of hepatitis A vaccination, cases of modified HAV infection may become more common.[35] These may pose a diagnostic dilemma

**Table 8.1** Frequency (%) of signs and symptoms associated with acute hepatitis A[23]

| Signs/symptoms | Frequency (%) |
|---|---|
| Dark urine | 94 |
| Fatigue/anorexia | 90 |
| Nausea | 87 |
| Weakness | 77 |
| Fever | 75 |
| Vomiting | 71 |
| Headache | 70 |
| Abdominal discomfort | 65 |
| Light-coloured faeces | 52 |
| Myalgia | 52 |
| Drowsiness | 49 |
| Irritability | 43 |
| Itching | 42 |
| Constipation | 29 |
| Diarrhoea | 25 |
| Arthralgia | 21 |
| Sore throat | 20 |
| Nasal discharge | 14 |
| Cough | 7 |

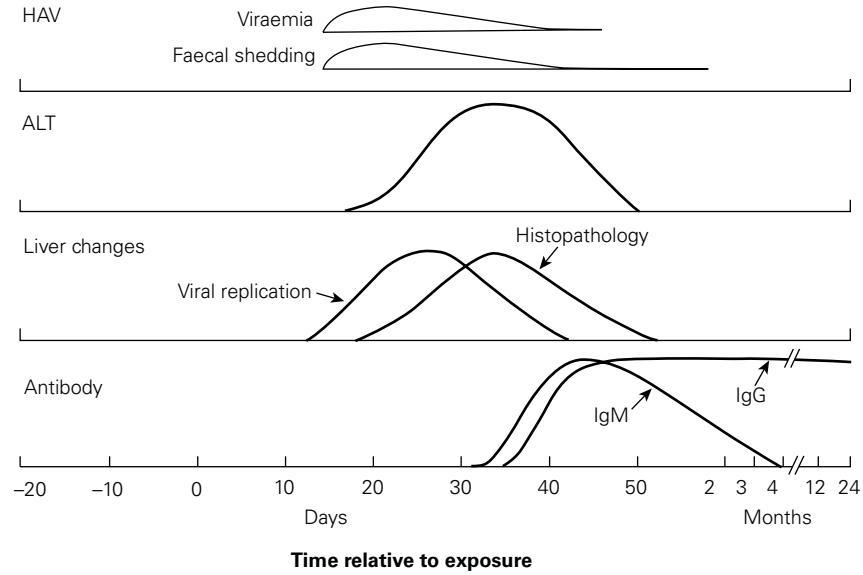

**Figure 8.2** Typical course of acute hepatitis A.

because commercially available tests for anti-HAV cannot differentiate between vaccination and infection. However, tests for antibodies to non-structural proteins of HAV, which appear only after infection, have been developed.[36]

Biochemical evidence of acute hepatitis is indistinguishable from that observed in other forms of viral hepatitis. Serum aminotransferases (alanine aminotransferase [ALT] and aspartate aminotransferase [AST]) are sensitive indicators of liver cell damage. They rise rapidly during the late incubation period, reaching peak levels (500–2000 U/L) generally within 1 week of the onset of symptoms and fall relatively rapidly after the onset of jaundice in uncomplicated cases. Early changes in the hepatocyte reflect altered permeability of the plasma membrane, resulting in loss from the cell of ALT, found in the cytosol, before loss of AST, which is found in the mitochondria. Thus, serum ALT levels are generally higher than serum AST levels in acute uncomplicated hepatitis A. High levels of AST indicate severe tissue necrosis. Generally, bilirubin reaches peak levels of 170–200 μmol/L shortly after the transferases peak. In uncomplicated hepatitis A, serum alkaline phosphatase and gamma-glutamyl transpeptidase levels are only slightly elevated. Transient elevation of total IgM and total IgG is often present and is more characteristic of hepatitis A than of other types of viral hepatitis. Transient elevation of smooth muscle antibodies may also occur. Changes in blood chemistry, such as minor coagulation defects and depressed fibrinogen levels without bleeding complications may occur, but severe depression of clotting factors is characteristic of fulminant hepatitis. Mild lymphocytosis with atypical mononuclear cells may be present early in the illness and mild pancytopenia may be present during recovery.

## Outcome of disease

### Uncomplicated course

In uncomplicated hepatitis A the duration of illness is generally brief. Clinical and biochemical indices of hepatitis A resolve rapidly and, in most patients, the serum aminotransferase levels have returned almost to normal by week 3 or 4. However, malaise, fatiguability and depression may sometimes persist for several months.

### Prolonged acute hepatitis A and relapse

Although hepatitis A is usually a benign disease of short duration, prolonged elevation of liver function tests has been documented.[17,24,37,38] In three studies of hepatitis A in adults, totalling over 600 patients, serum aminotransferase levels remained elevated for 4–12 months after onset in 14.5% of the patients.[20,39,40,41] Others have documented elevated aminotransferase levels for up to 15 months.[42] In such patients, HAV replication may persist and IgM anti-HAV remains detectable throughout the illness.[27,38,43–45] Although hepatitis A can persist for over a year, and even though histological changes resembling chronic hepatitis have been seen in liver biopsies from such patients, there are no documented cases of true chronic hepatitis attributable to HAV.

Hepatitis A may also recur within a few weeks of apparent recovery, even after liver function tests return to normal.[38,40,46–54] This second bout of disease may be icter-

ic or anicteric but is generally somewhat milder than the initial episode.[55] Rarely, a second relapse of acute hepatitis A has been described.[56] Reactivation of viraemia and/or viral shedding in the faeces can occur during such relapses, or may continue intermittently between episodes.[27,38,57]

### Fulminant hepatitis

Fulminant hepatitis is a rare complication of HAV infection but may be more common in developing countries.[12,58–64] The incidence of fulminant hepatitis and the incidence of fatal fulminant hepatitis both increase with age (Fig. 8.3).[2,8,11,17,65] The disease is characterized by increasingly severe jaundice, deterioration in liver function, especially synthesis of clotting factors, increasing encephalopathy and, ultimately, coma. The treatment of choice in potentially fatal fulminant hepatitis is liver transplantation. In patients who survive hepatic coma caused by acute hepatitis A and who have not undergone liver transplantation, the recovered liver does not contain evidence of fibrosis or cirrhosis.

### Fatal hepatitis

Although fulminant hepatitis A is often fatal, all fatal hepatitis A is not fulminant. The case-fatality rate in a large study of more than 2000 hospitalized patients was <0.2%; mortality increases with age.[65,66] Others have reported a much lower mortality rate of 0.015% among almost 311 000 cases in Shanghai, China in 1988. However, >90% of these cases were between the ages of 20 and 40 years, and older individuals in this population, who would be more likely to have a fatal outcome, were also more likely to have been immune by virtue of exposure to the virus as children.[12] Finally, the strain of HAV causing one waterborne epidemic of hepatitis A in China may have been somewhat attenuated.[67] A study by the Centers for Disease Control of 94 000 cases of hepatitis A in the United States in 1995 reported a case-fatality rate of at least 0.16% and a recent epidemic of hepatitis A among an estimated 555 individuals who were infected by eating contaminated green onions had a case-fatality rate of 0.54%.[16] The reason for these differences is unclear, but may simply reflect differences in the age distribution of the populations at risk. Causes of death from hepatitis A, other than uncomplicated fulminant hepatitis, may include acute hepatitis A superimposed on chronic hepatitis, with or without cirrhosis, caused by HBV or HCV, and other diseases not related to the liver.[8,12,68]

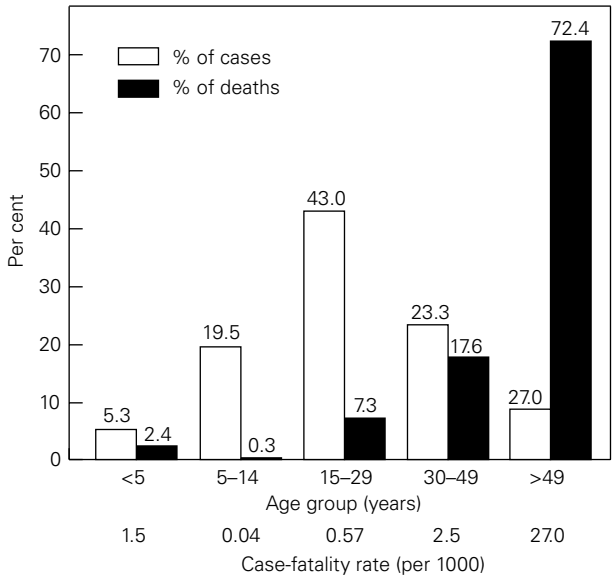

**Figure 8.3** Age-specific incidence of clinical hepatitis A and age-specific incidence of death from hepatitis A. The case-fatality rate is depicted at the bottom of the figure.[2]

### Cholestatic hepatitis

Acute hepatitis A with prolonged cholestasis is a syndrome characterized by pruritus, fever, diarrhoea, weight loss, bilirubin levels >170 μmol/L and a clinical course of at least 12 weeks.[17,55,69] Serum aminotransferase levels tend to be lower but alkaline phosphatase levels higher in this form of hepatitis A. Histologically, the liver of such patients displays centralobular cholestasis and portal inflammation.[69,70] Cholestatic hepatitis A is an unusual form of HAV infection that has a good prognosis and complete recovery. Cholestatic features have also been described in the relapsing form of hepatitis A.[50,52,53]

## Hepatitis A in pregnancy

Unlike hepatitis E in pregnancy, hepatitis A is not associated with increased mortality in pregnant women.[71,72] In the large food-borne outbreak of hepatitis A in Shanghai involving almost 311 000 cases and including >5000 pregnant women, there was no increase in morbidity or mortality associated with pregnancy.[73] Furthermore, there is no evidence that HAV infection causes chromosomal abnormalities or fetal deformities and there are only a few reports of HAV transmission to the newborn.[74–78]

## Hepatitis A in pre-existing liver disease

There is considerable evidence that acute hepatitis A is more severe in patients with pre-existing liver disease, regardless of the aetiology.[68] Thus, 15 of 47 patients who died with acute hepatitis A during the 1988 Shanghai epidemic had underlying chronic active hepatitis B or hepatitis B virus (HBV)-related cirrhosis.[12] In recognition of this, the Advisory Committee on Immunization Prac-

tices in the United States has recommended hepatitis A vaccination for persons with chronic liver disease. The cost-effectiveness of such a policy has been a continuing subject of debate.[79–85] The increased severity of hepatitis A in patients with underlying chronic infection with another hepatitis virus appears to be limited to those with actual disease.[86–91] Inhibition of viral replication in the underlying chronic infection has been reported for some cases of hepatitis A superinfection.[92,93] This probably stems from an interferon-induced antiviral effect of the superimposed infection.

## Hepatitis A and autoimmune liver disease

Autoantibodies are occasionally found transiently in acute hepatitis A and rarely, acute autoimmune hepatitis has been reported following acute hepatitis A. In a prospective study, healthy relatives of patients with type 1 autoimmune hepatitis developed similar disease following acute hepatitis A, suggesting a genetic predisposition for autoimmune hepatitis in such individuals.[94] Protracted HAV infection has been associated with HLA-DRB* 1301, a marker for paediatric autoimmune hepatitis.[95]

## Hepatitis A and extrahepatic disease

Extrahepatic manifestations of hepatitis A are rare. Transient Lupus-like syndrome, arthralgias, arthritis, skin rashes, vasculitis, cryoglobulinaemia and neurological complications, including encephalitis and Guillain-Barré syndrome, have been described.[20,47,96–111] In addition, cardiac involvement, characterized by electrocardiographic alterations (bradycardia, prolongation of the PR interval, T-wave depression), which are transient and resolve during convalescence, have been reported.[112] Haematological changes, including haemolytic anaemia, agranulocytosis, thrombocytopenic purpura, pancytopenia and aplastic anaemia have been reported, although most cases of aplastic anaemia following viral hepatitis are not related to hepatitis A.[113–118] Acute haemolysis associated with hepatitis A has been reported in patients with glucose-6-phosphate dehydrogenase deficiency.[119–121] Other uncommon non-hepatic manifestations of acute hepatitis A include pancreatitis, cholecystitis, glomerulonephritis, interstitial nephritis and nephrotic syndrome.[17,122–132] Lymph node enlargement located near the hepatic hilum, pancreas and small omentum has been described as a unique ultrasonographic feature in acute hepatitis A in children.[133]

## Hepatitis A and human immunodeficiency virus (HIV) infection

In contrast to patients with underlying chronic hepatitis who develop hepatitis A and have a more severe outcome, hepatitis A patients with underlying HIV infection have less severe disease, as indicated by lower serum ALT levels, a higher titre of HAV and a prolonged viraemia when compared with patients not co-infected with HIV.[134,135] In contrast, serum alkaline phosphatase and gamma-glutamyltransferase levels, but not total bilirubin, were higher in the HIV-infected patients. However, hepatitis A in well-controlled HIV patients may resemble disease in immunologically normal patients.[136] Thus, poorly controlled HIV-infected patients with hepatitis A may have a clinical course similar to that of other immunocompromised individuals and such patients may be important in maintaining and propagating HAV in the community.[135,137]

## Other associated diseases

Recently, HAV infections have been linked epidemiologically, but not clinically or causally, to two other diseases: atherosclerotic cardiovascular disease and allergic asthma. In each case, HAV infection is thought to be a contributing (or confounding) factor, rather than the sole aetiologic event.

### Atherosclerotic cardiovascular disease

An infectious aetiology for coronary artery disease has become an increasingly popular hypothesis in recent years.[138–142] Epidemiologic associations between serologic evidence of infection with several pathogens, including *Chlamydia pneumoniae*, *Helicobacter pylori*, cytomegalovirus, herpes simplex viruses 1 and 2 and HAV, and atherosclerotic coronary artery disease have been identified. The strength of the association paralleled the cumulative number of pathogens the patients had encountered, but the strongest association was with HAV infection. The associations held not only for coronary disease but also for C-reactive protein levels as a marker of ongoing inflammation. Although a number of hypotheses for this association were put forward, including chronic HAV replication, it is likely that a causal association, if any, is related to the overall pathogen burden or some other environmental factor and that HAV infection is an indirect marker of that association.

### Allergic asthma and atopy

Atopic diseases have increased in prevalence in recent

years in western Europe, the United States and Australia.[143] In 1989, Strachan proposed the 'hygiene hypothesis' to explain these epidemiologic observations.[144,145] An inverse relationship between family size and the development of allergic disease was noted and it was proposed that frequent infections, which were likely to be transmitted among numerous siblings, might modulate the developing immune system through stimulating Th1 lymphocytes and inhibiting the clonal expansion of allergen-specific Th2 lymphocytes.[146–149] Among other associations, such as the household presence of pets and diminished atopy, were associations between serologic evidence of infection with measles, hepatitis A and *Mycobacterium tuberculosis* and a diminished prevalence of asthma.[150] More recently, epidemiologic studies have strengthened the association between the diminished prevalence of serologic evidence of HAV infection and an increased prevalence of asthma.[151,152] HAV is believed to enter susceptible cells via a receptor initially designated HAVcr-1 and subsequently shown to be related to the cell surface receptor TIM-1, a marker that is expressed by activated CD4+ T cells during the development of helper T-cell (Th2) responses and a regulator of cytokine production.[153–155] Close association between Th2 lymphocyte responses and allergy has led some to postulate a molecular association between infection of activated lymphocytes by HAV and modulation of the allergic response early in life.[154] However, as with the direct association between the prevalence of HAV infection and coronary artery disease, the inverse association between the prevalence of HAV infection and atopy is likely to be an indirect marker of an inverse relationship between pathogen burden early in life and the development of allergy, especially asthma.[156]

## Histopathology

Much of our knowledge of histopathological changes in the liver during hepatitis A is derived from experimental infections of chimpanzees, in which periportal liver cell necrosis sparing the perivenular region of the lobule was seen early in the disease.[157–159] Liver biopsies are rarely performed on patients with acute hepatitis, but they have demonstrated that changes in humans are similar to those observed in chimpanzees.[160–162] In one study of 34 patients who were biopsied during different stages of acute hepatitis A, portal infiltration by lymphocytes, plasma cells and macrophages was a prominent feature of biopsies obtained within 10 days of onset of disease, but it was also present in later biopsies when a prolonged course or relapse occurred.[163] The infiltration of the portal triads may spill over into the lobular parenchyma and mimic piecemeal necrosis and chronic hepatitis.[164] Very severe periportal necrosis may lead to portoportal bridging. Other histological changes include iron storage in Kupffer cells.[163] In other large studies of biopsies obtained during the acute phase of infection with patients with hepatitis A, hepatitis B or hepatitis C, hepatitis A was characterized by more pronounced periportal inflammation but less conspicuous parenchymal changes such as focal necrosis, Kupffer cell proliferation, acidophilic bodies or ballooning of hepatocytes.[165] Histological changes also resolved more quickly in hepatitis A, but non-specific changes could still be detected during convalescence.

Following recovery, lobular architecture is intact and there are no chronic changes. In general, histological changes in hepatitis A are not sufficiently distinct to be of diagnostic value and, as liver biopsies are associated with a small but finite risk to the patient, biopsies of acute hepatitis are not useful or warranted.

## Pathogenesis

The pathogenesis of hepatocellular injury in acute hepatitis A is poorly understood. HAV is difficult to adapt to growth in cell culture.[166–168] However, cell culture-adapted strains generally do not produce cytopathic changes, even when virtually every cell is infected, and such strains can be maintained as chronic infections *in vitro* indefinitely. To be sure, certain highly adapted strains of HAV produce a cytopathogenic effect in cell culture.[169] This has been shown to be mediated by apoptosis, but the parent virus does not produce this effect and its significance is uncertain.[170–173] During the incubation period of acute hepatitis A *in vivo*, HAV similarly produces few if any histopathological changes in hepatocytes, even though most hepatocytes at the peak of viral replication are infected.[14] As such *in vivo* infections never progress to chronicity but are terminated more or less in parallel with the appearance of the host's immune response, it is believed that both clearance and disease are the result of immunologically mediated responses.

The humoral response appears to be most important in preventing disease, as antibody alone can prevent or modify infection, and antibody is probably also important in limiting the spread of the virus during the incubation period, because antibody administered shortly after exposure can also modify the severity of the outcome, even after infection is established. However, resolution of hepatitis A is thought to be mediated principally by the cellular immune response. Thus, Vallbracht *et al*. demonstrated lysis of autologous skin fibroblasts infected with HAV by peripheral blood lymphocytes from all hepatitis A patients tested, but not from controls.[174] The cytolytic activity peaked 2–3 weeks after onset of icterus and was mediated by a subset of CD8+ HLA class I-dependent T cells that were also able to produce interferon-γ (IFN-γ).[175] Both functions of cytotoxicity and IFN-γ release were virus-specific. Furthermore, human

T lymphocytes cloned from liver biopsies of hepatitis A patients also belonged to the CD8+ subset and were HAV-specific, HLA class I-dependent, cytotoxic and IFN-γ-producing.[176,177] In one patient, from whom a biopsy was obtained later in the course of illness, CD4+ T-cell clones were also generated in substantial numbers, in addition to the CD8+ clones. This observation is consistent with the demonstration by immunohistological staining of CD4+ cells in the portal tracts of biopsies obtained during acute hepatitis A, although the specificity and functional capacity of these CD4+ cells was not determined.[178,179] Finally, natural killer cells have been shown to be capable of lysing HAV-infected cells *in vitro*, suggesting that they may also have a role *in vivo* in the host response to HAV infection.

However, the actual mechanisms by which HAV is removed from the liver during acute hepatitis A remain to be determined. Clearance of all of the hepatitis viruses during the resolution of viral hepatitis has been thought to be mediated solely by CD8+ T-cell-mediated lysis of infected hepatocytes, but this has proven to be a simplistic view of the pathogenesis of viral hepatitis, at least for hepatitis B and probably hepatitis C.[180,181] Thus, at least in animal models of the disease, clearance of HBV from the liver is effected principally by non-cytolytic mechanisms mediated by CD8+ T cells. The synthesis of the various components of HBV replication is downregulated and, in some cases, disrupted by cytokines, principally IFN-γ and tumour necrosis factor-alpha (TNF-α) released by virus-specific T cells, and removal of hepatocytes by cytolytic T cells is a late, but important, component of viral clearance. This scenario makes sense because, during the peak of viral replication, virtually every hepatocyte is infected and removal by cytolytic means would result in fulminant hepatitis in most infections, rather than the rare case that is actually observed. Indeed, the histologic picture of fulminant hepatitis A is that of massive destruction of virus-infected hepatocytes. Furthermore, viraemia, as measured by serum HAV RNA, is markedly diminished when compared with less severe infections, suggesting an excessive host response.[182] It is not yet known whether such non-cytolytic mechanisms are operative in acute hepatitis A. Antiviral cytokines such as IFN-α, a product of the innate immune response and TNF-α, a product of the adaptive immune response, have been detected during acute hepatitis A, suggesting that non-cytolytic antiviral mechanisms mediated by cytokines are operative in this disease also.[92,183–187]

## Animal models of hepatitis A

Before the development of animal models for viral hepatitis, these diseases were studied by experimental transmission to human volunteers, both adults and children.[18,188,189] Although important information that could not have been obtained by other means was obtained from these studies, they did lead to the death of several adult volunteers and unexpected chronic infections in adults and children, raising serious ethical questions about this research. One positive aspect of the studies in humans was the generation and characterization of clinical materials containing high titres of virus, and these were used to develop and validate serologic tests for HAV and HBV.[190–195] Such serologic tests proved to be the key to identifying animals that were seronegative and therefore might be useful for *in vivo* studies of the hepatitis viruses. The characterized virus pools, of known infectivity, derived from the volunteer studies were also essential for establishing the susceptibility of various animal species to the hepatitis viruses. In turn, the development of useful animal models heralded the end of volunteer studies for ethical reasons. Ironically, ethical reasons are currently put forward as reasons for discontinuing studies in animals. However, despite progress in our understanding of molecular aspects of infection, animals remain essential for the study of pathogenesis and for vaccine development. Neither can be appropriately studied in *in vitro* models.

### Historical perspective

Early attempts to transmit hepatitis A to a variety of laboratory animals were generally unsuccessful.[196,197] This is perhaps not surprising because there were no known infectious pools of the viruses and there were no serological tests with which to distinguish among them or to select susceptible animals. Among the first reports of infection of non-human primates with a hepatitis virus was the report by Deinhardt and colleagues of transmission of hepatitis to white-lipped tamarins (*Saguinus nigricollis* and *Saguinus fuscicollis*) and cotton-topped tamarins (*Saguinus oedipus*) in 1967.[198] One successful transmission utilized an inoculum of serum obtained from a surgeon, whose initials were G.B. and who had developed acute hepatitis without known exposure. Deinhardt believed this virus to be hepatitis A virus, but Parks and Melnick recovered a similar virus from an uninoculated tamarin and provided evidence that the GB virus had physical characteristics that were distinct from those ascribed to HAV.[199,200] This controversy was resolved when Deinhardt's group successfully transmitted bona fide HAV from one of the volunteer studies to tamarins, and the GB agent was subsequently shown to be distinct from HAV.[201–206] Ironically, it was not until 1995 that the mystery of the GB agent was solved, when scientists at Abbott Laboratories resurrected the GB agent from frozen stocks of the original transmission series in tamarins and demonstrated by molecular means that the GB agent was actually two agents, which they designated GB virus-A and GB virus-B.[207] Both are mem-

bers of the *Flaviviridae* family of viruses and, therefore, distant relatives of hepatitis C virus. It is probable that both GB viruses are tamarin viruses that were inadvertently picked up in the earliest animal passages.

Other groups subsequently confirmed the susceptibility of tamarins to infection with HAV, even before serological tests for the virus were developed.[208–210] This was possible because the animals apparently were not exposed to HAV before entry into the laboratory and most, if not all, animals were susceptible.

Such was not the case for chimpanzees. Most attempts to infect chimpanzees with hepatitis virus yielded negative or equivocal results, probably because they were exposed to hepatitis in the wild or shortly after capture.[211,212] Nevertheless, there was epidemiological evidence for susceptibility of chimpanzees. Animal handlers and non-human primates occasionally developed hepatitis after handling newly caught chimpanzees.[211,213–215] The development of sensitive serological tests for antibody to HAV provided a means of screening captive chimpanzees as well as other primates for evidence of prior exposure to HAV. Such tests revealed that most jungle-caught chimpanzees had antibody to HAV, whereas chimpanzees that had been bred in captivity were less likely to have such antibody.[216,217] Attempts to infect seronegative chimpanzees with HAV were successful and confirmed that previous transmission failures probably stemmed from the use of immune animals.[218,219]

Similarly, serosurveys of different species of animals have detected anti-HAV only in non-human primate species.[33] Some, but not all, of these primate species have proven to be useful animal models for the study of hepatitis A.[33,217] These include, in addition to the tamarin and the chimpanzee, the owl monkey and, to a lesser extent, certain macaque species (see below).

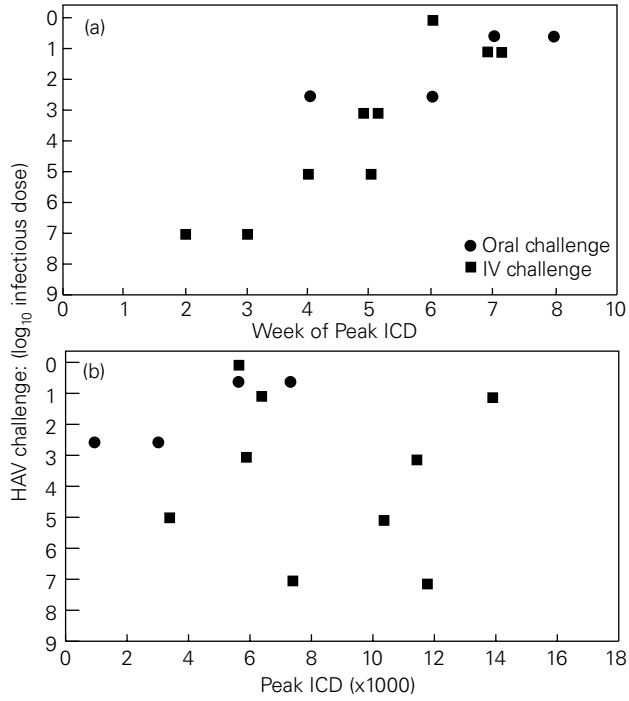

**Figure 8.4** Response of tamarins to oral or intravenous (IV) challenge with different doses of virulent hepatitis A virus. (a) Relationship between challenge dose and interval to peak serum isocitrate dehydrogenase (ICD) level. Challenge by the oral route required $10^{4.5}$ more virus to achieve an incubation period comparable to challenge by the intravenous route. (b) Relationship between challenge dose and magnitude of peak serum ICD level. There was no relationship between challenge dose and severity of hepatitis as measured by peak serum ICD level.[22]

## Course of HAV infection in animal models

Based on data obtained principally from tamarins, chimpanzees and owl monkeys, a picture of the pathogenesis and natural history of hepatitis A in non-human primates has emerged. Exposure of humans to HAV usually occurs via the oral route and such is probably the case for naturally infected non-human primates. However, the virus can be transmitted parenterally to all of these species. Ironically, HAV is more readily transmitted to non-human primates (at least tamarins and chimpanzees) by intravenous inoculation than by oral inoculation.[22] In fact, oral administration of HAV to these two species is 3200-fold less efficient than intravenous inoculation[22] (Fig. 8.4).

After exposure, the first evidence of infection usually is detection of virus in the liver.[220–225] Soon thereafter it can be detected in the blood, bile and faeces. A site of replication in the intestinal tract has been sought but never unequivocally found. Thus, viruses found in saliva, the pharynx and the intestinal tract probably reached those sites via replication in hepatocytes and excretion into the blood and into the bile.[218,220,221,223,226–228] Peak shedding of the virus into the blood and into the intestinal tract via the biliary tract occurs before onset of disease, which is almost always very mild in non-human primates.[30,218,229,230] In fact, there is only one report of serious, fulminant hepatitis in non-human primates (a chimpanzee).[231] Onset of clinical disease usually coincides with diminished replication of the virus and the first detection of the humoral immune response.[232] Thus, as in patients, non-human primates develop IgG and IgM anti-HAV at approximately the time of onset of liver damage, and this is taken as indirect evidence that hepatitis A is an immunologically mediated disease.[232] Viraemia may persist for approximately 1–3 weeks after onset of disease and faecal shedding may persist for 2–3 weeks longer, but both may persist much longer in more protracted infections.[27] Liver damage is detected by liver biopsy and by measuring serum levels of liver enzymes. The most useful enzyme measurement for hepatitis in

humans and chimpanzees is alanine aminotransferase. The most useful enzyme measurement for tamarins is isocitrate dehydrogenase. Histological changes in the liver are not unique to hepatitis A but resemble those seen during the acute phase of infection with the other hepatitis viruses.[146,159] Histological changes consist of focal necrosis, Kupffer cell proliferation and ballooning degeneration and apoptosis of hepatocytes. Necrosis and mononuclear cell inflammation of the periportal tract are seen more frequently in hepatitis A than in the other types of viral hepatitis. Heavy infiltration of inflammatory cells and bile retention are also features of hepatitis A in non-human primates. The severity of acute hepatitis A in non-human primates may range from mild, with focal necrosis, to moderate, with necrosis bridging portal tracts or joining portal areas and central veins. Severity of hepatitis A in non-human primates is not related to the infectious dose (Fig. 8.4).[22] More severe hepatitis is rarely seen in non-human primates but does occur in humans. Non-human primates are almost never symptomatic during experimental HAV infection, and all recover completely.

## Tamarins and marmosets

Tamarins comprise a group of more or less closely related species of small arboreal monkeys that are distributed in Central and South America. They vary in susceptibility to infection with HAV: *S. mystax* and *S. labiatus* (sometimes referred to as '*S. rufiventer*') have proven the most susceptible and *S. nigricollis, S. fuscicollis* and *S. oedipus* somewhat less susceptible. The true marmosets (*Callithrix* species) are still less susceptible to HAV infection but have been used for the study of HAV.[203,210,221,225,234–236]

## Chimpanzees

Chimpanzees are as sensitive to HAV infection as tamarins but have the advantage of being man's closest relative. Thus, chimpanzee proteins are very similar to those of man and reagents developed for studying immunological and other responses in man can be used for experimental studies in chimpanzees.[36,237,238] Similarly, chimpanzee immunoglobulins are closely related to human immunoglobulins, and chimpanzee monoclonal antibodies that neutralize HAV have been derived from combinatorial phage libraries prepared from bone marrow aspirates of chimpanzees convalescent from hepatitis A.[239] Such 'human' monoclonal antibodies may be useful for the prevention and treatment of hepatitis A in humans.

One discrepancy between humans and chimpanzees has been identified. Whereas infections with HBV or HCV or treatment with polyIC polyLC (an inducer of interferon) stimulate the production of type 1 interferon *in vivo* and, at least in HBV infections, this is associated with a demonstrable antiviral effect, the administration of human interferon to chimpanzees does not elicit a demonstrable antiviral effect. The reason for this is unknown.

## Owl monkeys

Locally caught owl monkeys that were introduced into a colony of these animals in Central America developed hepatitis A and a unique HAV strain was recovered from one such infected monkey.[240] The virus was subsequently shown to be endemic in the facility and most animals eventually became infected. Originally, the virus obtained from these animals was thought to be of simian origin but similar strains were subsequently recovered from humans.[240–244] Owl monkeys were shown to be susceptible to other strains of human HAV and the course of infection was similar to that seen in tamarins and chimpanzees.[230,245–247]

## Old World monkeys

The susceptibility of Old World monkey species to infection with HAV has been controversial. Some studies have shown various macaque species to be quite susceptible to infection with HAV, whereas other studies have found them to be sparingly susceptible.[33,248–253] Molecular characterization of strains of HAV recovered from such monkeys (often used for subsequent transmission studies) revealed them to be unique from human isolates.[248,254] Both molecular and epidemiological data strongly suggest that at least three such genetically distinct viruses are true simian strains of HAV.[243,255] Unlike human strains of HAV, these strains are readily transmissible to Old World monkey species and some New World monkey species, but they are sparingly infectious in chimpanzees.[256] Thus, Old World monkey species – principally rhesus, cynomolgus and possibly stumptailed macaques and African Green monkeys – have proven to be excellent animal models if a simian strain of HAV is employed, but the results are less predictable if human strains of HAV are used.

## Bushbabies

Lesser bushbabies (*Galago senegalensis moholi*) have been reported to be susceptible to HAV in transmission studies.[257,258] Clinical hepatitis was not observed but liver pathology, seroconversion, excretion of HAV antigen in the faeces and serum liver enzyme elevations resembled those in human hepatitis A. However, other studies have failed to confirm the susceptibility of bushbabies to

infection with HAV.[217] The susceptibility of this species awaits resolution.

### Guinea pigs

Recent *in vitro* studies demonstrated that, contrary to current dogma, HAV replication was not restricted to cells of primate origin. Thus, HAV replication was demonstrated in guinea pig cells.[259] To determine if HAV can be transmitted to guinea pigs, HAV that had been adapted to growth in monkey kidney cells and a variant that had been further adapted to growth in guinea pig cells were inoculated intraperitoneally or orally into guinea pigs.[260] Guinea pigs that were inoculated with mock-infected cell culture material served as controls. Most of the HAV-inoculated guinea pigs developed infection as measured by RT-PCR amplification of HAV RNA from faeces and/or serum, regardless of the virus or route of administration. Virus was detected as early as 14 days and as late as 52 days after inoculation. Serum liver enzyme tests and bilirubin levels remained normal but histopathological changes were detected in the liver, spleen and intestinal tract. However, none of the animals developed antibody to HAV and histological changes were seen in one or more of the control animals, making interpretation of the study difficult. Additional studies will be necessary to confirm the susceptibility of guinea pigs to infection with HAV.

### Applications

Evaluation of the safety and efficacy of hepatitis A vaccines has been an important use of non-human primates in hepatitis research. Such studies confirmed the effectiveness of inactivation procedures and protective levels of anti-HAV for inactivated vaccines and they have been essential for evaluation of the level of attenuation of candidate live vaccines.[261–264] More recently, they were essential for demonstrating that certain candidate live vaccine strains were genetically unstable *in vivo* and reverted to a virulence phenotype following transmission to tamarins.[14]

Non-human primate species are also important for studies of pathogenesis. Microarray analysis of the host global response to HCV infection has been reported. This revealed a very complex modulation of factors related to the innate and adaptive immune responses as well as to other metabolic pathways.[237,238] Undoubtedly, such molecular analyses of HAV infection of non-human primates will yield comparably illuminating results.

An important tool for evaluation for HAV infections in non-human primates was provided by the development of practical methods for transfecting animals with RNA transcripts of full-length cDNA clones of HAV strains. Such infectious cDNA clones of viruses provide a method for molecular engineering and analysis of the viral genome. For viruses that grow in cell culture, such clones can be tested for infectivity by transfecting susceptible cells.[265] However, for viruses that do not grow in cell culture, transfection must be performed *in vivo*. Initially, this method required laparotomy and direct inoculation of the cDNA or its RNA transcripts directly into the liver.[266] However, percutaneous intrahepatic transfection, guided by ultrasound, has become a simple and repeatable technique for testing the viability of cloned viral genomes and their molecularly modified variants.[14]

Molecular biology has not replaced animals for studies of pathogenesis but it has enriched such studies. New assays for quantifying messenger RNAs of host proteins, either singly or by microarray, and new single and multiplex assays for circulating cytokines and other host entities are yielding much more sophisticated analyses of *in vivo* studies than were feasible only a few years ago. Such studies will probably provide the first comprehensive understanding of pathogenic mechanisms in viral hepatitis.

# Chapter 9
# Prevention

Beth P Bell

Hepatitis A can be prevented by three general approaches. Because the predominant mode of hepatitis A virus (HAV) transmission is by the faecal-oral route, good standards of hygiene and sanitation, including the appropriate disposal of human waste and provision of clean drinking water, are important contributors to preventing HAV transmission. These considerations currently are most relevant for the developing world, in some parts of which improvements in socio-economic and hygienic conditions have resulted in measurable shifts in the age-specific prevalence of HAV infection.[1–3] In the developed world, where transmission is usually from person to person, good hygienic practices, such as careful hand-washing, can contribute to preventing transmission in settings such as day-care centres and food service establishments.[4,5]

The most exciting new development in hepatitis A prevention in recent years is the availability of safe and effective hepatitis A vaccines for active immunization. In addition to protecting individuals at increased risk of infection, these vaccines, if used broadly, provide the opportunity to substantially lower disease incidence in populations. Indeed, recent evidence of such reductions has been reported from the United States and some other parts of the developed world in which hepatitis A vaccination of children has been implemented widely.[6–9] Because the existence of an animal reservoir has not been demonstrated and there is no chronic infection in humans, strategies of widespread vaccination afford the potential to ultimately eliminate HAV transmission.

A third approach that continues to have a role to play in the prevention of hepatitis A is passive immunization with immune globulin. With the widespread availability of hepatitis A vaccine to prevent hepatitis A before exposure, the most common indication for immune globulin is to provide passive protection to persons recently exposed to HAV (post-exposure prophylaxis), such as household contacts of hepatitis A cases. However, effective post-exposure prophylaxis requires recognition that an exposure has taken place, which occurs in only a minority of hepatitis A cases. In addition, the protection conferred by immune globulin is short-lived.

## Active immunization

Hepatitis A vaccines were developed in a manner similar to polio vaccines. The critical advance came when Provost and Hilleman developed a method for *in vitro* propagation of HAV in cell culture, and produced cell lines suitable for vaccine production.[10] Several years later, Binn and colleagues were the first to produce an inactivated vaccine from HAV propagated in cell culture.[11]

### Inactivated hepatitis A vaccines

A number of inactivated vaccines have been developed by commercial vaccine manufacturers. Two, Havrix (GlaxoSmithKline, Philadelphia) and Vaqta (Merck & Co. Inc., West Point, PA), are approved for use in the United States as well as much of the world.[12,13] Two other vaccines (Avaxim, Sanofi Pasteur, Lyon, France, and Epaxal, Berna Biotech Ltd, Bern, Switzerland) are available in Europe, Canada and selected other countries.[14,15] All are manufactured from HAV that has been propagated in cell culture and is subsequently purified and inactivated by exposure to formalin. All but Epaxal are adjuvanted by adsorption to alum; Epaxal uses a virosome adjuvant. The majority of this chapter will focus on the two vaccines available in the United States and also used widely in Canada and Europe, as these are the vaccines with the most available information and experience to date.

#### *HAV strains used in inactivated vaccines*

Vaqta contains the CR326F strain, initially isolated in Costa Rica and the first strain to be successfully cultivated *in vitro*.[10] CR326F was initially isolated in a fetal rhesus kidney line, FRhK6. After 15 passages, it was transferred to human embryonic lung diploid fibroblasts (MRC-5 cells) for an additional 28 passages.[12] Havrix contains the HM175 strain, isolated from the stool of a

patient in Australia.[16] It was originally adapted to cell culture by a series of 30 passages in green monkey kidney cells followed by adaptation to MRC-5 cells.[13] Avaxim contains the GBM strain of HAV, which was isolated and propagated in human kidney cell culture for 10 passages, followed by adaptation to MRC-5 cells during 20 passages.[17–19] Epaxal contains the RG-SB strain, grown and then harvested from disrupted MRC-5 cells.[14,20,21]

### *Constituents*

All available inactivated vaccines include HAV antigen, but the antigen content is not standardized and the units by which the antigen content is expressed are different for each vaccine. Because of the different assays used and the absence of an international antigen reference reagent, it is not possible to compare the antigen content among vaccines. Based on quantitative analysis of a highly purified standard, the antigen content of the formulation of Vaqta evaluated in early clinical trials was measured as 25 ng of viral protein, and subsequent vaccine lots with equivalent antigenic activity are considered by the manufacturer to contain 25 units (U) of HAV antigen.[22] The viral protein contained in Havrix is expressed in terms of enzyme-linked immunosorbent assay (ELISA) units (ELU), established by the manufacturer according to an in-house reference standard.[13]

Hepatitis A viral particles found in the inactivated vaccines include both 155S particles (intact virions) and 70S empty capsids. The 70S particles appear to have antigenic activity similar to that of wild-type virus.[23] There are differences in the amount of non-virion protein contained in the available vaccines, but these differences have not been found to be clinically relevant. Havrix and Avaxim contain 2-phenoxyethanol as a preservative; Vaqta and Epaxal are formulated without a preservative.

The antigens in Havrix, Vaqta and Avaxim are adsorbed to aluminium hydroxide (alum) as an adjuvant.[13,15,24] Epaxal uses a liposome adjuvant, immunopotentiating, reconstituted influenza virosomes (IRIV), composed of phosphatidylcholine, phosphatidylethanolamine and haemagglutinin from an H1N1 strain of influenza virus.[20,21] It is hypothesized that IRIVs may stimulate both hormonal and cellular immunity by binding to macrophages and other cells primed by influenza virus.[20]

### *Manufacture*

All inactivated hepatitis A vaccines are produced in similar ways. Most vaccines are grown in MRC-5 cell culture and harvested by cell lysis. The HAV in Havrix is concentrated and purified by sterile filtration, ultrafiltration and column chromatography. The antigen is then inactivated by 250 µg formaldehyde per mL for 15 days at 37 °C. The purified/inactivated virus is adsorbed on aluminium hydroxide, and each millilitre contains approximately 0.5 mg of aluminium as aluminium hydroxide.[13]

Vaqta is grown in MRC-5 cells, extracted by organic solvents, concentrated by precipitation in polyethylene glycol, and purified by chromatography. Following inactivation by 100 µg formaldehyde per mL for 20 days at 37 °C, the antigen is adsorbed on aluminium hydroxide, in a concentration of approximately 0.45 mg/mL of aluminium as aluminium hydroxide.[12]

Formalin inactivation conditions have been set empirically by determining the killing kinetics, extrapolating the curve to the zero intercept where 100% inactivation is theoretically achieved, and exceeding that time by a factor of three.[13,24] Because HAV grows slowly in cell culture without cytopathic effect, completeness of inactivation is difficult to prove. Inactivation of these vaccines has been demonstrated by serial blind passages designed to amplify a low level of residual live virus to the point that it would be immunologically detectable.[11]

### *Preparations and dosage (Table 9.1)*

Inactivated hepatitis A vaccines, with the exception of Epaxal, are available in paediatric and adult formulations. Epaxal is prepared in a single formulation. A combination inactivated hepatitis A and recombinant hepatitis B vaccine (Twinrix; Glaxo SmithKline) is available in the United States for persons ≥18 years old; a paediatric formulation is available in Europe, Canada and other parts of the world.

Havrix and Vaqta are licensed in the United States in two formulations, paediatric for persons aged 2–18 years, and adult for persons older than 18 years. Both formulations are given as a two-dose series.[25,26] In other countries, the paediatric formulations are licensed for children as young as 1 year old.[27] The paediatric dosage of Havrix is 720 ELU (0.5 mL) and the adult dosage is 1440 ELU (1.0 mL). Both vaccines are administered in two intramuscular injections, with the second dose given 6–12 months after the first. The paediatric formulation of Vaqta contains 25 U (0.5 mL), and the adult formulation contains 50 U (1.0 mL), with the second dose of each formulation given 6–18 months after the first.

The paediatric formulation of Avaxim consists of 80 'antigen units' and the adult of 160 'antigen units', each in 0.5 mL for intramuscular administration in a two-dose series. The package insert indicates that the paediatric formulation is recommended for children aged 1–15 years old, with the second dose being given 6 months after the first, and the adult formulation for

**Table 9.1** Recommended doses and schedules of inactivated hepatitis A vaccines

| Age (years)* | Vaccine | Dose | Volume (mL) | Number of doses | Schedule (months)† |
|---|---|---|---|---|---|
| 2–18 | Havrix® | 720 ELU | 0.5 | 2 | 0, 6–12 |
| | Vaqta® | 25 U | 0.5 | 2 | 0, 6–18 |
| ≥19 | Havrix® | 1440 ELU | 1.0 | 2 | 0, 6–12 |
| | Vaqta® | 50 U | 1.0 | 2 | 0, 6–12 |
| >15 | Avaxim®‡ | 160 antigen units | 0.5 | 2 | 0, 6–12 |
| 1–15 | Avaxim®‡ | 80 antigen units | 0.5 | 2 | 0, 6 |
| ≥2 | Epaxal®‡ | 24 IU | 0.5 | 2 | 0, 6–12 |
| 1–15 | Twinrix®‡ | 360 ELU | 0.5 | 3 | 0, 1, 6 |
| ≥18 | Twinrix® | 720 ELU | 1.0 | 3 | 0, 1, 6 |

ELU, enzyme-linked immunosorbent assay (ELISA) units; U, units; IU, international units.
*For vaccines licensed in the United States, US-licensed age groups for paediatric and adult formulations are indicated. Recommended age groups vary among other countries in which vaccines are licensed.
† 0 months represents timing of initial dose; subsequent numbers represent months after the initial dose.
‡Not licensed in the United States. Age group for which paediatric and adult formulations licensed varies among countries.

persons older than 15 years, with the second dose being give 6–12 months following the first.[28] However, recommended schedules may be different in various countries.[29]

The dose of Epaxal for adults and children >1 year old is 500 radioimmunoassy (RIA) units of hepatitis A antigen, associated with 10 µg of influenza haemagglutinin and 300 µg of phospholipids.[30] The recommended schedule is two doses at 0 and 6–18 months.

The adult formulation of the combination vaccine, Twinrix, includes 720 ELU of the hepatitis A component and 20 µg of the hepatitis B component in 1.0 mL, 0.45 mg of aluminium in the form of aluminium phosphate and aluminium hydroxide as adjuvants and 5.0 mg of 2-phenoxyethanol as a preservative.[31] The paediatric formulation consists of 360 ELU of the hepatitis A component and 10 µg of the hepatitis B component in 0.5 mL. Both are administered as a three-dose series, with the second and third doses given 1 and 6 months after the first. The vaccine's performance appears to be equivalent to that of each of the single antigen vaccines administered separately.[32–34]

Results of a number of studies indicate that the response of adults vaccinated according to a schedule that mixed the available alum-adjuvanted inactivated vaccines was equivalent to that of adults vaccinated according to the licensed schedules.[35–37] Mixed schedules that include the virosome vaccine have not been studied. Based on results of several studies, the response to a second dose delayed for 24–77 months appears to be equivalent to that after the licensed schedules.[38–41] Schedules with shorter intervals between doses have not been studied using the currently licensed single antigen formulations. Among persons vaccinated according to a three-dose schedule, all study subjects seroconverted, but the peak antibody concentrations were lower among persons vaccinated at months 0, 1 and 2 compared with persons who were vaccinated according to a schedule with a longer time interval between the second and third dose.[42,43] The response of persons vaccinated with the combined hepatitis A/hepatitis B vaccine on a four-dose schedule with doses at 7 and 21 days and 12 months after the first was equivalent to that of persons vaccinated with single antigen hepatitis A vaccine on a two-dose schedule, with the second dose given 12 months after the first.[44]

### *Vaccine stability*

The vaccines should be stored at 2–8 °C. Havrix and Vaqta have been shown to retain potency when kept for at least 2 years under those conditions.[25,26] The reactogenicity and immunogenicity of Havrix after storage at 98.6 °F (37 °C) for 1 week, and the stability profile of Vaqta when stored at this temperature for >12 months did not differ from those of vaccines stored at the recommended temperature.[6,45] Freezing destroys the vaccine, causing aggregation of the alum particles.

### *Immunogenicity*

In extensive studies in children and adults, the inactivated hepatitis A vaccines have been found to be highly immunogenic. The concentration of antibody after vaccination varies with the dose and schedule of the vaccine. However, after a single dose, antibody concentrations are higher than those produced by doses of immune globulin known to be protective. In general, by 4 weeks after one dose of vaccine, 95–100% of children 2 years of age or older and adults respond with concentrations of antibody considered to be protective.[46–58] A second dose 6–18 months later results in a boost in antibody concentration, but the final concentration is

generally lower than those measured after natural infection.[14,46,47,49,50,52,53,55,59–61] This boost in antibody concentration following the second dose is probably important for long-term protection.[14,47,53,55,59,60,62,63] IgM antibody to HAV (anti-HAV) can occasionally be detected by standard assays, primarily if measured soon (i.e. 2–3 weeks) after vaccination.[61,64,65]

Some studies have indicated that, in many subjects, concentrations of antibody above the defined protective level can be measured as early as 2 weeks after one dose.[56,57,62] When neutralizing antibody appears after vaccination is not clear from published reports, owing to differences among assays, dosages of vaccine, and when antibody measurements were obtained. In one study, depending on the assay, 42–100% of children vaccinated with the currently licensed formulation had neutralizing antibody when measured 1 month after a single vaccine dose.[65] In another study, approximately two-thirds of adults vaccinated with a lower dosage than the currently licensed formulation were positive for neutralizing antibody 4 weeks after one dose, and virtually all were positive 2 weeks after a second dose, given 1 month after the first.[67]

Studies in infants and children <2 years old suggest that the vaccine is safe and immunogenic, but the antibody response is blunted by the presence of passively transferred antibody from previous maternal HAV infection.[40,68–70] In studies of infants who received hepatitis A vaccine according to a number of different schedules, those with passively transferred maternal antibody at the time of vaccination responded, but final antibody concentrations were approximately one-third to one-tenth those of infants who did not have passively transferred antibody and were vaccinated according to the same schedule.[48,67,70,71] The clinical significance of these lower antibody concentrations is unclear. One study found that all infants vaccinated in the presence of passively transferred maternal antibody at ages 2, 4 and 6 months responded to a booster dose 6 months later with an anamnestic response, suggesting that they had been primed by the primary series.[72]

As the majority of infants born to anti-HAV-positive mothers have lost detectable antibody by 12–15 months of age, it is likely that any effect of passively transferred maternal antibody on the response to vaccination would be observed primarily when vaccination is begun in infancy.[73–76] This was illustrated by the results of one study in which two groups of infants – those whose mothers were anti-HAV-positive or anti-HAV-negative – were randomized to three different two-dose vaccination schedules, using a currently licensed paediatric formulation of vaccine and beginning the series at ages 6, 12 and 15 months of age. The majority of infants born to anti-HAV-positive mothers and randomized to receive the first dose of vaccine at 6 months of age had detectable antibody at the time of the first dose, and the final antibody concentration after completing the vaccine series was lower than that of the group of infants whose mothers were anti-HAV-negative and who were vaccinated according to the same schedule. In contrast, few infants born to anti-HAV-positive mothers had detectable antibody when administered the first dose of vaccine at either 12 or 15 months of age, and there was no difference in geometric mean concentrations (GMCs) after completing the vaccination series among these children compared to those whose mothers were anti-HAV-negative.[73]

Other conditions that may result in reduced immunogenicity include human immunodeficiency virus (HIV) infection, chronic liver disease and older age. In published reports of hepatitis A vaccination of men with HIV infection, approximately 50–75% had protective antibody concentrations after completing the vaccination series, and final antibody concentrations were considerably lower than those among HIV-negative persons.[77–79] Among HIV-infected men, higher CD+ T-lymphocyte count at baseline was associated with response to vaccination.[77,78] In one study, only one of nine participants with CD4 cell counts <200 at baseline responded to vaccination compared with eight of eleven participants whose baseline CD4 cell counts were ≥500.[78] However, even among participants with CD4 cell counts ≥500, the antibody concentration after completing the two-dose vaccination series was considerably lower than generally reported from studies of persons who do not have HIV infection. Among adults and children with chronic liver disease, seroprotection rates were similar to those observed among healthy adults, but the final antibody concentrations were substantially lower.[80–82] Limited data suggest that the final antibody concentrations achieved among persons >40 years may be somewhat lower than among younger individuals, but response rates were similar.[43,55,83,84] Other factors, such as smoking and obesity, have not been evaluated for the currently licensed formulations.

### *Correlates of protection*

Consideration of how anti-HAV is measured can be useful when interpreting the results of studies of the immunogenicity of hepatitis A vaccines. Anti-HAV concentrations are expressed in milli-International Units per millilitre (mIU/mL), measured in comparison to a World Health Organization (WHO) reference immunoglobulin reagent.[85] The concentrations of antibody achieved after passive transfer by immune globulin or active induction by vaccination are 10–100-fold lower

than those produced in response to natural infection, but the absolute lower limit of antibody needed to prevent HAV infection has not been determined. In one study, the geometric mean antibody concentration of vaccinated children who were protected against hepatitis A was 42 mIU/mL, similar to peak anti-HAV concentrations following receipt of immune globulin.[62,66,86] Concentrations of 10–20 mIU/mL, achieved about 1–2 months after administration of immune globulin, also are known to protect against hepatitis A. Results of *in vitro* studies using cell culture-derived HAV indicate that even antibody concentrations <20 mIU/mL can be neutralizing.[87]

Because no absolute protective antibody level has been defined, in immunogenicity studies generally the lower limit of detection of the particular assay being used has been considered to be the protective level. However, the WHO reference reagent contains in large part high affinity late convalescent antibody, while antibody that develops soon after vaccination appears to have a lower affinity for HAV.[66,85] Thus, caution should be exercised in comparing results of clinical studies of hepatitis A vaccines, as differences in quantitative antibody concentrations may be the result of the configuration of the particular assay being used, even if the WHO 'standard' was used to develop the assay. Clinical studies of Havrix have used levels >20 mIU/mL or 33 mIU/mL, as measured using enzyme immunoassays. Studies of Vaqta have used levels >10 mIU/mL as measured with a modified radioimmunoassay (HAVAB; Abbott Laboratories, N. Chicago, IL).[47,60,72]

Although the minimum level of antibody needed to protect against HAV infection is unknown, serological correlates of protection have been demonstrated using specialized assays, including a radioimmunofocus inhibition test (RIFIT) and an antigen reduction assay (HAVARNA), that measure neutralizing antibody, and a radioimmunoprecipitation assay (RIPA) that measures the capacity of antibody to immunoprecipitate metabolically labelled HAV particles.[66,87,88–90] In one such study, among children participating in two vaccine trials who were tested 4 weeks after receiving one dose of hepatitis A vaccine, the geometric mean titres (GMTs) of anti-HAV measured by HAVAB were 49.3 and 45.2 mIU/mL, but the reciprocal GMTs of neutralizing anti-HAV were 6.5 and 15.0 by RIFIT and 55.6 and 92.0 by HAVARNA, and the GMT of anti-HAV detected by RIPA was ≥401.[66]

Differences between the types of antibody induced by vaccine and those detected in people who received immune globulin (which should be similar to antibody induced by infection) can be identified when results using these specialized assays are compared.[66,67] In one study, when measured 4 weeks after administration, with equivalent titres measured by radioimmunoassay, adult immune globulin recipients had higher neutralization titres, as measured by RIFIT and HAVARNA, but negligible RIPA titres, compared with a group of children who received one dose of vaccine.[66] In another study, the neutralizing GMTs of persons who received immune globulin with hepatitis A vaccine were five times higher than those who received hepatitis A vaccine alone, when measured 4 weeks after administration, using the RIFIT assay.[67] These results provide further evidence that the antibodies produced by active immunization have lower affinity for HAV than those present after passive immunization.[66] However, it is clear that active immunization provides a high level of protection against hepatitis A (see the section on Efficacy below).

In contrast to the humoral immune response to hepatitis A immunization, which has been fairly well characterized, data are limited regarding cellular immune responses following immunization. That re-exposure to the antigen with a booster vaccine dose results in what has been considered to be an anamnestic response suggests that vaccine recipients have immune memory.[72,91,92] However, only a few studies have directly measured cellular immune response. In one study, seven of ten vaccinated adults had evidence of HAV-specific T-cell proliferation by the 10th week after vaccination, and such proliferation could be detected in all vaccine recipients by week 30.[93] Immunization also induced interferon-gamma (IFN-γ) in the three subjects studied. Among 36 vaccine recipients studied 72 months after completing the vaccine series, 19 had *in vitro* lymphoproliferative responses to HAV, and 24 had measurable IFN-γ.[94]

### *Safety*

Experience to date indicates that hepatitis A vaccine has a safety profile equivalent to that of other widely recommended vaccines. After vaccination, local injection site reactions (pain, tenderness or erythema) that are mild and transient have been reported in as many as 21% of children and 56% of adults. Systemic reactions that include fatigue, fever, diarrhoea and vomiting occur in <5% of vaccinees. Headache has been associated with vaccination in up to 16% of adults and 2–9% of children.[15,25,26,28,30,31,51,62,95–97]

Rare adverse events reported post-marketing include syncope, jaundice, erythema multiforme, anaphylaxis, brachial plexus neuropathy, transverse myelitis, encephalopathy and others.[25,26,98] No serious adverse events among children or adults have been identified that could be definitively ascribed to hepatitis A vaccine.[96,99] For events for which incidence rates are available, such as Guillan-Barré syndrome, reported rates were not higher than reported background rates.[6] Based

on limited data, vaccination of immunosuppressed persons does not appear to be associated with a greater risk of adverse events compared to persons with normal immune systems.[77,100]

### *Contraindications and precautions*

The inactivated hepatitis A vaccines should not be used in persons with a history of a severe reaction to a prior dose of hepatitis A vaccine or allergy or hypersensitivity to the vaccine or any of its components. The safety of the inactivated hepatitis A vaccines in pregnancy has not been determined. Because the vaccine is produced from inactivated HAV, the theoretical risk to the fetus is likely to be low.

### *Concomitant use with other vaccines*

Several studies that evaluated administration of inactivated hepatitis A vaccine concomitantly with immune globulin have shown that although the proportion of persons who responded to vaccination was not reduced by co-administration of immune globulin, the antibody concentrations elicited were lower than after receiving vaccine alone.[101–104] However, because the concentrations induced by vaccination far exceed that needed for protection, these reductions are not considered clinically significant. The use of hepatitis A vaccine with other vaccines that might be used for travellers has been studied among adults. There was no effect on either the immunogenicity or reactogenicity of hepatitis A vaccine administered concurrently with diphtheria, polio (oral and inactivated), tetanus, hepatitis B, yellow fever, typhoid (oral and intramuscular), cholera, Japanese encephalitis or rabies vaccines.[105–109] In one study among infants, simultaneous administration of hepatitis A vaccine did not affect the immunogenicity or reactogenicity of diphtheria-tetanus-acellular pertussis (DtaP), inactivated polio and *Haemophilus influenzae* type b (Hib) vaccines.[72]

### *Duration of immunity*

Antibody has been shown to persist in persons vaccinated as adults or children for at least 5–10 years after completion of the vaccination series.[92,110–115] Among children vaccinated during infancy, approximately two-thirds had detectable anti-HAV 4–6 years later.[91,116] It is estimated from mathematical models using data from adults that protective levels of antibody following completion of the vaccination series could persist for 20 years or longer.[110,112–114] Whether other mechanisms (e.g. cellular memory) also contribute to long-term protection is unknown. Because the incubation period for hepatitis A is relatively long and the anamnestic responses observed after the second vaccine dose are rapid and robust, it has been suggested that vaccinees who have seroconverted will be protected even if their antibody levels have fallen below protective levels.[63] However, few such vaccinated cohorts are available to date. In two studies of persons completing the vaccination series 2–6 years after receiving the primary dose, all of those who did not have detectable antibody at the time of the booster responded with a high antibody concentration.[39,117] In one follow-up study of infants who did not have passively transferred maternal antibody at the time of the primary series, all of those who had lost detectable antibody at the time of follow-up had an anamnestic response to a booster dose.[91] However, a small proportion of those who were vaccinated initially in the presence of passively transferred antibody and had lost detectable antibody at the time of follow-up did not have an anamnestic response to the booster dose.[91,116] In 9 years of follow-up, no hepatitis A cases have been reported among children vaccinated as part of a clinical efficacy study in one US community.[118] Additional long-term follow-up studies are needed to evaluate the long-term protective efficacy of hepatitis A vaccine and determine the need for booster doses.

### *Efficacy*

The high efficacy of inactivated hepatitis A vaccines in preventing clinically apparent disease was demonstrated in two double-blind, randomized field trials. In one study, 1037 healthy seronegative children 2–16 years of age in a community with high hepatitis A rates and periodic outbreaks, received either a single dose of 25 U of the inactivated vaccine derived from strain CR326F, or placebo. The mean follow-up period was 103 days. Beginning 50 days after injection, no cases of hepatitis A occurred in the vaccinated group compared with 25 cases in the placebo group, yielding an estimated 100% clinical efficacy, with a lower bound of the 95% confidence interval (CI) of 87%.[39] In the vaccinated group, no cases of hepatitis A occurred with onset ≥17 days after vaccination.[118]

In a large field trial of approximately 40 000 Thai children aged 1–16 years, the vast majority of whom were 3–14 years old, participants were randomized to receive either inactivated hepatitis A vaccine (HM175 strain) or a recombinant hepatitis B vaccine. Measurement began after the second of two doses (360 ELU per dose) administered 1 month apart was given and continued for approximately 1 year. A total of 40 hepatitis A cases was detected, 38 among the controls and two among the hepatitis A vaccine recipients, yielding a clinical efficacy of 94% (95% confidence interval, 79–99%).[97] The two cases among vaccine recipients occurred 257 and 267 days after receipt of the first dose of vaccine, and were relatively mild, with a mean peak

alanine aminotransferase level of 58 U/L and lasting a total of 2–4 days.

The efficacy of the inactivated hepatitis A vaccine formulated with a virosome adjuvant was evaluated in a randomized trial among 274 children aged 1.5–6 years in Nicaragua. Study participants received either a single dose (0.5 mL) of vaccine or a placebo consisting of a virosome suspension, and were followed beginning 1 week after vaccination and continuing for 18 months.[119] Using IgM anti-HAV positivity as the end-point, the efficacy of hepatitis A vaccine among susceptible children was 84.6% (95% CI, 54.7–96.1%). All infections among children in the vaccinated group occurred in the first 6 weeks after vaccination.

### *Efficacy after exposure to HAV*

Several lines of evidence suggest that hepatitis A vaccine may have some efficacy when administered after exposure to HAV, and public health agencies in Canada and several countries in Europe recommend hepatitis A vaccine in this setting.[29,120,121] Hepatitis A vaccine administered soon after exposure prevented infection in a chimpanzee model.[122] Only one small randomized trial in humans has been completed. Among persons aged 1–40 years who were household contacts of hospitalized hepatitis A cases, hepatitis A vaccine was found to be 79% efficacious compared with no treatment in preventing infection when given within 8 days of symptom onset of the index case.[123] However, the CI was wide (7–95%), and the study did not include a comparison group that received passive post-exposure prophylaxis with immune globulin.[124] Because of the demonstrated high efficacy of immune globulin when administered after exposure to HAV (see section on Passive immunization below) and in the absence of more definitive data comparing the efficacy of vaccine to that of immune globulin, immune globulin continues to be recommended by most US advisory groups for post-exposure prophylaxis.[6,125]

### *Effectiveness in populations*

When reviewing evidence of the impact of hepatitis A vaccination in populations, the epidemiology of hepatitis A in the particular population in which it is being used provides an essential context. Transmission patterns are influenced by many factors, including the age-specific prevalence of immunity, prevailing hygienic conditions, and how pervasive HAV is in the environment. It is also important to take into account whether the outcome of interest is control of a community-wide outbreak or a longer-term, sustained reduction in the occurrence of hepatitis A in the population.

#### *Populations with high hepatitis A rates*

A number of studies and demonstration projects have evaluated the effectiveness of hepatitis A vaccine in controlling and preventing hepatitis A in populations with high hepatitis A rates. Populations studied tend to be relatively small, homogeneous, usually rural communities. Examples include indigenous communities in North America and Australia and selected communities in central and eastern Europe and Israel.[7,118,126–132] Hepatitis A epidemics typically occur every 5–10 years in these communities. Few cases occur among persons >15 years old. Seroprevalence data indicate that 30–40% of children acquire infection by 5 years of age, and almost all persons have been infected by young adulthood.[118,127,129,131,133,134] Demonstration projects conducted soon after hepatitis A vaccines became available showed that vaccination of children living in these communities was feasible, and that vaccination of the majority of children, and in some cases adolescents and young adults, resulted in a rapid decline in disease incidence.[126,128,135] For example, a 1992–1993 community-wide epidemic among Alaska Natives in one rural area was ended within 4–8 weeks of vaccinating approximately 80% of children and young adults.[128]

The most extensive information about the impact of ongoing hepatitis A vaccination on hepatitis A rates in these populations over time comes from the United States. In the US vaccine efficacy study site, vaccination of successive cohorts of 2-year-old children has continued since completion of the study in 1991, and in 1998 it was estimated that 76% of 2–16-year-old children were immune. The periodic community-wide epidemics that occurred before vaccination was undertaken have disappeared, while such outbreaks continue to occur in similar neighbouring communities.[118]

In US American Indian and Alaska Native communities, following publication in 1996 of recommendations for routine vaccination of children living in areas with high hepatitis A rates, surveys indicated vaccination coverage of 50–80% among preschool and school-aged American Indian and Alaska Native children, suggesting that recommendations were being implemented.[136,137] National surveillance data demonstrate a dramatic decrease in hepatitis A incidence (Fig. 9.1).[136] By 2000, hepatitis A incidence among American Indians and Alaska Natives had declined by 97% compared with the beginning of the decade, and was lower than the overall US rate.[136] A decline of this magnitude has not been observed in the previous 30 years of surveillance, and suggests a fundamental alteration in hepatitis A epidemiology in American Indian and Alaska Native communities.

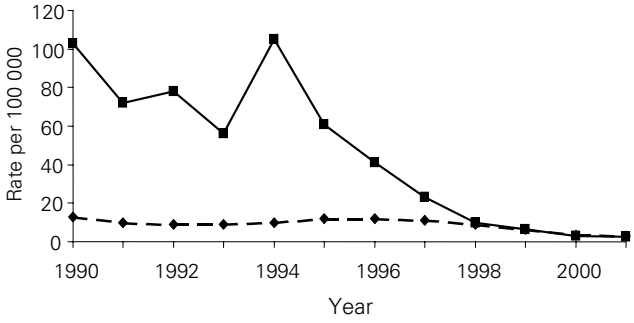

**Figure 9.1** Hepatitis A incidence, United States and Native Americans, 1990–2001. The solid line represents the rate among Native Americans and the dashed line represents the overall US rate (data from Bialek *et al*.[136]).

*Populations with consistently elevated rates*

In some countries, primarily in the developed world, large, heterogeneous communities with hepatitis A rates that are consistently elevated with respect to a national average can be identified. Examples include the Puglia region of Italy, Catalonia in Spain, and the western and south-western areas of the United States.[138–143] Periodic community-wide epidemics can be identified in these communities, but the inter-epidemic period is variable and the majority of the population remains susceptible to HAV infection into at least middle age.[138,139,141] There has been considerable interest in using hepatitis A vaccine to interrupt ongoing community-wide epidemics by vaccinating children in these populations, but the strategy has proven difficult to implement.[140] First-dose coverage has generally been low (20–45%) and the impact of vaccination often has been limited to vaccinated age groups, which may not represent the majority of cases. Because of logistical difficulties, accelerated vaccination to control outbreaks should be undertaken with caution, and this practice is not recommended by many public health authorities.[6,144,145] Efforts are probably better directed towards sustained routine vaccination of children to maintain high levels of immunity and prevent future epidemics.

Results of the longest demonstration project of ongoing, routine vaccination of children, conducted during 1995–2000 in Butte County, California, a community with consistently elevated rates, suggest that this strategy can markedly reduce hepatitis A incidence over time.[138] During the 5 years before the demonstration project, Butte County's average annual hepatitis A incidence rate was 47.9/100 000, and ranged from 122.5 to 11.8/100 000. From 1995 to 2000, children ≥2 years were offered hepatitis A vaccine without charge, and 66% of the almost 45 000 eligible children received at least one dose. The number of reported cases declined 94%, and the four cases reported in 2000 was the lowest number ever reported in the county since hepatitis surveillance began in 1966. Butte County's 2000 incidence rate of 1.9/100 000 was the lowest of any California county (Fig. 9.2).[138]

Several countries, including Italy, Spain and the United States, have implemented routine vaccination of children living in selected parts of the country, and since 1999 successive cohorts of 18-month-old children in Israel have been vaccinated.[6,7,29,141,146] Experience to date using hepatitis A vaccine to vaccinate children routinely suggests that considerable reductions in morbidity can be achieved with fairly modest vaccination coverage, a reflection, at least in part, of a strong herd immunity effect.[7,9,138]

In the Catalonia region of Spain, in September 1998 hepatitis A vaccine was added to an ongoing programme to vaccinate 11–12-year-old children with hepatitis B vaccine, by changing to the combination hepatitis A/hepatitis B vaccine. With an estimated vaccination coverage of 94% in the vaccinated cohorts, the overall average

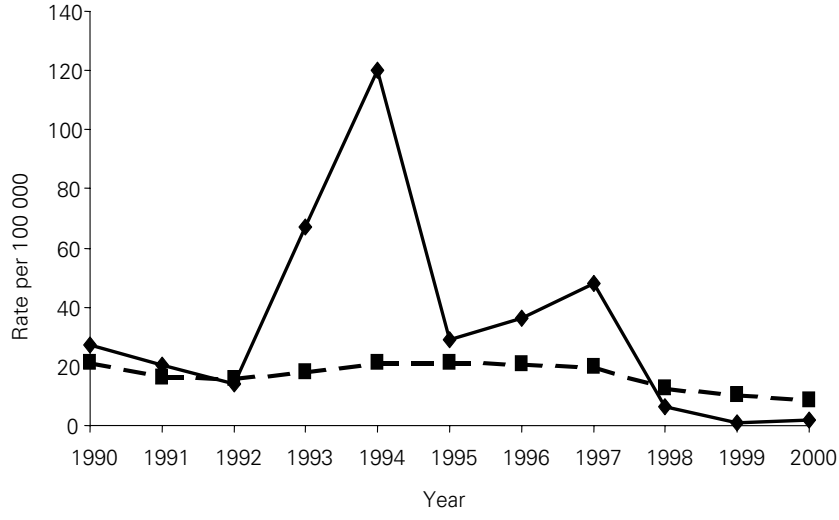

**Figure 9.2** Hepatitis A incidence, Butte County, California, and all of California, 1990–2000. The solid line represents the rate in Butte County, and the dashed line represents the overall rate in the state of California (data from Averhoff *et al*.[137]).

hepatitis A rate in the region declined from 6.2/100 000 during the 3 years before implementation of the vaccination programme to 2.6/100 000 during the subsequent 3 years. The greatest decline occurred in the vaccinated age group, children aged 10–14 years, in which the average rate fell from 10.3/100 000 to 1.8/100 000.[8]

In the United States, vaccination of children living in the western and south-western parts of the country has been recommended since 1999 (Table 9.2).[6] These areas include approximately one-third of the US population, but historically accounted for approximately one-half of hepatitis A cases nationwide.[6] Fairly low vaccination coverage of children in these areas appears to have resulted in appreciable declines in hepatitis A rates (Fig. 9.3).[147] Compared with the average 1987–1997 rate of 22.4/100 000, the 2001 rate in these states declined by approximately 80% to 4.6/100 000, compared with a 39% decrease from 5.6 to 3.6/100 000 elsewhere.[9,147] Rates declined most dramatically among children 2–18 years old. These precipitous declines are reflected in overall national hepatitis A rates. The 2001 overall rate of 3.7/100 000 is a historic low. Because hepatitis A incidence is cyclic in the United States, the precise contribution of vaccination of children to the observed decline in rates is difficult to quantify. However, modelling studies suggest that between 1995 and 2001, an estimated 97 800 hepatitis A cases were averted because of immunization, including 39% of potential cases in 2001.[9]

### *Recommended uses*

Recommendations for the use of hepatitis A vaccine vary considerably among countries. The World Health Organization position on hepatitis A vaccines provides general guidance, including an indication that consideration of the cost-benefit and sustainability of various prevention strategies in the context of the relevant hepatitis A epidemiology is important.[27] In general, hepatitis A vaccination currently has little relevance in countries in the developing world in which hepatitis A is highly endemic and the vast majority of the population develops HAV infection in early childhood.[1] In more developed, industrialized countries, hepatitis A vaccine is being used most widely to protect individuals at increased risk of hepatitis A or its consequences, such as travellers to areas where hepatitis A is endemic.[6,29,119,148,149] However, in some of these countries, such as the United States and Italy, the epidemiology of hepatitis A is quite heterogeneous, and in certain parts of the country large community-wide epidemics occur.[139,150] Areas with consistently elevated rates with respect to the national average can be identified and these areas have been the focus of routine hepatitis A vaccination programmes for children (Table 9.2).[6,141]

#### *Vaccination of children*

Recommendations for routine vaccination of selected populations of children have been made in Israel, Italy and selected other European countries, the United States, and a number of other countries.[6,7,29,125,141,146] In the Puglia region of Italy, a programme to vaccinate 15–18-month-old children with hepatitis A vaccine when they receive MMR vaccine and 12-year-old children when they receive hepatitis B vaccine (using the combination hepatitis A/hepatitis B vaccine) was implemented in 1997.[141] In Israel, all 18-month-old children have been

**Table 9.2** US recommendations for routine pre-exposure use of hepatitis A vaccine*

| Group | Comments |
|---|---|
| Children living in communities with consistently elevated hepatitis A rates | Includes Alaska, Arizona, California, Idaho, Nevada, New Mexico, Oklahoma, Oregon, South Dakota, Utah, Washington and selected areas in other states†‡ |
| International travellers§ | Immune globulin may be given in addition to or instead of vaccine; children <2 years old should receive immune globulin |
| Men who have sex with men | Includes adolescents |
| Illicit drug users | Includes adolescents |
| Persons with chronic liver disease | Increased risk of fulminant hepatitis A with HAV infection |
| Persons receiving clotting factor concentrates | |
| Persons who work with HAV in research laboratory settings | |

*Hepatitis A vaccine is not licensed in the United States for children <2 years old.
†Where the average reported hepatitis A incidence during 1987–1997 was ≥20/100 000 population (approximately twice the national average).
‡Routine vaccination can also be considered for children living in Arkansas, Colorado, Missouri, Montana, Texas, Wyoming and selected areas in other states where the average reported incidence during 1987–1997 was ≥10/100 000 population but <20/100 000.
§Persons travelling to Canada, Western Europe, Japan, Australia or New Zealand are at no greater risk than in the United States.
From US Centers for Disease Control and Prevention.[6]

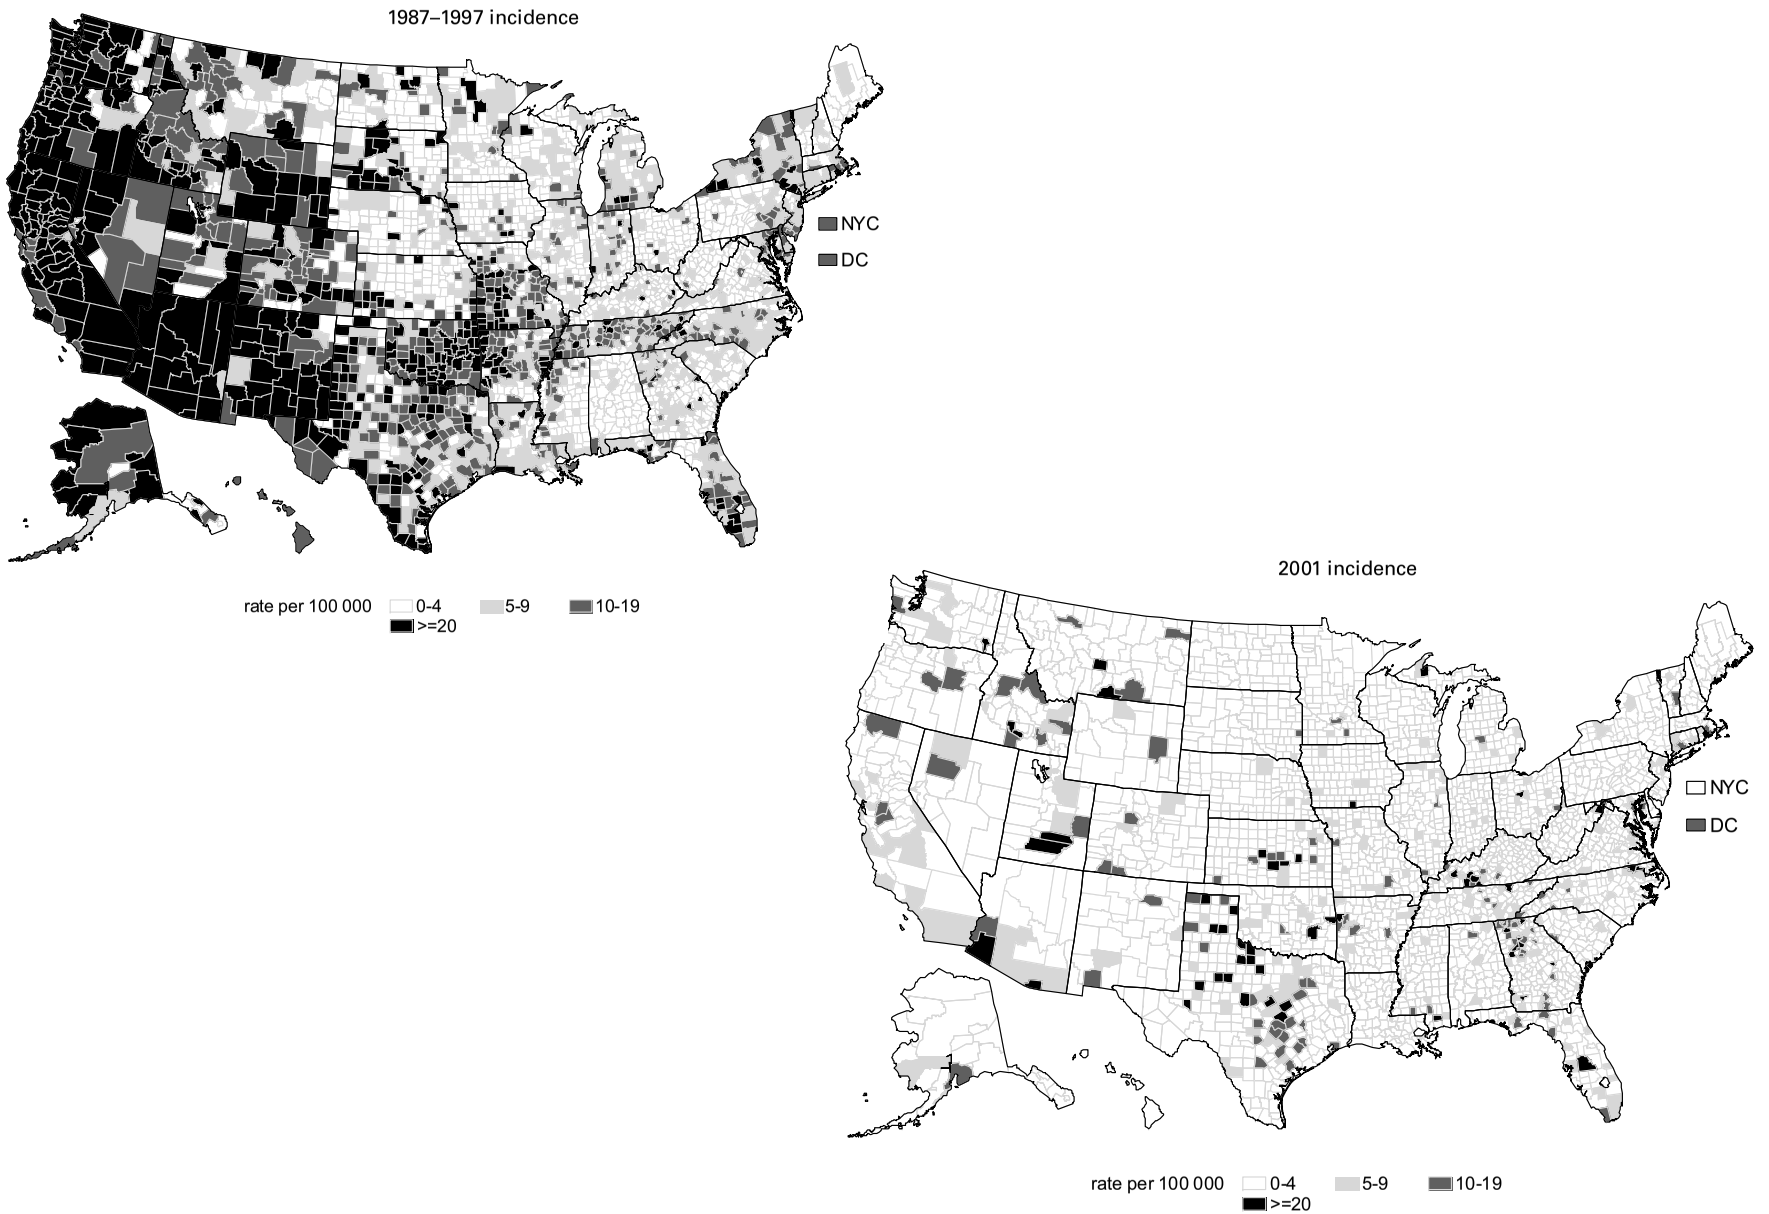

**Figure 9.3** Hepatitis A incidence rates, by county, United States, 1987–1997 (top) and 2001 (bottom) (data from US Centers for Disease Control and Prevention[147]).

vaccinated each year since 1999.[7] In the United States, in 1999 the Advisory Committee on Immunization Practices (ACIP) of the US Public Health Service, the American Academy of Pediatrics (AAP) and other groups recommended routine vaccination of children living in areas where rates of hepatitis A have been consistently elevated, beginning at or after 2 years of age (Table 9.2). These areas include 17 states, located primarily in the western and south-western United States, and comprise approximately one-third of the US population, but historically accounted for approximately one-half of hepatitis A cases nationwide.[6]

*Persons at increased risk of hepatitis A or severe consequences*

Persons from the developed world who travel to countries where hepatitis A is of high, transitional or intermediate endemicity should receive hepatitis A vaccine (Table 9.2).[6,27,63,148] Immune globulin can be used if hepatitis A vaccine is contraindicated or refused. A considerable proportion of these travellers are children, who may acquire hepatitis A while visiting family in the developing world, and transmit it to others when they return.[151–153] Other groups at increased risk of infection for whom hepatitis A vaccination is recommended in the United States and in some other countries include adolescent and adult men who have sex with men and persons who use illegal drugs, because of recurrent hepatitis A outbreaks among persons who report these behaviours; members of the military, persons who work with HAV in research settings; and persons who have clotting factor disorders.[6,29,148,154–156] Vaccination is also recommended for persons with chronic liver disease because of the high case-fatality rate among these persons if they acquire hepatitis A.[6,157–159]

*Other groups and settings*

Although hepatitis A outbreaks occur in child-care centres, in most countries their frequency is not high enough to warrant routine vaccination of attendees or staff to prevent them, and there is little experience of using vaccine to control outbreaks when they occur.[160–162] When outbreaks are recognized, aggressive use of immune globulin is effective in limiting transmission.[163] In areas where routine vaccination of children is recommended, previously unvaccinated children can be vaccinated when they receive post-exposure prophylaxis with immune globulin.[6] In addition, child-care centre attendees can be a readily accessible target population for ongoing routine vaccination programmes.

The frequency of outbreaks in hospitals, institutions and schools is not high enough to warrant routine vaccination of persons in these settings, and there are no data with respect to using vaccine to control outbreaks in these settings. Persons who work as food handlers are not at increased risk of hepatitis A because of their occupation, and vaccination of food handlers has not been shown to be cost-effective.[4,164]

Prevaccination serological testing can be considered to reduce costs by not vaccinating persons with prior immunity. In the developed world, this might include older adolescents and adults born in areas of high hepatitis A endemicity. However, the cost of testing, vaccine cost and the likelihood that the person will return for vaccination should be taken into account.[165,166] In the developed world, prevaccination testing of children is generally not cost-effective. Vaccination of immune people is not harmful. Post-vaccination testing is not indicated because of the high rate of vaccine response. Furthermore, testing methods that can detect the low anti-HAV concentrations generated by immunization are not widely available.

## Alternative approaches to vaccine development

### *Attenuated vaccines*

In theory, attenuated vaccines might have advantages over inactivated vaccines, including potential oral administration, lower cost, fewer doses and possibly a longer duration of immunity. A number of candidate vaccines, including variants of the CR326 and HM175 strains of HAV, have been tested in primates and humans and shown to be safe when given orally or parenterally.[167,168] An attenuated H2 strain vaccine was developed and has been used fairly widely in China, particularly among children.[169–171]

Using the HM175 strain, a full-length infectious cDNA was assembled and a full-length RNA was transcribed from the cDNA that on transfection into permissive cells resulted in complete HAV replication.[172] Many of the mutations responsible for cell culture adaptation and attenuation have now been identified, and appear to accumulate especially in the 5′ non-translated and P2 regions of the genome.[173,174] However, to date, a virus with the ideal characteristics of *in vitro* growth combined with attenuation and immunogenicity in humans has not been produced.[175–177] Unfortunately, the vaccines studied do not induce a satisfactory immune response when given orally, and thus must be given by parenteral injection.[168,178] These vaccine candidates also appear to replicate poorly in humans or chimpanzees, although studies have demonstrated limited faecal shedding of virus following inoculation.[167,179–181] Antibody responses to attenuated vaccines generally have been found to be above those considered pro-

tective, but considerably lower than those measured in recipients of a complete course of inactivated vaccine.[168,169] Whether T-cell responses are also induced is unknown. The efficacy of the CR326/F′ and HM1275 vaccine candidates has not been evaluated in humans. Based on very limited data, the H2 vaccine appears to be immunogenic and to provide clinical protection for Chinese children.[6,171,182]

Two concerns with respect to adverse events related to attenuated vaccines warrant mention. Mild hepatitis has been demonstrated in a small proportion of adults and children participating in clinical trials of the CR326/F′ and H2 strain vaccines, and the worry is that with more widespread use, more severe hepatitis could be observed.[168,169] A second concern, as with any attenuated vaccine, is the potential for the virus to revert to a virulent phenotype. The only available relevant data to date indicate that cell culture-adapted viruses have a stable attenuation phenotype when passed up to three times in primates.[181,183]

### *Recombinant vaccines*

The important neutralizing epitopes of HAV appear to be conformational.[184] For this reason, immunization with synthetic peptides or expressed capsid proteins has not induced an effective neutralizing antibody response.[185–187] Because of the conformational nature of neutralization epitopes, the approach has been taken of expressing the entire open reading frame of the HAV genome in recombinant vaccinia virus or baculovirus expression systems.[187–189] Complete or partial capsid assembly seems to occur in cells infected with the recombinant vaccinia, and antibodies raised to these purified HAV synthetic capsids are neutralizing *in vitro* and protective in animals. Although the immunizing effect of such a vaccine might not be greater than that of inactivated vaccines, theoretically production costs might be lower. However, these types of vaccines have undergone little further development since the early 1990s.

## Passive immunization

Until the licensure of hepatitis A vaccines, immune globulin was the mainstay of prevention of hepatitis A for people who either were likely to be exposed or had recently been exposed to HAV. Over several decades, this product has proven useful for prevention of hepatitis A in travellers, Peace Corps volunteers, military personnel, individuals recently in close contact with a person with hepatitis A, and to control outbreaks in child-care centres.[190–193] For example, the rate of HAV infections among Peace Corps volunteers dropped from 1.6–2.1 cases per 100 per year to 0.1–0.3 cases per 100 per year after the institution of a mandatory programme of immune globulin every 4 months.[191]

### Efficacy

In general, when administered before exposure or within 2 weeks after exposure, immune globulin is >85% effective in preventing hepatitis A.[194–196] Its efficacy was first demonstrated during an outbreak in a summer camp in 1944, when 6% of immune globulin recipients developed hepatitis compared with 45% of persons who did not receive it, an 87% reduction in the attack rate.[196] Similar reductions in hepatitis attack rates were observed among adults in the military and children in institutional settings who received immune globulin. The lowest effective dose and duration of protection were defined in studies that compared various immune globulin doses conducted during the 1950s and 1960s at the Willowbrook State School and other settings where hepatitis was common.[194–198] Results of a number of studies showed that a dose of 0.05–0.06 mL/kg provides protection for 4–6 months. The efficacy of lower doses has not been studied as completely, but it is generally thought that a dose of 0.02 mL/kg protects for about 3 months.[192,194,199–201] Immune globulin has not been effective in controlling community-wide hepatitis A epidemics, largely because its use requires timely recognition of exposure and most infections that occur during these epidemics are not recognized.[143,202,203] Furthermore, the protection afforded by immune globulin is temporary.

Whether immune globulin completely prevents infection or results in asymptomatic infection and the development of persistent anti-HAV (passive-active immunity) probably is related to the amount of time that has elapsed between exposure and immune globulin administration, as well as the concentration of anti-HAV achieved by the immune globulin dose, and the size of the HAV innoculum.[196,204] Evidence of both phenomena has been reported. For example, the results of several studies suggest that the proportion of HAV infections that are anicteric is higher among persons who receive immune globulin.[191,200] However, other studies have shown a very low rate of HAV infection among recipients of immune globulin.[192,205]

### Antibody levels after receiving immune globulin

It is the circulating anti-HAV that results from administration of immune globulin that provides passive protection against hepatitis A. A WHO International Reference Reagent for HAV Immunoglobulin provides a way to standardize anti-HAV levels, and has been used to compare the anti-HAV concentrations of immune globulin lots as well as measure the immune response to passive

or active immunization.[85] One millilitre of this immune globulin preparation has been assigned a value of 100 IU, and the lower limit of detection of commercially available immunoassays, such as HAVAB, is approximately 100 mIU/mL.

Following immune globulin administration, anti-HAV is not detectable by commercially available assays.[206] Studies suggest that peak serum concentrations of anti-HAV following receipt of standard immune globulin doses (0.02–0.06 mL/kg body weight) are approximately 20–45 mIU/mL, when measured using modified immunoassays, such as the modified HAVAB.[62,66,181] In view of the length of protection afforded by a single dose of immune globulin, it is likely that the minimum protective antibody level is extremely low, possibly below a level that could be reliably detected by any assay.

## Manufacture and safety

Immune globulin is a sterile solution of antibodies prepared by a serial cold ethanol precipitation procedure from large pools of plasma, collected from tens of thousands of donors, that has tested negative for hepatitis B surface antigen (HBsAg), antibody to HIV, and antibody to hepatitis C virus (HCV).[207,208] This precipitation procedure has been shown to inactivate HBV and HIV.[207] Since 1995, immune globulin prepared in the United States has been required to be negative for HCV RNA by PCR amplification, or to be produced using a method that ensures additional virus inactivation.

Serious adverse events from immune globulin are rare. Because anaphylaxis has been reported after repeated administration to persons with immunoglobulin A deficiency, these persons should not receive immune globulin.[209] Pregnancy or lactation is not a contraindication to immune globulin administration. For infants and pregnant women, a preparation that does not include thimerosal is preferable.

Commercial lots of immune globulin contain variable concentrations of anti-HAV. In the United States, at least, there is no standard for anti-HAV levels in immune globulin preparations. Because the prevalence of antibody to HAV in the population has been declining, a concern has been raised that declining anti-HAV concentrations in immune globulin preparations might reduce its effectiveness. However, in the United States, no evidence of this has been identified to date.[210]

## Indications

Immune globulin is recommended for post-exposure prophylaxis in selected settings at a dose of 0.02 mL/kg, if it can be administered within 2 weeks of last exposure to HAV. If hepatitis A vaccine is also indicated, the series can be initiated simultaneously with the immune globulin dose. Household and sexual contacts of patients with hepatitis A should receive immune globulin as soon as possible, but no later than 2 weeks after exposure.[6] Casual contacts such as school classmates or co-workers who have not had close physical contact usually do not require immune globulin prophylaxis. Aggressive use of immune globulin is indicated to control hepatitis A outbreaks in child-care centres where a child or employee is diagnosed with hepatitis A and in other settings (e.g. hospitals, facilities for developmentally disabled persons) when outbreaks occur.[5,6] When a food handler is identified with hepatitis A, US recommendations call for immune globulin to be administered to other food handlers at the food establishment and under limited circumstances to patrons.[4,6] Once cases are identified that are associated with a food service establishment, it generally is too late to administer immune globulin to patrons because the 2-week post-exposure period during which immune globulin is effective will have passed.

Immune globulin also may be used for pre-exposure prophylaxis for persons who are travelling to countries with high, transitional or intermediate hepatitis A endemicity, particularly those whose departure is imminent (e.g. within 2–4 weeks), instead of or in addition to hepatitis A vaccine.[6] Immune globulin should be given to travellers younger than the minimum age for which hepatitis A vaccine in licensed (e.g. 2 years of age in the United States), to prevent the rare severe cases that occur and transmission to others after returning from abroad.[6] Economic analysis studies have shown that, in general, hepatitis A vaccine becomes more cost-effective than immune globulin as the number of expected trips during a 10-year period involving exposure to HAV or the duration of each trip increases.[211,212] Immune globulin is also recommended for pre-exposure prophylaxis for anyone with known allergy to the vaccine or a component.

The usual dose of immune globulin is a single intramuscular injection of 0.02 or 0.06 mL/kg. The lower dose is adequate to provide protection for up to 3 months and the higher dose is effective for up to 5 months.[210] Re-administration every 5 months is necessary for extended trips, and hepatitis A vaccine, if not contraindicated, is a better choice for such travellers. Intramuscular preparations of immune globulin should never be given intravenously, and the intravenous preparations of immune globulin are not intended for hepatitis A prevention and are formulated at a lower globulin concentration.

## Future directions in hepatitis A prevention

Experience to date has shown the inactivated hepatitis A vaccines to be highly efficacious and effective in preventing hepatitis A in individuals and in reducing disease incidence in communities. In areas, primarily in the developed world, in which the vaccine has been used with the latter objective in mind, a strong herd immunity effect has been observed, as evidenced by marked declines in incidence with relatively modest vaccination coverage. More widespread vaccination of successive cohorts of children would sustain and extend these observed reductions, providing the opportunity to eliminate HAV transmission. A determination of the cost-effectiveness, feasibility and acceptability of this strategy is needed to inform public policy on this issue.

In the developing world, most would agree that hepatitis A vaccine is not necessary for those countries with high endemicity where infection in early childhood is nearly universal and disease is uncommon. In these areas, reductions in the incidence of HAV infection will accompany improvements in hygienic and living conditions. However, in countries with transitional or intermediate endemicity, a growing proportion of older children, adolescents and adults in selected areas, such as urban centres with good water and sanitation facilities, are susceptible to HAV infection. As the inevitable community-wide epidemics occur, interest in more widespread use of hepatitis A vaccine in these areas may increase. The availability of lower cost inactivated vaccines or alternatives to the inactivated vaccines that offered an economic advantage would make such strategies more attractive in terms of cost-effectiveness and feasibility.

# Section IV
# Hepatitis B Virus and Other Hepadnaviridae

# Chapter 10
# Structure and molecular virology

Michael Kann, Wolfram H Gerlich

Hepatitis B virus (HBV) was the first human hepatitis virus from which the proteins and genome were identified and characterized. Before discovery of the viruses, two types of hepatitis transmission were differentiated on the basis of epidemiological observations: type A was considered to be predominantly transmitted by the faecal-oral route, whereas type B was transmitted parenterally. In 1963, Blumberg and colleagues, in a search of polymorphic serum proteins, discovered a previously unknown antigen in the blood of an Australian Aborigine (Australia antigen). Four years later, it was recognized that the appearance of this antigen was related to type B hepatitis.[1] Using immune electron microscopy, Dane and co-workers eventually discovered virus-like particles that carried this antigen on their surface, in the serum of hepatitis B patients,[2] and these particles were considered to be the hepatitis B virus. Further unrelated viruses that caused parenterally transmissible hepatitis in humans were discovered subsequently, but HBV retained its name. In 1973 the viral nature of the particles discovered by Dane was confirmed by the detection of an endogenous DNA polymerase activity within their core.[3] This enzyme allowed Robinson *et al*.[4,5] to detect and characterize the HBV genome as a small, circular partially double-stranded DNA molecule.

HBV infection was known to result in acute and chronic liver disease and, based on epidemiological data, it was postulated as early as the 1970s that this virus might represent a cause of liver cancer. This led to a search for an HBV-like agent in woodchucks (marmot-like animals from North America), which had been observed to develop liver cancer. Woodchuck hepatitis virus (WHV) was discovered subsequently[6] and a similar virus was found in seemingly healthy ground squirrels (GSHV),[7] and arctic ground squirrels,[8] which are both distantly related to marmots. In primates, hepadnaviruses could be isolated from Old World and New World monkeys including chimanzees, orang-utans, gorillas, gibbons, woolly monkeys.[9] More distantly related hepadnaviruses were found in avians including Pekin ducks (duck hepatitis B virus, DHBV),[10] grey herons (HHBV),[11] Ross' goose (RGHBV), snow goose (SGHBV),[12] white storks (STHBV)[13] and cranes (CHBV).[14]

HBV and its relatives throughout the animal kingdom comprise a virus family termed *Hepadnaviridae*, the name derived from their hepatotropism and DNA genome.[15] The hepadnaviruses of animals are currently not of particular interest to veterinary medicine, but they serve as important models for human HBV. A highlight was the discovery of reverse transcription of viral RNA into DNA within core particles of DHBV as an essential step of the viral genome replication.[16] This replication strategy is common in retroviruses. Thus, hepadnaviruses, badnaviruses and caulimoviruses (two plant virus families), which use a similar type of replication, are also termed pararetroviruses in contrast to orthoretroviruses, which have an RNA genome.

## Biology of *Hepadnaviridae*

### Immune pathogenesis

To understand the biology of hepadnaviruses, it is necessary to note that the wild-type members of this virus family are not highly cytotoxic *per se*, certainly not to the extent that massive cell death occurs. Acute and chronic hepatitis B are the result of the adaptive immune defence mechanisms against HBV (Chapters 18 and 19), which result in the death of HBV protein-expressing cells. Immunologically deficient or immature individuals, such as newborns, do not develop a typical hepatitis, but they become chronic carriers of the virus in >90% of individuals. In this case, the virus continues to replicate in hepatocytes and, to a small extent, in other sites, causing HBV reinfection after liver transplantation of HBV-infected individuals.

### Viraemia

The infected hepatocytes secrete complete virus particles (virions) resulting in concentrations of up to $10^8$–$10^{10}$ particles per millilitre of serum. The great majority of

the virions in the blood are not cell-bound, but replication was reported in a small number in certain subpopulations of leukocytes and primary bile duct epithelial cells.[17,18] The significance of the persistent viraemia for the virus appears obvious. If these viruses are unable to replicate in cells of the mucosa, they require the bloodstream of the host to leave the site of replication as well as to reach it in a newly infected individual. Blood-to-blood contact is not common between individuals and may lead to exchange of only minute amounts of serum. Thus, long-lasting, high-level viraemia seems to be essential for the survival and spread of hepadnaviruses in the population of its host species.

## Host range

Typical for hepadnaviruses is their narrow host range. Human HBV infects only higher primates such as chimpanzees and, surprisingly, primary hepatocytes of *Tupaia belangeri*.[19,20] The hepadnaviruses of marmot-like animals do not infect other rodents and even the duck virus, DHBV, does not infect all species of ducks. However, the crane HBV seems to have a broader host range including ducks.[14] Important transmission-effective contacts such as sexual activity, squabbles and similar activities would usually occur between individuals of the same species. Thus, a wide host range would not be useful for a virus that is transmitted by blood, unless a vector is involved. It must be noted, however, that replication of hepadnaviruses in arthropods has never been reported, nor have hepadnaviruses been demonstrated in insects. Hepadnaviruses are relatively stable against heat and therefore can maintain infectivity while circulating in the blood. As enveloped viruses having a lipid shell they appear to be sensitive to detergents and additionally to proteases. Thus, passage through the bile to the faeces, if it occurs at all, would not lead to spread of infection as it does so efficiently for hepatitis A virus.

## Antigenaemia

The unusually high level of viraemia is accompanied by antigenaemia. In the typical high-viraemic individuals of all host species, the hepadnaviral surface (HBs) proteins are present at concentrations of 10–1000 µg/mL serum. The HBs proteins are secreted by the infected cells as particles of variable morphology and size (see below), which exceed the number of virions 100–10 000-fold. Moreover, it appears that all hepadnaviruses are able to induce secretion of their core protein (HBc protein) in a non-assembled soluble form that is referred to as HBe antigen. This molecule reaches such high concentrations that it can be detected by a technique as insensitive as agar-gel immunodiffusion, indicating levels of 10 µg/mL and more.[21] The origin and meaning of the 'e' in the name of this protein are an enigma.

## Immune tolerance

It appears that even in immunologically competent individuals who are able to resolve the infection, the onset of the adaptive immune response is delayed by several weeks. However, among HBV-infected humans with seemingly normal immune systems, approximately 5% never develop an effective cytotoxic immune response and proceed directly to persistent infection with high viraemia and antigenaemia. The mechanisms by which hepadnaviruses suppress or escape immune elimination are not fully known, but the HBeAg may play a crucial role in viral persistence. It appears that variability of the surface proteins, as occurs in hepatitis C virus (see Chapters 19 and 21), does not play a major role during the high-viraemic phase. Several serological subtypes and genotypes of HBV are recognized, but variability within these types is very low, even at those genomic sites known to vary most between genotypes.[22] Infection of immune cells has been described,[23] but a general decrease of immune functions has not been observed in HBV carriers.

## Immune complex disease

High-dose tolerance induction may be one possible function of the viral proteins that are excessively produced and secreted. However, this immune tolerance is not complete, as circulating immune complexes of HBsAg or HBeAg and their antibodies are often detectable in viraemic carriers[24] that may lead to immune complex diseases such as glomerulonephritis, periarteritis nodosa and acrodermatitis.

## HBe seroconversion

In HBV carriers, a state of low-level viraemia may often develop after elimination of HBeAg from the blood, whereas HBsAg persists to circulate in the blood. Disappearance of HBeAg seems to indicate that HBc protein-expressing cells are no longer tolerated by the immune system. Once most of the HBV-producing cells are eliminated, the state of 'healthy' HBsAg carrier is reached. However, some latent HBV genomes seem to remain and are able to reactivate infection when the immune system is weakened. Certain variants that cannot synthesize HBeAg may be selected out during immune pathogenesis and lead to considerable viraemia. Such variants are often found in fulminant hepatitis or chronic hepatitis B without HBeAg (see Chapter 11) and occur during treatment of hepatitis B infection with interferon (see Chapter 16). In contrast to HBeAg-positive strains,

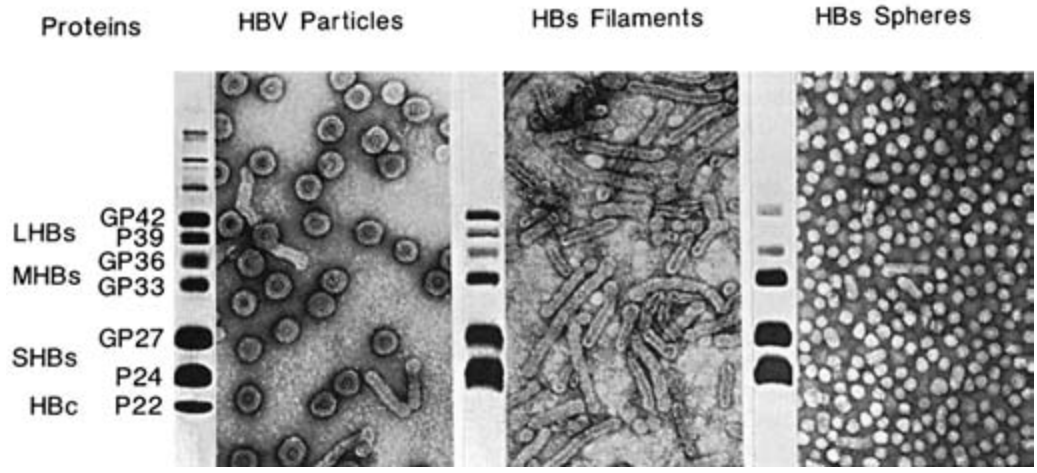

**Figure 10.1** Morphology and protein composition of purified HBV and HBs particles. The particles were isolated from high-titre HBV carrier plasma and separated from each other using ultracentrifugation and gel chromatography. The HBV particles were enriched approximately 1000-fold to about 10 µg/mL, the filaments approximately 10-fold, whereas the HBs spheres were slightly diluted for preparation of these three negatively stained electron micrographs. The same purified particle preparations were denatured by sodium dodecyl sulfate/dithiothreitol (SDS/DTT) and run through a 13% polyacrylamide gel and stained with colloidal silver. The apparent size and the nomenclature of the viral proteins are shown on the left. The viral surface antigen contains a small, middle-sized and large protein (SHBs, M, L), which appear in variably glycosylated forms. The core protein (HBc) forms a single P22 band in gel electrophoresis.

the HBeAg-negative variants have highly variable genomes (see Chapter 11).

### Integration of HBV DNA and oncogenesis

As will be pointed out later, integration of HBV DNA, in contrast to orthoretroviruses, is not an essential step in the replication of HBV. However, integration of fragments of HBV DNA occurs often in chronic carriers. In some cases cells may gain an illegitimate growth advantage by this insertion of viral DNA. Furthermore, viral proteins themselves, if expressed by integrated HBV DNA fragments in a deregulated and/or altered manner, may favour uncontrolled growth. There can be no doubt that certain hepadnavirus species have an oncogenic potential but possibly depend on different mechanisms that vary among species. WHV has the highest oncogenicity, showing typically an integration close to the cellular N-myc oncogen, HBV has intermediate oncogenicity showing a random integration, whereas DHBV and GSHV have the lowest oncogenicity, if any (see Chapter 44).

## Structure of *Hepadnaviridae*

### Virion morphology

Figure 10.1 shows the three types of virus-associated particles present in the blood of HBV-infected persons. Similar particles are also found in the serum of hepadnavirus-infected woodchucks or ground squirrels.[6,25] Using electron microscopy after negative staining, the virus is spherical with a diameter of 42–45 nm, showing a double-shelled structure. The outer protein shell (or envelope) is formed by the HBs proteins.[2] Surface structure details are not reliably visible by negative stain, but cryoelectron microscopy revealed small spikes at the surface of virions.[26] The inner protein shell is referred to as the core particle or capsid.[27] It is composed of HBc protein (also termed capsid- or core protein) and encloses a complex of viral polymerase and DNA, which is often positively stained. Morphologically, there are two different forms of capsids. They consist of 180 or 240 identical core proteins, which form capsids with a T=3 and T=4 symmetry. In cryoelectron microscopy they show diameters of 32 and 36 nm,[28,29] but there is no functional difference known to be related to the symmetry.

### HBs particles

The sera of highly viraemic carriers contain large numbers of non-infectious particles composed of excessive HBs protein (HBsAg). Most abundant are spherical particles of 17–25 nm, which are secreted in 100–10 000-fold excess to the virus, typically reaching numbers of up to $10^{13}$/mL. The spheres seem to be small vesicles with approximately 4-nm thick walls and an interior diameter of 10–15 nm. Less numerous (up to $10^{11}$/mL or 1 µg/mL) are the filamentous (or tubular) particles of approximately 20 nm diameter and variable length. Sera from low-viraemic HBsAg carriers contain up to $10^{12}$/mL HBs spheres and few or no HBs filaments. Neither

of these subviral structures contain the capsid and HBV DNA and thus they are not infective. Avian hepadnaviruses have a virion morphology similar to that of the mammalian hepadnaviruses.[25] The serum from DHBV-infected ducks also contains excessive HBs particles, but their morphology differs in that the spheres have a variable diameter of 40–60 nm. No filaments are detectable.

### HBs particles in the liver

The virion envelope and the HBs particles are synthesized and assembled at the membrane of the endoplasmic reticulum (ER) and bud to the lumen of the ER. From the ER, the particles are transported and excreted by vesicles. However, when the largest of the three HBs proteins (LHBs) is overproduced in comparison to the smaller HBs proteins, filamentous particles are formed, which are retained within the ER. This may lead to the accumulation of HBs protein to the point that the ER becomes dilated.[30] In light microscopy, such LHBs-storing hepatocytes appear opaque like ground glass.

### Core particles in liver

In HBV-producing cells, the core particles are synthesized and assembled independently from the HBs proteins in the cytosol. Thereafter, they probably attach to patches of HBs protein in the ER membrane. By enclosing the whole core particle, the HBs proteins mediate budding of the virions to the ER lumen. Non-enveloped core particles of human HBV, being devoid of the viral genome, are often found in the nucleus where they are obviously stored.[31] In highly viraemic individuals without high disease activity, virtually all hepatocytes may contain considerable amounts of nuclear or cytoplasmic core particles, which can be extracted, purified and visualized by electron microscopy. The appearance of cytoplasmic capsids seems to be related to high replication and high viral load in the serum. A certain HBV-producing cell line, Hep G2.2.15, releases not only virions and HBs particles but also naked core particles.[32] However, no naked core particles are found in the serum, even in that of immune tolerant HBV carriers without anti-HBc.[33]

## Protein composition of HBV particles

### Surface proteins

Virions and large structures such as the HBs or HBc particles are built from protein subunits that are held together by non-covalent interactions and, in the case of HBV proteins, by disulfide bonds between cysteines of different protein molecules. These interactions can be disrupted by the anionic detergent sodium dodecyl sulfate (SDS) and disulfide-cleaving reagents such as β-mercaptoethanol or dithiothreitol (DTT). Moreover, the protein subunit is denatured to form a random coil. For analysis of HBs proteins, gel electrophoresis after treatment with SDS/DTT was applied to separate them by size. Thereafter, the gel slabs were stained with colloidal silver (Fig. 10.1).

In HBs filaments, six protein bands are visible, ranging from 24 to 42 kDa apparent molecular weight. All of these proteins can also be stained specifically by immune blotting with an antibody against the smallest component P24, which demonstrates that at least one epitope of the smallest protein is present in the larger proteins. Four of the proteins contain an oligosaccharide linked to one or two of their asparagine residues (N-linked glycan). These glycoproteins migrate as somewhat larger molecules in electrophoresis than the non-glycosylated forms. Enzymatic removal of the glycan shows that HBs filaments contain only three different HBs polypeptides: (1) the largest (LHBs) is converted by partial glycosylation *in vivo* from P39 to GP42, (2) a middle-sized protein (MHBs) that is either single or double-glycosylated as GP33 or GP36, and (3) a small protein (SHBs) that may be glycosylated as GP27 or non-glycosylated as P24.

SHBs is the most abundant polypeptide in all three HBV-associated particles, whereas MHBs is a minor component in all three. LHBs is more prevalent than MHBs in virions and filaments, but less prevalent in HBs spheres. It appears that the proportion of LHBs determines the morphology of the HBs particles,[34] whereas the proportion of SHBs to MHBs does not significantly alter morphology. A model of the HBs particles is shown in Fig. 10.2.

### Core proteins

In addition to the HBs proteins, purified virions possess a non-glycosylated protein P22, which may be phosphorylated and which builds up the core particle. Naked core particles from liver show the same P22 protein in SDS gel electrophoresis,[35] but virion cores are known to contain the viral DNA polymerase covalently bound to the viral genome.[36,37] Details of structure and functions are described later.

## Genome of HBV

### Endogenous DNA polymerase of HBV

The first hint regarding the nature of the HBV genome was obtained by the discovery of an endogenous DNA polymerase activity in ultracentrifugation pellets from HBV-containing sera.[3] The reaction was dependent on all four desoxynucleotide triphosphates and divalent cations, but no primer or template was necessary. It

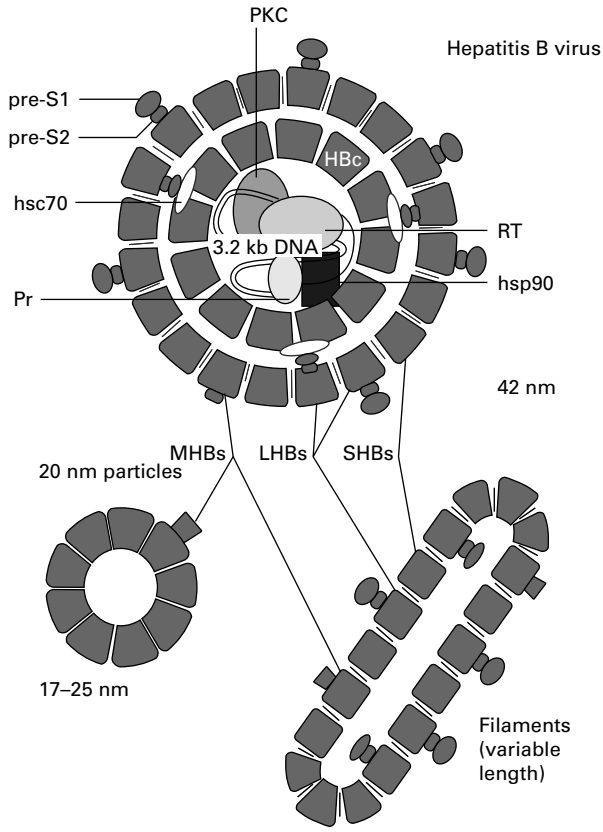

**Figure 10.2** Schematic model of the HBV and HBs particles. The SHBs protein of the viral envelope is identical to the S domain of MHBs and LHBs. MHBs contains a small pre-S2 domain facing towards the outside of the particle. LHBs contains a pre-S domain composed of the pre-S2 and pre-S1 sequences. The viral envelope encloses a symmetrical capsid consisting of 240 HBc protein subunits. These encapsidate the 3.2-kb long DNA genome of HBV to which a primase domain (pr) of the DNA polymerase (pol) is covalently linked. Protein kinase (PK) and the heat shock protein hsp90 are also encapsidated. The filaments consist of the same proteins as the virion envelope. The spheres contain fewer LHBs. The virion envelope and the HBs particles contain small amounts of ER-derived lipid between the protein subunit. Internal pre-S domains of LHBs are associated with the heat shock protein hsc70.

could be inhibited by actinomycin D, which intercalates into DNA templates. The enzyme was precipitable with antibodies against HBc protein if the HBs envelope was removed from virions by treatment with a non-ionic detergent. The DNA template was not accessible to DNase unless the core protein was lysed by SDS or digested by proteinase. The existence and properties of the endogenous DNA polymerase provided evidence that the virus contained a DNA genome.

## Structure of the virion DNA

Using electron microscopy, the DNA of HBV was shown to be circular, partially double-stranded, and 3200 nucleotides long.[4] The endogenous DNA polymerase reaction is possible because one of the DNA strands is incomplete.[38,39] The remaining gap is partially filled by the viral DNA polymerase if the dNTPs are added *in vitro*. *In vivo*, HBV particles are obviously secreted from the infected cell before the double strand is completed. Thus, the incomplete plus-strand has a defined 5′ end but a variable 3′ end (Plate 10.1c, found between p.786–7).

The complete minus-strand has defined 5′ and 3′ ends, with a terminal redundancy of 8–9 bases, resulting in a region in which the genome is triple-stranded.[40] The viral polymerase is covalently bound at tyrosine 63 via a phosphodiester bridge to the 5′ end of the minus-strand.[41] This linkage causes extraction of virion-derived DNA to the phenol phase during classical DNA extraction unless the sample is thoroughly digested with proteinase.[37]

The 5′ end of the plus-DNA strand is formed by an 18-base-long oligoribonucleotide, which is capped in the same manner as a messenger RNA (mRNA).[42] The genome contains two directly repeated sequences of 10 or 11 bases, DR1 and DR2.[43] This genome structure is typical for all hepadnaviridae, but in the case of the avian hepadnaviruses, the overlap and the distance between the DRs are shorter.

The structure of the hepadnaviral genome does not abide by the usual classification criteria for viruses[44] in several respects. It contains both DNA and RNA, and its genome contains partially single-stranded, double-stranded, and even triple-stranded DNA. These unusual features are a direct consequence of its replication mechanism, which will be explained later.

## Definition of open reading frames

From the nucleotide sequence of a double-stranded version of the DNA genome it is possible to derive six different sequences of amino acid encoding triplets of nucleotides (codons). If a sequence of potential codons does not encode a protein, it is randomly interrupted by one of the three possible stop codons, whereas protein-encoding sequences are usually free of stop codons for a distance of at least 50 codons. These stretches of codons are called open reading frames (ORFs). Protein biosynthesis additionally requires a start codon (AUG) in mRNA. By applying these rules, all genomes of mammalian hepadnaviruses contain four ORFs, which are encoded by the same DNA strand (Plate 10.1a, found between p.786–7). The polarity of the viral nucleic acid strands is defined in a way that mRNA has plus-polarity. Thus, the protein-

encoding DNA strand of the HBV genome, which is transcribed into mRNA, has minus-polarity. Additional ORFs can be identified both on the minus- and plus-strand, but they are not conserved, and are probably of minor importance, or generated by statistical sequence variations.

### Compact genome structure of HBV

Most functional ORFs of cellular organisms, as well as those from larger viruses, are arrayed in a linear fashion on the genomes and encode one protein. Moreover, they are interspersed by large non-coding regions (introns), which are removed after transcription by splicing. Regulatory and protein-coding regions are usually well separated. However, the genomes of hepadnaviruses seem to have evolved toward minimal length. Thus, the genome is not much longer than its longest ORF P, which encodes the viral DNA polymerase and its accessory functions (see Plate 10.1a, found between p.786–7). ORF S is completely located within the ORF P. ORF C and X overlap partially with ORF P. Furthermore, HBV encodes more than one protein from one ORF by using internal AUG codons in an ORF as additional start sites for protein biosynthesis. Thus, nested sets of proteins with different amino ends and a common carboxyl end are synthesized. ORF S encodes the three co-terminal HBs proteins.[45] ORF C encodes the HBe protein and the HBc protein.[46] ORF X may also encode more than one protein.[47] Furthermore, the numerous genetic elements that regulate transcription of the viral DNA into RNA, processing of the RNA and translation into protein are placed within coding regions.

Complete HBV genomes are between 3182 and 3221 bases long.[48] The numbering of the bases starts in most publications (as it does here) at the cleavage site for the restriction enzyme *EcoR*I or at homologous sites if a particular genome type does not have such an *EcoR*I site. Other numberings (e.g. beginning at the AUG start codon for the HBc protein synthesis or the first base of the RNA pregenome) (see later) are also in use.

## HBs proteins

### Protein sequence of SHBs

The amino acid sequence of SHBs at the amino and carboxyl ends has been determined biochemically.[49,50] The internal sequences could be only partially analyzed by this approach. However, together with the protein sequence predicted by the nucleotide sequence, it became clear that the sequence of SHBs begins at the third conserved AUG of ORF S, and that it ends at the stop codon of ORF S. The function of the 5′ terminal part of ORF S was originally unknown and was named region pre-S, simply to indicate its location upstream of gene S.[48] It is important to note that proteins containing the pre-S sequence are not precursors of SHBs.

SHBs is rich in hydrophobic amino acids. It has many tryptophans but few tyrosines and thus, unlike most proteins, possesses an ultraviolet absorption spectrum similar to tryptophan. Furthermore, it contains a very high number of 14 cysteines, which are cross-linked with each other.[51,52] At asparagine 146 there is a signal for addition of an N-linked glycan, which is present in approximately half of the molecules.[49] This glycan has two complex antennas with terminal sialic acids. In SDS gel electrophoresis, SHBs has a microheterogenicity, the pattern of which is typical for a virus carrier.[53] The origin of this microheterogenicity is unknown.

### Subtypes

SHBs occurs in stable subtypes that were originally defined by antibodies. Antigen reactivities that were present on all known HBs isolates were considered as determinant *a*. The best known subtypical determinants are *d* or *y*[54] and *w* or *r*. [55] Determinant *d* has a lysine at position 122, *y* an arginine.[50] Likewise, determinant *w* has a lysine at position 160, *r* an arginine.[56] Furthermore, a subdivision of *w* into w1–w4 is possible. These subtype-specific amino acids, however, may occur in quite divergent HBV genomes. Later subtyping has been done by DNA sequencing of the SHBs gene.[57] At least eight genotypes, A–H, which differ by >8% in the protein sequence, have been identified.[22,58–61] Because all SHBs subtypes are able to induce cross-protection after immunization, the significance of serological or other subtyping is mainly of epidemiological and phylogenetic interest. However, the genotypes may have different pathogenicity and epidemiology and have a typical geographic region. Genotype C is reported to cause more severe chronic course than genotype D.[59] In addition, it cannot be excluded that some of the neutralizing antibodies are subtype-specific, as is the case with most other viruses.

### Topology of SHBs

Circular dichroism of HBs spheres suggests that 50–60% of the polypeptide chain are folded to α-helices. Computer programmes used to model the secondary structure of proteins predict that these α-helices are formed by four or five hydrophobic stretches of SHBs (Fig. 10.3)[62,63] Biosynthetic studies suggest that α-helix I is inserted co-translationally into the ER membranes, and that it furthermore is able to translocate amino-terminal sequences to the lumen of the ER if they are not too long.[64] Helix II is also inserted into the ER membrane, but it translocates the carboxy-terminal sequences.[64] The topology implies that the hydrophobic sequence between helix I and II remains cytosolic. After budding of HBs particles

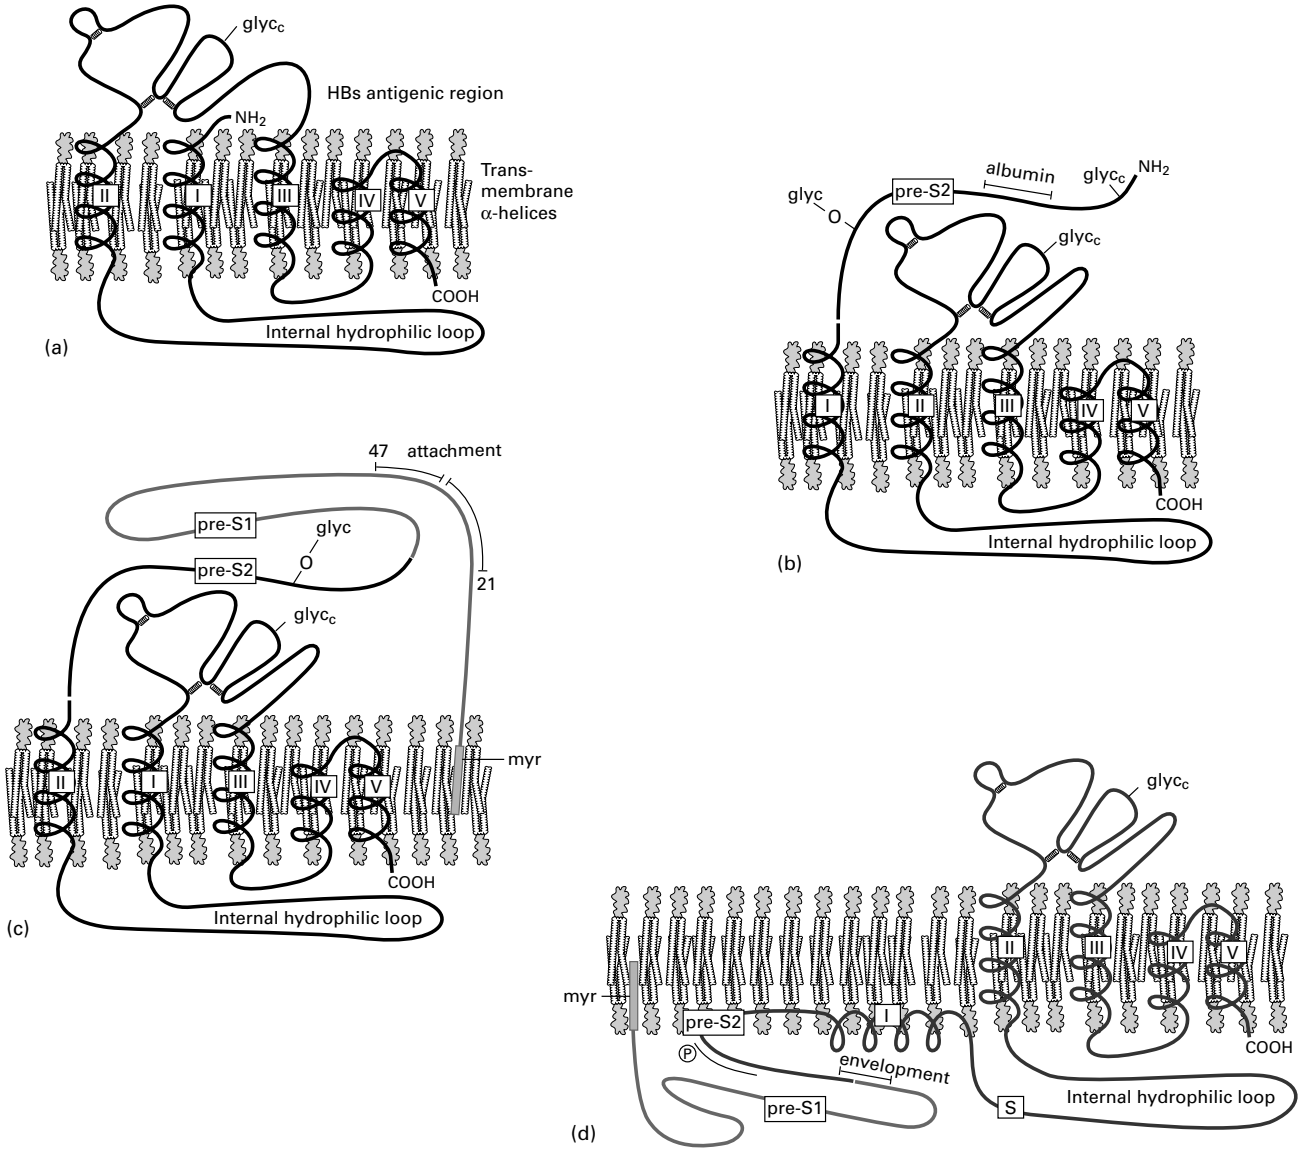

**Figure 10.3** Topological models of the three HBs proteins. The lipid bilayer of the ER membrane is symbolized by the lipid molecules. The top of the figures corresponds to the lumen of the ER or, after multimerization and budding of the HBs protein, to the surface of the virus particles. The bottom of the figure corresponds to the cytosol or to the interior of the particles. It is assumed that the ER membrane is crossed at least four or five times by hydrophobic α-helical segments of the S domain. (a) Structure of SHBs. A complex biantennary glycoside (glyc$_c$) is present in GP27 but not in P24. The HBs epitopes are generated by the complex folding of the external hydrophilic loop between α-helix II and III (as suggested by Chen *et al.*[65]) and are stabilized by cystine bonds the exact nature of which is not known. The structure downstream of helix II is not well understood. (b) Structure of MHBs. The arrangement of the transmembranous α-helices of the S domain seems to be slightly altered in that the amino end is more accessible, and that its hydrophilic loop is less often glycosylated. The pre-S2 domain carries a complex N-linked glycoside (glyc) and a part of the molecules an O-linked glycan. (c) Structure of LHBs in the virion. The structure is in principle similar to MHBs. The pre-S2 domain is not N-, but O-glycosylated. The pre-S1 domain partially covers the pre-S2 domain and is linked at glycine 2 with myristic acid (myr). (d) Presumed structure of LHBs soon after its synthesis in the ER. At the early phase of LHBs folding, it appears that the entire pre-S domain stays in the cytosol. Schematically, the proposed structure would result, but the true folding of the cytoplasmic pre-S domain is not known. At later phases of virion or HBs filament maturation in about 50% of the LHBs molecules, the entire pre-S domain is translocated through the particle membrane to the surface as shown in (c). The binding sites for attachment of the virus and for capsid envelopment are shown.

to the lumen of the ER, this sequence is in the interior of the particles. In agreement with this conclusion, B-cell epitopes have not been found in this region. However, the sequence from amino acids 99–168 is exposed at the particles' surface and forms the HBs antigen region. The composition of discontinuous epitopes was analyzed by a filamentous phage peptide library.[65]

Most of the SHBs epitopes depend on the presence of disulfide bonds. Mild treatment with DTT first destroys subtype-specific epitopes and at higher concentrations also the *a*-epitopes. Completely reduced HBs particles are almost non-immunogenic. Thus, SHBs is virtually undetectable in immunoblots when reduced and denatured proteins are reacted with antisera against native HBs particles.[66]

The exact topology of this region is not known. Binding experiments with antibodies suggest that amino acid 178–186 are surface-exposed.[67] Computer modelling of the following hydrophobic regions suggests formation of two or three membrane-spanning helices (III and V), which may insert post-translationally into ER membrane. Because of their polarity with one hydrophobic and one hydrophilic side, these helices are predicted to multimerize.[62,63] Multimerization may possibly also occur between different HBs subunits, and this event would potentially mediate budding of the HBs particles. In agreement with that presumption, truncated HBs proteins without this region no longer form HBs particles, but remain at the ER.[68] Such truncated HBs proteins have been found in certain hepatoma cells.[69] The most carboxy-terminal part (presumptive helix V) is dispensable for HBs particle formation.[68,70]

## MHBs

This minor component of the virion or HBs particles is composed of the S domain, a sequence that is identical to that of SHBs and of the 55 amino acid long pre-S2 domain.[71] The pre-S2 domain is hydrophilic and does not contain cysteines. It is very sensitive to proteases and can be removed selectively from HBs particles without destroying the S domain.[72] Thus, MHBs is virtually absent in HBV vaccines that contain protease-treated HBs particles from carrier plasma. The asparagine at position 4 is linked with a glycan consisting of two complex chains.[73] The glycosylation at this site is essential for secretion of MHBs-containing HBsAg particles.[74] In addition to N-glycan, pre-S2 of HBV genotypes C or D is linked at Thr 37 with an O-glycan.[73] With the exception of genotype A the corresponding O-glycosylation site is conserved in all other HBV genotypes or primate HBVs. WHV is multiply O-glycosylated in pre-S2.[75]

The pre-S2 domain is located at the surface and partially covers the S domain of MHBs. In mice, it may be slightly more immunogenic than the SHBs antigen. Furthermore, the epitopes are not conformation-dependent and can (in contrast to SHBsAg) easily be generated by synthetic peptides. Peptides with the sequence of the amino-terminal half of the pre-S2 were found to induce protective immunity,[76–78] but recent *in vitro* experiments with *Tupaia* hepatocytes suggested relatively weak neutralization capacity of pre-S2 monoclonal antibodies compared with pre-S1 and SHBs antibodies.[19] However, pre-S2-containing HBs particles from transfected Chinese hamster ovary (CHO) cells have been introduced in some countries as vaccine.[79]

The central part of the pre-S2 domain (amino acid 7–20), which also forms the major epitope, binds a modified form of serum albumin.[80–82] *In vivo*, approximately one in 10 000 serum albumin molecules is able to bind to pre-S2. HBV carriers with >10 µg HBsAg/mL usually have free albumin-binding sites on their particles, whereas at lower HBsAg concentration all binding sites are occupied. The nature of the modification is not known, but it can be mimicked by cross-linking of albumin with glutaraldehyde.[83] Serum albumin of non-primate origin does not bind.[81]

## LHBs

The largest HBs protein contains two domains: pre-S (composed of the pre-S1 and pre-S2 sequence) and S. In the mature virions or HBs particles part of the pre-S domains are accessible for antibodies,[45] receptors[84] and proteases.[72] The S domain and parts of the pre-S2 sequence are hidden by the pre-S1 sequence of LHBs (Fig. 10.3). During biosynthesis, the entire pre-S domain of LHBs seems to stay initially at the cytosol.[85–88] Thus, the asparagine 4 of the pre-S2 sequence is not glycosylated in LHBs,[45] because this modification can occur only cotranslationally in the ER lumen. The amino end of the pre-S domain carries the sequence methionine-glycine, which, together with neighbouring amino acids, serves as a signal for the replacement of the methionine by the $C_{14}$ fatty acid myristic acid.[89] Myristylation is not essential for virion formation but is essential for virion infectivity of HBV[90,91] or DHBV.[92]

During virion or HBs particle maturation, the pre-S domains reconfigure in about 50% of the LHBs molecules and translocate to the surface of the particle. The translocation occurs post-ER but intracellularly, because LHBs contains like MHBs O-linked glycan at Thr 37 of pre-S2. Half of the pre-S domains remain on the cytosolic side, which, after budding into the ER, becomes the internal side of the particle.[85,86] For DHBV, these pre-S domains are associated with the cellular heat shock protein hsc70.[93,94] The significance of the dual topology of LHBs is obvious. Several studies on the attachment of HBV to the target cell showed the necessity of the pre-S region for binding to the cellular receptor (see below),

implying that externally localized pre-S is essential for the viral life-cycle. On the other hand, pre-S seems to be required for envelopment of the core particles by the surface proteins, giving evidence for an essential localization of pre-S on the cytosolic side of the surface proteins.[95] Placement of the pre-S sequence behind a secretion signal peptide allows formation of secreted LHBs-containing particles but prevents envelopment of core particles.[96] Deletion analysis showed that only the sequence proximal to pre-S 108 is required. Shorter pre-S sequences are translocated as in MHBs and thus are not available for interaction with core particles.[86]

Overexpression of LHBs relative to expression of SHBs prevents secretion of HBs particles.[97] Instead, filaments become enriched in the ER[30] or in the intermediate compartment. Expression of MHBs and SHBs is independently regulated from expression of LHBs (see below). Hepatocytes appear to exist that express and secrete SHBs predominantly, whereas for unknown reasons others express more LHBs and store it intracellularly.[98] The degree of hepatic immune staining for HBsAg does not correlate with the level of HBsAg in the serum. Only hepatocytes that express LHBs, SHBs and the other viral components in a well-balanced manner are able to assemble and secrete virions.

The pre-S domain is one of the most variable regions between different hepadnavirus species. One reason may be that the part of the polymerase protein that is encoded by the same DNA region as pre-S1 is not essential for replication. The other reason is that this may be the surface structure that is responsible for host specificity and binding to hepatocytes. However, within a chronically infected person or within a defined chain of infection, pre-S1 is not mutated.[99] Thus, it is not similar to the hypervariable domains of human immunodeficiency virus (HIV) or hepatitis C virus (HCV) envelope proteins.

## Core proteins

### Products of ORF C

The essential product of ORF C is the HBc protein of either 183 or 185 amino acids, depending on the genotype of the virus. In most isolates from highly viraemic carriers, ORF C has 212 or 214 codons, but translation of HBc protein starts only at the AUG 29 codons downstream of the first AUG.[46] The region upstream is termed pre-C for historical reasons.[48] This name is misleading, because the product of the entire ORF C is not a precursor of HBc protein but of the secretory form of the core protein, which is termed HBe protein.

### HBc protein

This protein contains many hydrophilic and charged amino acids. It does not contain lipid or glycan, but if expressed in eukaryotic cells, it becomes phosphorylated.[35,100–104] It is synthesized in the cytosol of the infected cells. As an essential step in the viral life-cycle, it packages its own mRNA and the viral polymerase after formation of the RNA-polymerase complex and assembles into core particles.

The core protein can be separated into two different domains. The 144 amino terminal amino acids are the structural component, essential for capsid formation. They build up five α–helices arranged in an anti-parallel orientation forming a spike between helix 3 and 4.[28,29,105–107] The C-terminal part of this domain forms a flexible array that is located in the interior of assembled capsids.[108] Amino acids 145–185 (183 in some genotypes) are a multifunctional domain. It is essential for RNA packaging, plus-strand DNA synthesis of progeny virion DNA[109,110] comprises a nuclear localization signal (NLS) and serine residues that may become phosphorylated.

The core particles assemble spontaneously after reaching a threshold concentration of 0.8 μM[111] to isometric particle even when expressed in a heterologous system such as *Escherichia coli*, for example. Assembly is strongly enhanced by the presence of RNA, which interacts with the C-terminus of the core protein[110] and thereby becomes encapsidated into the lumen of the capsid.[111]

Assembly of a core particle is initiated by formation of a core protein dimer to hexamers. Apparently, this step is rate-limiting and is followed by a trimerization of dimers. These elements rapidly assemble to particles with a T=3 or – more frequently – T=4 symmetry. The ratio between T=3 and T=4 particles is influenced by the speed of assembly. As in chemical reactions a counter direction exists. This leads to a removal of a hexamer, a process called 'breathing'. However, the balance of the reaction strongly supports the formation of an intact particle.[112,113]

*In vivo*, the cytosolic assembly of the capsids is combined with the encapsidation of a complex formed from the viral polymerase and the so-called pregenomic RNA. In addition, cellular proteins such as some heat shock proteins and a cellular protein kinase become encapsidated (see below). In a coordinated fashion the polymerase converts the pregenomic RNA to viral DNA. This process depends upon the presence of the core protein.

For DNA synthesis of a mature viral genome approximately 5000 nucleotide molecules are required. Therefore, the core proteins do not form a completely closed protein shell but show 2-nm measuring holes that allow the nucleotides to enter the lumen.[28,29] It is believed that

these holes are subjected to a structural change of the capsid upon genome maturation, allowing the C-terminus to become exposed to the surface.[114,115] This conformational change is essential for NLS exposure that facilitates the transport of the viral DNA into the nucleus.[115]

Once core particles are assembled and have left the reducing environment of the cytosol,[116] their structure is stabilized by disulfide bonds, but the conserved cysteines are not required for assembly or envelopment.[117] Although showing the same morphology[29] *E. coli*-expressed and native capsids show different disulfide bonds. *In vivo* the core proteins are linked to dimers at cystein 48, 61 and 185.[118] In contrast, the carboxyterminal cystein 185 becomes linked to the cystein 185 of other dimers when the capsids are expressed in *E. coli*.[119]

## Function of HBc protein

The HBc protein is central in the viral life-cycle. After assembly to core particles and encapsidation of the viral genome, the particles allow envelopment by the HBs proteins and formation of the virus. In addition, the core particles mediate the transport of the mature viral genome into the nucleus of the infected cell, leading to restorage and amplification of HBV DNA in the nucleus of the persistently infected hepatocytes.[114,115]

A certain proportion of the HBc proteins is imported into the nucleus where the HBc units assemble to empty core particles.[35] The significance of the intranuclear core protein is not understood, but core protein associated with nuclear viral DNA was thought to modulate transcription.[120] The observation that the nuclei of rodent and duck livers infected with the corresponding hepadnaviruses are devoid of nuclear capsids suggests that nuclear particles may be a non-essential side-effect of HBV infection. It may be speculated that the assembly to particles is a pathway to dispose of the excess of core proteins that may interfere with the cellular RNA due to their RNA-binding capacity.

## HBe protein

All hepadnaviruses have evolved the ability to express a secretory form of their HBc protein. They achieve this by the 5′ terminal part of the ORF C, called the pre-C sequence. The pre-C sequence encodes a hydrophobic α-helix, which is a secretion signal and allows for translocation of the HBe protein into the lumen of the ER.[121,125] During that process, 19 of the 29 pre-C amino acids are cleaved off by the signal peptidase (Fig. 10.4). The 10 remaining amino acids of the pre-C sequence prevent assembly of HBe to core particles by interaction with the HBc protein sequence.[122]

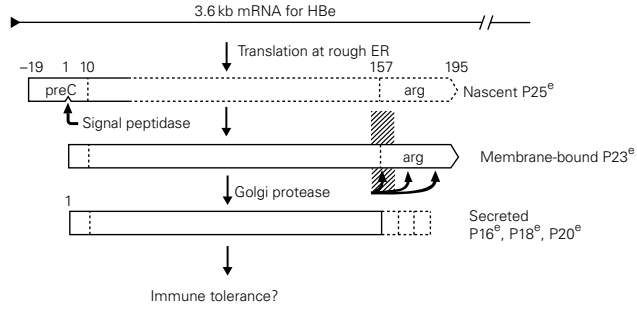

**Figure 10.4** Biosynthesis of HBe proteins. When the more-than-genome-length mRNA starts upstream of the HBe start codon, translation of the pre-C region prevents the necessary folding of ε. Thus, the HBe mRNA does not usually function as a pregenome. It is translated to the HBe precursor P25e, which may be co-translationally cleaved to a membrane-associated P23e. The 10 remaining amino acids of the pre-C sequence prevent folding of P23e to core particles. Secretion requires partial or complete removal of the arginine-rich carboxy-terminal domain by a Golgi protease. Thus, secreted HBe protein may be of variable size between 16 and 20 kDa. The HBe protein is not essential for virion replication but modulates the host's immune response to HBV.

Thus, HBe protein differs in almost all aspects from HBc protein, although the primary sequence of these two molecules is almost identical. Part of the HBe protein is transported to the plasma membrane.[123] Another part is further cleaved within the arginine-rich domain by a Golgi protease and then secreted as a dimeric protein with disulfide bonds between Cys-7 and Cys-61.[124–126] Another part of the HBe protein does not reach the ER lumen and is not cleaved at all. The $P25^e$ protein exposes a nuclear transport signal.[127] Thus, HBe proteins of variable length are found in practically all compartments of the cell and are secreted. Furthermore, uncleaved HBe precursor protein accumulates as phosphoprotein.[128]

## Function of HBe protein

HBe protein is not essential for the viral life-cycle. Variants without functional pre-C sequence and HBe protein arise often during acute or chronic HBV infection (see Chapter 11). Nevertheless, all known hepadnaviruses from duck to humans have an HBe protein, and revertants may occur after cessation of interferon treatment. Using a different expression strategy, murine leukaemia viruses have also developed the ability to produce a secretory form of their nucleoprotein, the glycosylated gag protein.

High levels of secreted HBe protein are found in low-symptomatic, highly viraemic virus carriers. Elimination of HBeAg is usually accompanied by a flare-up of immune pathogenesis and a decrease of viraemia (see Chapters 15 and 16). An HBe-negative variant of wood-

chuck hepatitis B virus was infectious for newborn woodchucks, but it could not induce persistent infection, whereas the HBe-expressing virus results in persistent infection.[129] These observations suggest that HBe protein may somehow suppress the immune elimination of HBV-producing hepatocytes. Indeed, HBeAg was found to induce immunotolerance against HBV-infected cells. Depleting inflammatory HBeAg- and HBcAg-specific Th1 cells that are necessary for viral clearance,[130] HBeAg is thought to support viral persistence.

## Products of ORF P

Although the products of ORF S and C have been identified and well characterized within virions, evidence regarding the products of ORF P is still circumstantial. There is no doubt that such a product or products are expressed during infection *in vivo*, but the modes of transcription, translation and post-translational processing are not exactly known.

### Domains of ORF P

As discussed later, mutational analysis of the 834–845 codon-spanning ORF P, sequence homologies with well-studied reverse transcriptases,[131] and studies on the mechanism of genome replication of HBV show that most parts of the ORF are indispensable for the virus. These studies suggest that ORF P has four clearly distinguishable domains.[132]

**1** The amino-terminal domain that encodes the part of the protein linked to the 5′ end of the minus-strand of virion DNA.[36] This part of ORF P is necessary for priming of minus-strand synthesis and is also termed *primase*.

**2** The next domain has no specific function except as a spacer or tether.

**3** The next domain encodes the RNA- or DNA-dependent polymerase, i.e. the reverse transcriptase (RT). This domain is supposed to have a similar spatial structure to the RT of retroviruses,[133] with fingers of a palm.[134] It is a target of current antiviral drugs against HBV.

**4** The last carboxy-terminal domain is an RNase H, which cleaves the RNA if it is present in hybrids of RNA and DNA. The ORF P of hepadnaviruses differs among other features from the ORF P of retroviridae in that it most likely has no protease and integrase domain, but it has a primase activity that is absent in orthoretroviruses and other pararetroviruses.

Interestingly, the enzymatically active domains of the polymerase are not active *per se*. At least the DNA-dependent DNA polymerase activity depends upon the presence of the core protein.[110] The RNase H is only active on the polymerase-bound substrate,[135] thus only active when incorporated into the viral capsid. However, complementation of primase, RT and RNase H domains on different proteins is possible.[136]

### Products of ORF P in virions

Studies on the viral polymerase have been hampered by its low abundance in viral particles. Thus, most of the results on the polymerase were obtained by introducing mutations in the ORF P. Extraction of an active endogenous DNA polymerase from virion core particles has been difficult, because disruption of cores requires harsh treatment and, thus, destroys the interaction of core protein and polymerase, which appears to be required for regular genome maturation. However, residual activities such as the priming reaction can be observed when expressing the polymerase in cell-free systems[137] or in *E. coli*.[138]

Bartenschlager *et al*.[139] found that the 90-kDa protein encoded by the entire ORF P is predominant in virions. The polymerase protein is packaged together only with the pregenomic RNA within core particles[140] probably caused by sterical changes of the polymerase resulting from its interaction with ε.[141] Because the pregenome contains only one packaging signal[141] and core particles seem to have only a packaging capacity for 3300 nucleotides,[142] probably one polymerase molecule is packaged. In both DHBV and HBV, the polymerase is associated with a dimer of heat shock protein hsp90 and one of its co-factors p23. Hsp90 is necessary for binding to ε.[143–147]

## HBx protein

The 154 amino acid-spanning ORF X is conserved in similar form in the hepadnaviruses of woodchucks and ground squirrels. The seeming absence of an ORF for HBx in DHBV suggests that it does not participate in the mechanisms of genome replication or virion assembly. However, recent studies revealed that duck hepatitis B virus expresses a regulatory HBx-like protein from a hidden ORF.[148] Nevertheless, like the mammalian HBx, the avian one does not interfere with infectivity or *in vivo* growth characteristics.[149]

### Function of HBx

Mutational studies suggest that the HBx protein is dispensable for virus production after transfection of permanent cell cultures *in vitro*.[150] However, transfection of WHV DNA without a functional X ORF into livers of susceptible woodchucks did either not yield infection or caused reversions, which shows that HBx is essential for efficient replication *in vivo*.[151,152] There is no clear indication that HBx protein is a structural component of virions or core particles. The amino acid sequence suggests that HBx does not have a specific intracellular

transport signal. Thus, reports on the occurrence of HBx protein in the serum of virus carriers[153] are difficult to explain. Several studies suggest a predominantly cytoplasmic localization and a minor nuclear fraction.[154] *In vitro*-expressed HBx is highly unstable in animal cells, with a short half-life of 20 minutes, during which time it becomes phosphorylated.[155] Most reports on various biochemical activities of HBx protein seem to be preliminary and need confirmation. It is clear that HBx protein activates transcription of many genes in a somewhat non-specific manner when it is introduced artificially into cells by co-transfection with reporter systems.[156–158] It has been suggested that nuclear HBx interacts with other transcription factors,[159,160] but others suggest activation of cytoplasmic signal transduction factors such as PKC,[161] raf,[162] or NF-κB.[163,164] The number of HBx proteins expressed from ORF X *in vivo* is unknown, but the results of mutational studies suggest that the smaller potential proteins are expressed, having transcription-activating activity. [47]

In addition to the transactivating activity, HBx comprises a second well-established activity. Correlating with transactivation, a pro-apoptotic potential was found to be present in both orthohepadnaviruses and the avihepadnaviral X-proteins. The corresponding domain was localized in the carboxy-terminal half of the different X-proteins.[165]

One of the most significant side-effects of HBx protein may be its tumorigenic activity in premalignant mouse hepatocyte cultures[166] and transgenic mice,[167] but this has not been found in all systems.[168] Particularly, an interaction with tumour suppressor protein p53 has been postulated.[169–171] An association with various other proteins has reported proteasomes and DNA-repair factor[172] being detected more consistently by the two-hybrid system.

## Replication of HBV

### The life-cycle of the virus

As with all other viruses, the life-cycle of HBV and its relatives in the animal kingdom can be divided into several steps: (1) attachment of the virus to the host cells, (2) penetration into the cell, (3) subsequent transport into the compartment in which replication occurs, (4) release of the viral genome, (5) transcription and translation of viral gene products, (6) replication of the viral genome, (7) assembly of virions, and (8) release of the virus. Unlike most other viruses, HBV comprises a further pathway, allowing the entry of newly synthesized viral DNA from the cytosol into the nucleus. The following section describes these various steps, which are shown schematically in Fig. 10.5.

### Attachment

Virus attachment is one of the crucial steps that determines, among other factors, the host range and organ tropism of viruses. Furthermore, blocking of attachment by neutralizing antibodies against surface epitopes is a major component of protective immunity and the basis of many antiviral vaccines. Thus, it is interesting to identify the viral attachment site(s) and the corresponding cellular receptor(s).

#### *Infectivity systems*

A great drawback of many of the studies on the attachment of HBs proteins to cell surface proteins is that target cell lines were not *susceptible* to HBV infection even if they were permissive for HBV replication after transfection. A striking example is the human hepatoma cell line HepG2, which cannot be infected but replicates and secretes infectious HBV quite efficiently after transient or stable introduction of HBV DNA.[32,173]

Obviously, the lack of replication in cell lines is not caused by their missing ability to synthesize progeny virus but by one of the steps required for viral uptake and establishment of infection. Established cell lines are not as differentiated as hepatocytes in their natural environment. Primary hepatocytes were thus used as infectivity systems. In fact, hepatocytes from newly hatched ducklings were shown to be susceptible for the duck hepatitis B virus[174] as well as primary woodchuck hepatocyte cultures[175] and primary hepatocytes of human origin[176–178] are also susceptible for WHV and HBV, respectively. All primary hepatocytes retained their specificity for their natural virus with the exception of primary hepatocytes from *Tupaia belangeri*, which turned out to support infection of HBV and the hepatitis B virus of the woolly monkey.[19,20] However, no *Tupaia* HBV is known.

All primary hepatocytes have in common that they lose their susceptibility to their corresponding virus within a few days after they are taken into culture. It is thought that this phenomenon is caused by an ongoing de-differention process, as the presence of differentiation supporting agents such as DMSO preserves susceptibility for up to 10 days.

Human hepatocytes are not readily available. The need for a readily available cell line allowing study of the entry process of hepadnaviruses and infectivity resulted in extensive research. After years, the problem was recently overcome by a newly established hepatocyte cell line of human origin.[179] This cell line preserved susceptibility to HBV and shows replication comparable to primary hepatocytes, but like all primary hepatocytes the number of progeny hepadnaviruses secrete from the cells is lower

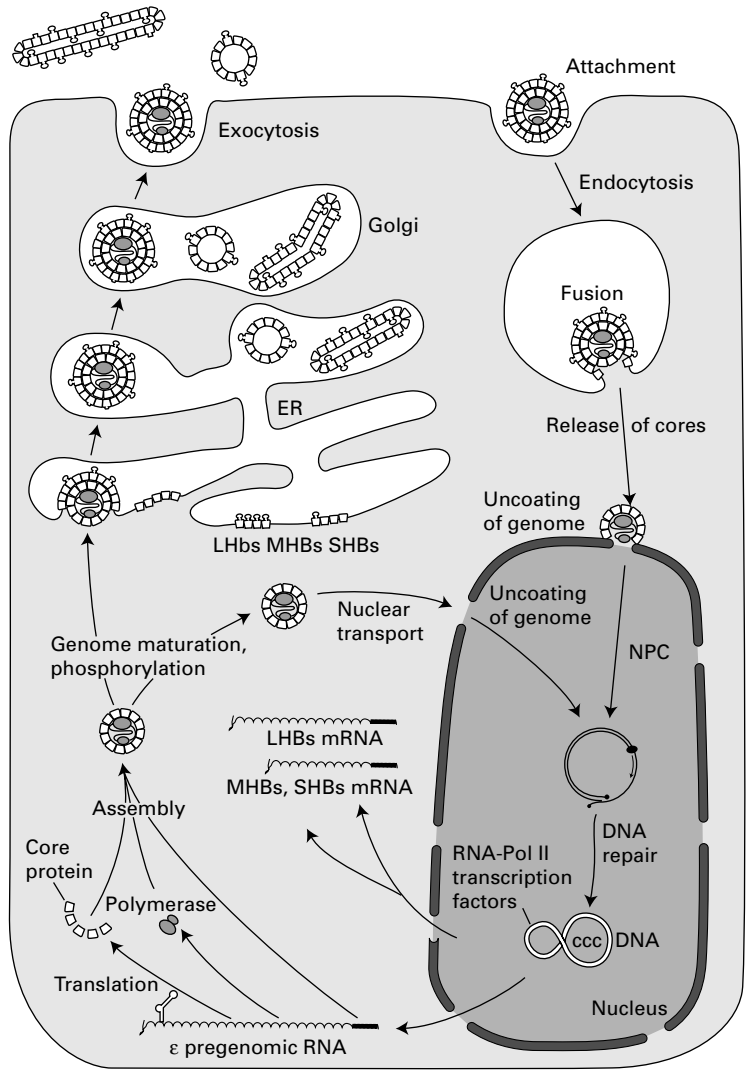

**Figure 10.5** Schematic view of the life-cycle of HBV. In many details, this model is still speculative. It is assumed that the virus is endocytosed after attachment, the nucleocapsid is released to the cytosol, transported via microtubules and binds to the nuclear pore. The capsid is transported into the nuclear basket where the genome is released, converted to cccDNA and transcribed to three essential classes of mRNA. The non-essential HBe and HBx synthesis is omitted for the sake of simplicity. Translation of the core/pol transcript in the cytosol allows for assembly of core particles that contain the pregenome. The transcripts for LHBs and M/SHBs are translated at the rough ER, and the HBs proteins are inserted in that membrane. The HBs particles bud to the lumen of the intermediate compartment, and at least a part of LHBs-rich ER membrane areas envelopes core particles. The HBV and HBs particles are secreted thereafter by the constitutive pathway.

than the number subjected to them.[176–179] This relatively high resistance of hepatocytes in culture contrasts sharply with the high infectivity of HBV *in vivo*.

To achieve high transfer efficiency, hybrids of adenovirus carrying a dimeric HBV genome were constructed, allowing the highly efficient adenoviral transfer.[180] Their use is restricted to the analysis of post-entry steps.

### *Attachment*

The reason for the insusceptibility of long-term hepatocyte cultures to HBV infection is not fully known, but it appears that it is due to a block in early steps of the viral life-cycle. It was thus speculated whether the block of infection is caused by a lack of HBV receptors that are lost when cultivating hepatocytes. However, an organ- and species-specific attachment of serum-derived HBs particles was found by Neurath *et al*.[181] with HepG2 cells, but not with animal liver cells or human carcinoma cells of non-hepatic origin. The binding could be *blocked* by antibodies to the pre-S1 sequence 21–47, and *competed* for by the peptide sequence itself. The relevance of this attachment site was confirmed by studies using natural, purified HBV particles and plasma membrane preparations from surgically obtained human liver specimens.[182] Furthermore, antibodies to peptide pre-S1 (21–47) were able to neutralize *in vitro* HBV inocula, which were no longer infectious.[78] Monoclonal antibodies to this region could block attachment to HepG2 cells or infectivity for primary human or *Tupaia* hepatocyte cultures.[19,183,184]

Avian hepadnaviruses comprise only a single non-glycosylated pre-S region. The involvement of the pre-S region in hepadnaviral attachment was supported by Ishikawa and Ganem using the DHBV system.[185] Pseudotyping heron hepatitis B virus with an envelope containing instead of HHBV pre-S the DHBV pre-S region, or parts thereof, allowed efficient infection of duck

hepatocytes for which HHBV is poorly infectious. Most recent studies indicate, however, that species-specificity is more complex. Replacing – vice versa – the apparently critical DHBV pre-S part by HHBV sequences in a replication-competent DHBV allowed efficient *in vivo* infection of ducks, arguing against the assumption that pre-S is restricting the avian host range (Dallmeier, Schultz, Nassal, unpublished observations).

Pre-S of avian hepadnaviruses and pre-S1 of mammalian hepadnaviruses are essential for viral attachment. It was shown consistently that pre-S of DHBV binds to a membrane-bound member of the carboxypeptidase gene family (carboxypeptidase D, CPD),[186,187] formally termed gp180. Binding to this receptor and infectivity can be blocked by peptides of the pre-S region and the affinity was shown to be extremely high.[188] The mode of pre-S-CPD binding appears to occur in two steps. Initially, a short α-helix in the C-terminus of the receptor binding domain facilitates formation of a primary complex, followed by stabilization, which involves approximately 60 most randomly structured amino acids.[189] Interestingly, the receptor becomes downregulated in infected hepatocytes,[190] which is in accordance with the observation that co-infections of single cells are rare. However, carboxypeptidase D is expressed in a variety of tissues so that the specificity for hepatocytes must be given by additional factors. This may include the fact that to reach the hepatocytes circulating hepadnaviruses have to pass the liver sinusoidal endothelial cells (LSECs) and the space of Disse first. Such a model was proposed from observations showing that DHBV shows a preferential uptake into LSECs. Intracellularly, fluorescent virus particles co-localized with CPD, suggesting receptor-mediated rescue from lysosomal degradation. To comply with the high efficiency by which hepatitis B viruses infect hepatocytes *in vivo*, it was proposed that DHBV is thereafter released to infect adjacent hepatocytes, which are the only cells capable of replicating the virus.[191]

### *SHBs and attachment*

Studies with HepG2 cells,[181] liver plasma membranes[180] and *Tupaia* hepatocytes[19] suggested that SHBs is not involved directly in attachment, but Hertogs *et al*.[192,193] observed attachment of SHBs particles to hepatocyte-bound endonexin II. Furthermore, attachment of SHBs to an altered form of apolipoprotein H has been reported[194] for HBV. The significance of these findings remains unclear. The existence of neutralizing antibodies toward SHBs and of escape mutants to those antibodies (see Chapter 11) suggests that SHBs structures participate in the attachment, entry, or both. Alternatively, such antibodies may mediate aggregation and immune elimination of HBV or hinder sterically the pre-S domains.

## Virus penetration

Three mechanisms are known by which animal viruses can enter a cell. The first is a direct fusion of the viral envelope with the plasma membrane once the virus is bound by the receptor. This process is restricted to enveloped virus such as herpes simplex virus 1, for example.[195] In both other pathways, the virus becomes incorporated into a vesicle after binding to the cell surface. The vesicle – either caveosomes as described for SV40 or endosomes that are apparently the most frequently used pathway – is released from the plasma membrane into the interior of the cell. Within the cell, these organelles are subjected to complex shuttling that is mediated by the cellular microtubule network.

Endosomes are transported towards the microtubule-organizing centre that is located in the periphery of the nucleus. For successful infection, the virus has obviously to escape from the endosomal pathway before the endosome is converted to an acidic phagolysosome. Most viruses using the endosomal uptake make use of the stepwise acidification. The decrease of the pH causes a structural change in the topology of the surface proteins, which allows their insertion into the endosomal membrane, as described for influenza virus. In addition, essential proteolytic modifications can be involved, as demonstrated for adenoviruses, for example. Both strategies result in a pore of the endosome allowing the viral interior to enter the cytoplasm.

The mechanism of HBV entry into hepatocytes is not completely understood. Using primary hepatocytes, an uptake via endocytosis has been shown for DHBV.[196,197] In contrast to most other viruses, this initial step was shown to be independent of acidification. It must be thus assumed that fusion of envelope and endosomal membrane is triggered by receptor binding and/or proteolysis leading to the release of the capsid into the cytoplasm. Consistently, all hepadnaviruses contain a conserved fusion-peptide-like sequence at the amino-terminal end of SHBs that functions in swap experiments with influenza haemagglutinin.[198]

### *Genome release*

It is known that 24 hours after infection with DHBV, DNA occurs in the nucleus and is converted to covalently closed circular molecules.[174] During this time the virus has to penetrate the cell, must be transported through the cytoplasm, followed by the import of the viral genome into the nucleus.

Because of the presence of HBV core particles in the nuclei of infected hepatocytes, it was speculated in the past that the entire core particles were transported into the nucleus. However, recent studies draw a more sophisticated picture of this process, as illustrated in Fig. 10.6.

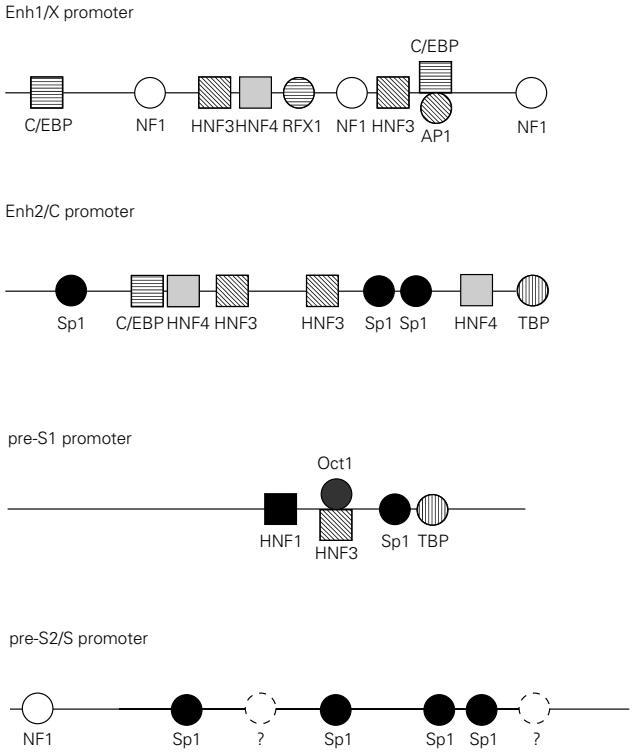

**Figure 10.6** Binding sites for transcription factors in the enhancers and promoters of HBV. C/EBP, CCAAT/enhancer binding protein; NF1, nuclear factor 1; HNF4, hepatocyte nuclear factor 4; AP1, activator protein 1; Sp1, SV40 promoter protein 1; TBP, TATA-box binding protein. Squares represent liver-specific/liver-enriched transcription factors; circles represent ubiquitous transcription factors.

Following the release of the capsid into the cytoplasm (Fig. 10.6 [1]), the capsids are actively transported towards the nucleus. Like other viruses, they make use of the microtubule network, which is the long-range transport system in the cytoplasm (B. Rabe, M. Kann, unpublished observations) (Fig. 10.6 [2]). The interaction with the cellular transport machinery is mediated by the carboxy-terminal portion of the core protein, which becomes exposed to the capsid surface upon phosphorylation within this region.[114] This sequence contains a multifunctional domain. Beside its interaction with cytosolic proteins that facilitate the binding to tubulin, it comprises a nuclear localization sequence (NLS).[114] The NLS causes interaction with importin α, which is an adaptor protein for binding to importin β. The cellular transport receptor importin β mediates binding to the cytoplasmic fibres of the nuclear pores and the subsequent transport through the pore into the nuclear basket (Fig. 10.6 [4, 5]).[199] This structure is a cage-like structure formed by eight filaments at the inner surface of the pore. In fact, electron microscopy after microinjection into oocytes of *Xenopus laevis* showed that HBV capsids entered the basket as entire particles with diameters of 32 and 36 nm (T=3 and T=4 symmetry).[199] This finding was surprising because the maximal functional diameter of the nuclear pore was previously though to be 26 nm. The subsequent re-evaluation of the pore diameter by NLS-coated gold particles consistently showed that cargoes up to 39 nm are able to enter the nucleus.[199]

Another striking result of these studies was that *in vitro* phosphorylated capsids, derived from *E. coli*, entered the nuclear basket but were unable to diffuse deeper into the karyoplasm.[114] In fact, these data obtained by the use of permeabilized cells, which allow a direct addition of capsids into the cytosolic space, are consistent with the observation in HBV-transgenic mice in which the nuclear membrane was shown to be impermeable for nucleocapsids.[200] The data on *E. coli*-derived capsids were confirmed using HBV capsids containing an immature genome[115] (Fig. 10.6). In contrast, virus-derived capsids containing the mature, partially double-stranded genome did not show this arrest but generated intranuclear released viral genomes and intranuclear capsids (Fig. 10.6 [8]), as observed in HBV-infected human livers.

Although the detailed mechanism by which mature capsids release their genomes into the nucleus is still not fully understood, it appears that the mature capsids enter the basket, become arrested as immature capsids but disintegrate during arrest. Consequently, the genome and core proteins that are not subjected to arrest can diffuse into the karyoplasm. The core proteins are thought to reassemble into capsids again once they have reached the threshold concentration for assembly.[111] As unpublished results have shown that the reassembly process is combined with the encapsidation of cellular RNA (Fig. 10.6), it can be speculated that the affinity to RNA – which is known to be higher than affinity to double-stranded DNA[142] – is the driving force for capsid formation.

## Generation of episomal DNA

Recent studies on single DHBV-infected duck hepatocytes revealed that every infected cell contains between 1 and 17 copies of episomal cccDNA showing fluctuation over time.[201] In human livers, copies up to 173 were described as correlated with the activity of infection.[202] It must be assumed that the episomal DNA undergoes degradation, but the half-life was documented to be long. Thus, for persistent infection the pool of the intranuclear viral cccDNA has to be refreshed. Beside degradation, external factors affect the pool of cccDNA. For example, cell division was shown to cause a loss of cccDNA. Most recently, it became evident that this reduction of episomal DNA is triggered by interferon-gamma (IFN-γ)-producing CD8+ T cells in the liver.[203]

To generate the cccDNA, which is the template for transcription and thus generation of progeny virus, the viral genome has to be repaired. This involves (1) the removal of the covalently bound viral polymerase, (2) the conversion of the eight nucleotide-long triple-

stranded region into double-stranded DNA, (3) removal of the RNA primer bound to the 5′ end of the DNA plus-strand, (4) filling the single-stranded gap of the genome and (5) the close of the nicks between the 5′ and 3′ ends of each plus- and minus-DNA strand. After the conversion to the plasmid-like cccDNA, the genome becomes associated with histones forming a mini-chromosome.[204] Interestingly, some viral core protein molecules remain bound to the DNA,[120] raising the speculation that the core protein may be involved in viral transcription by regulating the nucleosomal arrangement of the HBV regulatory elements.

However, most of the conversion processes remain unclear. Based on *in vitro* activities of the topoisomerase I on isolated DHBV virion DNA, Pourquier *et al*. speculated that topoisomerase I activity may be a candidate enzyme for removal of the polymerase.[205] More direct evidence exists for the filling reaction of the single-stranded region. Treating DHBV-infected primary duck hepatocytes with different inhibitors, Köck and Schlicht[206] showed that cellular DNA polymerase and not the viral polymerase is probably involved. However, more recent findings on HBV showed that the polymerase plays an essential role in filling the gap of the plus-strand DNA.[207]

In contrast to the retroviridae, integration of HBV DNA into host cell DNA is not only unnecessary for replication of HBV but even detrimental, because linearization of the circular HBV DNA would disrupt at least one gene. Caused by illegitimate replication, however, a significant proportion of viruses contain a linear viral DNA,[208] thus being a potential source for integration.[209,210] However, depending on the supergenomic size of the functional RNA pregenome, such an RNA pregenome can be transcribed only from linear DNA that is longer than the genome. Such artificial HBV DNA constructs have often been used to transfect cell lines *in vitro*, but integrated replication-competent HBV DNA molecules are not found in HBV-infected liver or naturally occurring hepatocellular carcinomas (HCCs). Integrated HBV DNA often contains fusions between HBV genes and host cell genes. The resulting neoproteins may acquire novel properties and have been found in certain HCCs as potentially oncogenic factors (see Chapter 44).

## Transcription of HBV DNA

### *General aspects of transcription*

Transcription of double-stranded DNA into RNA is a highly regulated process that controls the expression of all genes, whether from the host or the virus, in a timely and structurally ordered manner. Thus, all genomes, including those of the smallest replication-competent DNA elements, contain not only structural genes that encode protein sequences but also regulatory elements. These DNA sequences bind a number of cellular or viral proteins that act as positive or negative transcription factors. Positive factors bind the cellular RNA polymerase II at a more or less defined position of the DNA sequence, where it initiates RNA synthesis. The RNA polymerase transcribes one strand of the double-stranded DNA into RNA until a termination signal for this enzyme in the DNA sequence occurs.

Two types of DNA sequence elements contribute to the binding of transcription factors. Promoters are necessary for binding of essential transcription factors and bring the RNA polymerase into position, where it begins to transcribe only one DNA strand at a defined site. Many promoters contain the so-called TATA box, which binds transcription factor TFIID. This factor binds RNA polymerase II in a way that transcription initiates approximately 30 bases downstream. *Enhancers* are DNA segments that enhance transcription initiation at a given promoter, but they do not need to be in an exactly defined position next to the promoter, and their sequence orientation may even be inverted without impairing their activity. Many enhancers, like those of HBV, may act on expression of several genes.

The rate of RNA synthesis beginning at a promoter is controlled by the amount, type and activity of positive transcription factors available in the host cells and by the accessibility of enhancers and promoters. There are some essential ubiquitous transcription factors, others are organ-specific, and furthermore factors may be inducible by intracellular or extracellular signals. Most regulatory gene sequences also contain negative elements that counteract the effect of promoters and enhancers by binding negative transcription factors. Such sequence elements are termed *silencers*.

### *Promoters of HBV*

At least four promoters and two enhancers have been identified in the HBV genome.[211,212] These promoters direct initiation of RNA synthesis upstream of the HBc/e gene, LHBs gene, M/SHBs gene, and the HBx gene (Plate 10.1a, found between p.786–7). Only the LHBs promoter (often referred to as S promoter I, SPI) has a typical TATA box, which positions RNA-polymerase II via TFIID (transcription factor IID) and only the mRNA-encoding LHBs protein has a sharply defined 5′ end. The TATA-less promoters usually have multiple initiation sites, and this is indeed the case for the HBc/e, M/SHBs and X mRNAs. As a result, the corresponding sets of mRNAs with microheterogeneities at their 5′ ends are able to encode nested sets of co-terminal proteins. The two longer of the HBc/e mRNAs encode HBe protein, the shorter starts four bases after the start codon for the HBe protein. In this case, the ribosome can only use the

next start codon for protein synthesis that defines the amino end of HBc protein. A similar phenomenon occurs in the mRNAs encoding MHBs and SHBs. Only the largest of three mRNAs that are initiated at this promoter (also known as SPII promoter) contains the start codon for MHBs. The other two mRNAs contain only the proximal start codon of SHBs. Whether there are mRNAs that encode only smaller HBx proteins but not full-length HBx protein is not clear.

The relative activity of the four identified promoters and the fine specificity of the heterogeneous 5′ ends depend on the cell type in which the HBV genome or fragments thereof are expressed. It appears that the M/SHBs promoter and the HBx promoter are constitutively active in all mammalian cell lines.[213] The M/SHBs promoter contains, for example, four binding sites for ubiquitous constitutive transcription factor SpI.[214] The relatively weak LHBs promoter requires the hepatic nuclear factor 1 HNF123 and HNF3.[215] The HBc/e promoter overlapping enhancer II also binds liver-specific transcription factors such as HNF3, C/EBP[216] and HNF4[217] in order to be activated. Thus, transcription predominantly occurs in liver cells. It is not completely clear whether the promoter for the HBe mRNA (i.e. the 'precore' mRNA) and HBs mRNA (i.e. the 'pregenomic' RNA) can be sharply divided, but it is evident that core and HBeAg synthesis are not always correlated[218] and are activated by different transcription factors (see below). However, RNA synthesis from the core promoter is thought to represent a major determinant governing the hepatotropism of this virus.[219] In addition, mutations in the core promoter are correlated with the response to interferon-alpha therapy.[220] A survey on some binding sites for transcription factors in the promoter/enhancers and regulatory elements of HBV is shown in Fig. 10.7.

Because the proteins expressed by the corresponding mRNAs are absolutely necessary for genome replication and virion assembly, the liver specificity of the transcription signals in the HBV genome may already sufficiently explain its organ tropism. Replacement of the liver-specific HBc/e promoter by a ubiquitously active promoter such as the immediate early promoter of cytomegalovirus allows replication of the HBV genome and assembly of complete core particles in non-hepatic cell lines.[221] Addition of the SV40 enhancer to the HBV genome also allows for generation of virus-like particles in mouse fibroblasts,[222] but the secreted HBV-like structures lacked HBc and LHBs proteins.

### *Enhancers*

To ensure that mRNA synthesis occurs in an orderly manner enhancers may up- or downregulate the activity of the promoters. In addition to host-specific uptake, these promoters restrict expression of a virus to certain cell types. To date two enhancers (I and II) have been identified on the hepadnaviral genomes. The major stimulating element is the enhancer I that enhances the initiation of transcription by a factor of 10–50 in liver cells. Enhancer I is located between the S and the X gene. It spans approximately 200 nucleotides to which numerous factors can bind. While some of them are ubiquitous (e.g. NF-1, AP-1, NFκB), others (e.g. C/EBP, HNF-4, HBLF[223,224]) are liver-specific, restricting the stimulating effect on the hepadnaviral promoters mainly to hepatocytes.[212,225] However, the liver specificity is predominantly caused by enhancer II, which overlaps the pre-C/C-promoter.[216] Its liver specificity is determined by binding to liver-specific transcription factors such as C/EBP, retinoid X alpha (RXRα), the peroxisome proliferator-activated receptor alpha (PPARα) heterodimer and HNF-4, which act differentially on different promoters and thus modulate viral synthesis.[226] Whereas HNF-4 and the nuclear hormone receptors RXRα and PPARα support HBV replication by supporting transcription of the pregenomic RNA, HNF-3 inhibits pregenomic RNA synthesis compared with that of precore RNA. Downstream of the core promoter located promoters in contrast are stimulated by HNF-3, possibly by interfering with the elongation rate of these transcripts.[226] Corresponding to these observations, the enhancer II does not stimulate all viral promoters. While the S promoter is stimulated 10-fold both *in vivo* and *in vitro*, the LHBs promoter appears to be unaffected in both experimental situations.

### *Other regulatory elements*

In addition to the enhancers, three other regulating elements of hepadnaviral transcription were identified. Addition of dexamethasone activates the glucocorticoid receptor, which then binds to the glucocorticoid responsive element (GRE) of the HBV genome. The GRE is located between enhancer I and II and contains two copies of the hexanucleotide 'TGTTCT'. Binding to the GRE enhances transcription further by a factor of 2–5,[227] but does not interact as an independent enhancer element. The stimulating effect may be also be present *in vivo* because glucocorticoid-treated patients express very high levels of HBV, HBeAg and HBsAg.[228]

Two other *cis*-acting elements were identified on the hepadnaviral DNA. The negative regulating element (NRE) inhibits only the transcription from the core/precore promoters with which the NRE overlaps.[229] The so-called CCAAT element was identified overlapping the S promoter.[230] It negatively effects transcription from the upstream located pre-S1 promoter, at least when the CCAAT binding protein is present in high amounts. In contrast, the CCAAT element enhances transcription of the S mRNA, so it was hypothesized that the element is involved in ordered

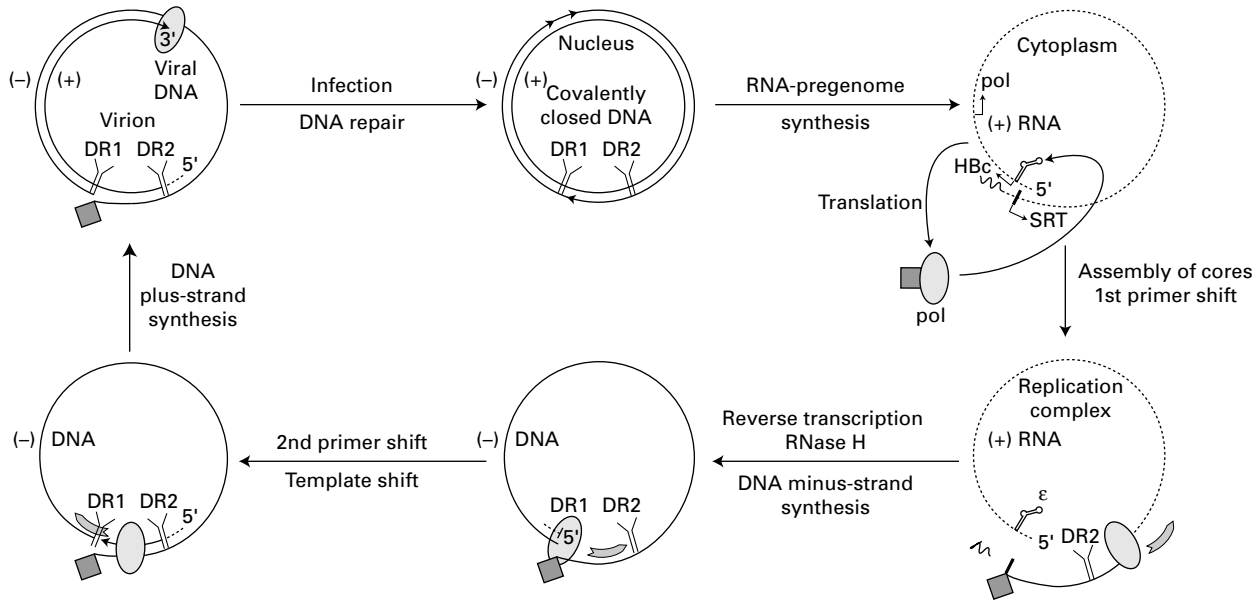

**Figure 10.7** Replication of the HBV genome. The virion DNA (top left, see also Plate 10.1a, found between p.786–7) is brought by the pathway shown in Fig. 10.5 to the cell nucleus and is converted to covalently closed DNA. This episomal DNA is transcribed to various RNAs (see also Plate 10.1a, found between p.786–7 and Fig. 10.5), one of which serves as a template for the polymerase protein (→) and HBc protein (→). These two proteins assemble together with their mRNA to the replication complex. The encapsidation signal ε at its 5′ end governs the packaging of the RNA and the priming of the minus-strand DNA. The redundant part at the 3′ end serves as a signal for the reverse transcription (SRT) after priming. The primase domain of the polymerase (♦) serves as a primer for the reverse transcriptase. Thus, the growing minus-DNA strand (see bottom right) is linked at its 5′ end to the primase. Details of the priming at ε and the first primer shift to the DR1* at the 3′ end of the pregenome are shown in Fig. 10.9. The reverse transcription proceeds until the 5′ end of the RNA template is reached (bottom centre). Thus, a short redundancy is generated in the minus-strand. The RNase H activity associated with the reverse transcriptase degrades the RNA template and leaves at its 5′ end an 18-base-long capped RNA fragment. This fragment has a 6-base homology to the direct repeat DRI and DR2. This weak interaction allows shifting of the fragment and of the reverse transcriptase/DNA polymerase from DR1 to DR2. There, the RNA fragment functions as primer for the plus-strand DNA. The DNA polymerase is able to cross the discontinuity in the minus-strand template because of its short terminal redundancy. Thereafter, the structure of the virion DNA is reproduced. The multiplication effect originates from the fact that one episomal HBV genome can be transcribed to many pregenome molecules by the cellular RNA polymerase II.

expression of,surface proteins to ensure correct virion morphogenesis. Indeed, cloning and expression of naturally occurring mutations of this element were shown to cause retention of the LHBs in the endoplasmic reticulum and one mutation resulted in secretion of malformed viral particles.[231]

### *Viral transcription activating proteins*

All double-stranded DNA viruses and retroviruses contain positive sequence signals for initiation of transcription, but at least in mammalian viruses these *cis*-acting elements are obviously insufficient to warrant highly efficient expression and replication of the viral genome. For most viruses, the first gene products to be expressed are transcription factors that activate promoters of other viral genes in a time-ordered manner. Such products are called immediate early (*i.e.*) genes. The time order of HBV gene expression has not yet been fully analyzed, but it appears that HBx protein is the first protein to be expressed[232] and it has been shown that HBx activates many enhancers (see above). The significance of almost all studies on HBx is hampered by the fact that the effects were observed in cellular systems that either cannot replicate HBV or do not need HBx for expression of HBV from transfected cells. In addition, side-effects of HBx caused by the frequently used high-level transient expression of HBx cannot be excluded.

### *Transcription factors of HBV*

HBx compares with the immediate early proteins of oncogenic DNA viruses such as E6/E7 of papillomaviruses, or EIA/B of adenoviruses. These viral transcription activators are also quite non-specific and also act on cellular growth-controlling genes. It may be noteworthy that the HBx gene contains a weak polyadenylation signal,[233]

which induces a fusion between a truncated HBx protein and polylysine.[234] This HBx variant may be less active in transactivation, but more active in malignant transformation. An effect of an HBV protein on Rb has not yet been observed. However, further transcription activators of HBV have been discovered in HBV DNA-containing HCCs. These are truncated LHBs[235] or MHBs[236] proteins that have lost the sequences necessary for budding and secretion of HBs particles. Although these truncated forms may be rare accidental consequences of the DNA integration, the transactivating effect of the pre-S2 domain[237,238] may also be relevant during normal HBV infection. The transactivating activity depends on the cytosolic localization of pre-S2, which not only occurs with truncated MHBs but also during expression of normal LHBs.[239]

### *Termination of transcription*

As in mammalian mRNAs, all hepadnaviral mRNAs are polyadenylated at their 3′ end. Not only the start but also the stop of transcription is a well-defined and regulated process. It ends at a single polyadenylation signal so that all viral mRNAs are 3′ co-terminal. In all mammalian hepadnaviruses the TATAAA stop signal is located shortly after the start of the HBc gene (Plate 10.1a, found between p.786–7). Thus, the polyadenylation signal for transcription of the supergenomic RNAs encoding for HBeAg, core and polymerase has to be ignored by RNA polymerase II during the first passage. In fact, it was shown that the stop signal needs an additional sequence element upstream of the HBc/e promoter and, furthermore, only becomes active if the initiation site of the RNA is >400 bases distant.[240] In transgenic mice, the recognition of the polyadenylation signal was shown to be tissue-specific.[241]

Due to the leaky stop signal an RNA of supergenomic length is generated, starting upstream or within the pre-C sequence and ending within the core gene. It has redundant ends ('R'), which are essential for the genome replication of hepadnaviridae (Plate 10.1b, found between p.786–7). All other RNAs of HBV are shorter than genome length. Thus, RNAs of 3.5 kb for HBc/e, 2.4 kb for LHBs, 2.1 kb for M/SHBs and 0.8 kb for HBx are formed. They are all 3′ co-terminal and are, with the exception of the X-mRNAs, polycistronic. The existence of several promoters and one common stop signal is an elegant way to express several different translation products from one very compact genome with overlapping genes. This expression strategy is unique to *Hepadnaviridae*.

### *Processing of HBV RNAs*

After transcription, RNAs are modified by addition of methylated bases to the 5′ end (known as cap) and addition of a polyA tail at the 3′ end. Eukaryotic mRNAs are further modified by splicing, i.e. removal of internal non-coding RNA regions (introns) and ligation of the remaining fragments (exons) which finally constitute the mRNAs. The splicing is essential for export of the mRNAs from the nucleus.

However, like many retroviral mRNAs, all known HBV genes are contiguous and, thus, the mRNA precursors mentioned previously must not be spliced, although numerous potential splice signals are present in the RNA. HIV has solved the problem by using the *cis*-acting so-called Rev responsive element (RRE) that binds the viral Rev protein to access the RNA-export pathway Rev mediated by CRM1-mediated nuclear export that is normally used for export of cellular proteins and RNAs (U snRNAs and 5 S rRNA). In contrast, other retroviruses use a constitutive transport element (CTE) for the same purpose. The CTE directly recruits the cellular mRNA export receptor TAP to the viral RNA to override nuclear retention.[242]

Although the molecular mechanism of nuclear export of hepadnaviral mRNAs is not fully understood, a bipartite splicing inhibiting RNA sequence was identified.[243–245] Termed post-translational regulatory element (PRE) it consists of two conserved RNA stem-loops – HPREα and HPREβ – that are required for function.[246] The PRE overlaps the X promoter and most of the X gene. Without the PRE abundance of cytoplasmic HBV RNA is much lower. Thus, the element may be necessary for both splice regulation and RNA transport.

However, recently a spliced RNA has been found in DHBV. This RNA starts at the 5′ end of the pregenomic mRNA and fuses the core with S gene. Mutations of the splice acceptor and donor sites showed, surprisingly, that this RNA appears to be essential for virion production.[247] Spliced HBV RNAs are also found in human HCCs.[248] In chronic HBV carriers a fusion protein of polymerase and an unused ORF was described,[249] inducing antibodies in patients. The appearance of these antibodies was correlated with liver fibrosis.[250]

## Translation

### *General aspects of translation*

Protein synthesis in eukaryotic cells is predominantly regulated by the site and frequency of its initiation at the mRNA. The scanning model of this process applies to most mRNAs. The small ribosome subunit binds to the 'capped' 5′ end of the mRNA and scans thereafter the sequence until an AUG start codon for methionine occurs. Protein biosynthesis starts from this site after binding of initiation factors and the large subunit of the ribosomes. Flanking bases influence the efficiency of protein synthesis at a start co-

don. A purine at the +4 and/or –3 position is usually found in initiation codons, but not in internal codons for methionine.[251] Additionally, a stem-loop structure on the RNA, about 30 bases downstream of the start codon, can enhance the start of protein synthesis.[252] Synthesis stops at one of the three possible stop codons UAA, UAG or UGA, which occurs first in this particular ORF. Thus, the position of the 5′ ends of the mRNAs in the HBV genome determines which gene product is expressed. Exceptions to this rule are internal ribosome entry sites (IRES), leaky scanning for start codons, usage of atypical start codons, read-through of stop codons, frame shifting and reinitiation. Some of these exceptions may apply to the translation of certain HBV proteins.

An important early step in protein biosynthesis is the distribution of the protein synthetic complex between the cytosol and the ER. Nascent protein chains that contain a hydrophobic α-helical stretch of 16–20 amino acids bind to a signal recognition particle that attaches the ribosome to a pore-like structure at the ER. The growing peptide is transported through this pore to the lumen of the ER. The particular structure and number of such hydrophobic signal sequences determine the intracellular distribution, membrane topology or secretion of the protein. Proteins without signal sequence are synthesized by free ribosomes and released after completion to the cytosol. Enveloped viruses with subgenomic mRNAs such as HBV normally use free ribosomes for synthesis of their nucleocapsid proteins, and ER-bound ribosomes for synthesis of the enveloped protein (Fig. 10.5).

### *HBe protein*

The HBe protein is translated from the longest mRNA. As mentioned above, this RNA differs from the pregenomic mRNA in that it comprises an additional start codon at its 5′ end. The translation initiation at this precore start suppresses the use of downstream-located AUGs.[253] This includes the core start codon that is 'in frame' with the precore AUG. In consequence, the primary translation product comprises a 29 amino acid signal sequence amino-terminally of the core protein. The precore targets this 25-kDa protein to the ER lumen where a cellular signal peptidase at the ER lumen removes the first 19 amino acids of the precore region.[125] The remaining 10 amino acids of the precore cause a folding different to that of the core protein, allowing dimerization but no further assembly of these dimers to capsids. Further proteolytic processing of the HBe-protein probably occurs in the trans-Golgi apparatus.[126] This cellular compartment contains proteases that cleave within the arginine-rich carboxy-terminal domain of the HBe protein so that the processed protein has a molecular weight of only 15 kDa. However, as the signal peptide of HBe protein is not particularly strong, a significant part of the HBe protein remains cytoplasmic.[127] The amount of synthesized HBe protein relative to other HBV proteins is probably regulated by the level of mRNA containing the start codon of an uninterrupted HBe gene. Many patients have HBV variants where little or no HBe mRNA is made because of mutations in enhancer II or the HBc/e promoter. Even more frequent are variants with a stop codon in the pre-C sequence (see Chapter 11).

### *HBc protein*

The start codon of HBc protein has two guanosines at position –3 and +4, which is a relatively good but not optimal context for initiation because it is localized within the stem of the encapsidation signal ε. Nevertheless, a highly efficient translation of the HBc mRNA is necessary, because at a critical level of HBc protein and polymerase protein, this mRNA is encapsidated into core particles and is no longer available for protein synthesis.[140] The overlapping use of this mRNA could suggest that core and polymerase are translated from the same RNA species but from different RNA molecules. However, recent data showed *cis*-preferential recruitment of duck hepatitis B virus core protein to the RNA/polymerase preassembly complex.[254]

### *Polymerase*

An intensive search for an mRNA containing a 5′ end slightly upstream of the presumed amino end of the polymerase sequence was not successful, although a very low abundant mRNA for polymerase cannot strictly be excluded. Most members of the orthoretroviridae express their polymerase via a frame shift between the ORFs of gag (i.e. the analogue of HBc protein) and pol, thus generating a gag-pol fusion protein. Mutational analysis excluded this possibility for HBV. Instead, an unusual internal initiation of the pol protein synthesis at the HBc mRNA is implied. This would generate a full-length non-fused HBV polymerase by translation initiation.[132,255] A leaky scanning mechanism appears possible, because an optimal start codon of ORF C seems to reduce the efficiency of pol expression.[256] There are, however, several initiation codons upstream in the HBc mRNA, which should be even stronger. The existence of a weak IRES in proximity to the pol start codon would be another obvious explanation.[257] Ideally, the relative frequency of initiation at the HBc or pol start should regulate the required proportion of HBc to pol protein, which is probably 240:1. However, recent analysis revealed that the polymerase is relatively overexpressed and

that the majority of hepatitis B virus reverse transcriptase in cells is non-encapsidated but is bound to a cytoplasmic structure,[258] as was determined for DHBV. Polymerase was translated at a rate of 10% compared to core, whereas the half-life of non-encapsidated polymerase was very short, indicating that the translation rate of the polymerase is not limiting for encapsidation.[259] The inability of the polymerase to act on exogenous substrates lacking epsilon prevents massive interference with host RNAs.[135,260]

### *LHBs*

Initiation of LHBs protein synthesis follows the usual rules.[261] It occurs initially in the cytosol because the pre-S domains do not contain an ER translocation signal peptide. The signal peptides I and II of the S domain insert into the ER membrane, but the entire pre-S domain is too long to be translocated to the ER lumen during protein synthesis[86] and interacts with cytosolic factors. In agreement with this conclusion is the absence of glycoside in the pre-S2 domain of LHBs. The amino-terminal methionine is substituted by myristic acid. The central hydrophilic part of the S domain, however, is in the lumen of the ER and more efficiently glycosylated than the S domain of MHBs or SHBs.[262] The mRNA for LHBs is not translated into MHBs or SHBs.[261,263]

### *MHBs and SHBs*

These two gene products are usually co-expressed because of the common promoter for their mRNAs. It is not clear which factors control the relative ratio between the mRNAs containing a start for MHBs or only for SHBs. Irrespective of this transcriptional regulation, the ratio between MHBs and SHBs is also regulated at the translational level. The start codon of MHBs does not have the optimal flanking bases, whereas that of SHBs is optimal for initiation of protein synthesis. Thus, mRNAs for MHBs also always express some SHBs unless the start codon of SHBs has been mutated.

Signal I of the S domain is obviously able to translocate the pre-S2 domain of MHBs to the ER lumen, because most of the MHBs is glycosylated in secreted HBs particles.[264] However, the folding of the nascent S domains seems to be slightly different in MHBs and SHBs, because the S domain is only rarely glycosylated in MHBs.[262] Truncation of MHBs at the predicted transmembrane helix III leads to a topology where pre-S2 is not translocated to the ER lumen.[238]

### *HBx*

Translation of HBx protein(s) may occur also from mRNAs that contain or do not contain the first start codon of ORF X,[213] but the size of naturally occurring HBx proteins has not yet been reliably elucidated. Sequence predictions suggest that it is a cytosolic protein. Overexpression of HBx protein using vaccinia vectors suggests that it is a very labile phosphoprotein within the cell, with a half-life of 20 minutes.[155] The high insolubility of HBx protein suggests that it oligomerizes rapidly or binds to other cellular proteins.

## Assembly of HBV

### *General strategy of genome maturation*

The actual multiplication of the HBV genome occurs in the nucleus of the infected cell by the cellular RNA polymerase II, which transcribes the circular HBV DNA to more than genome-length mRNA with redundant ends (see Plate 10.1b, found between p.786–7). All gene products of HBV (probably with the exception of HBx protein) are used to encapsidate that RNA, transcribe it to a circular DNA, and secrete it as an enveloped virion with attachment sites for new target cells. An overview is shown in Fig. 10.8.

### *Encapsidation of pregenomic RNA*

After translation of sufficient amounts of HBc and polymerase proteins, these proteins assemble together with their mRNA, and cellular proteins, including the heat shock protein Hsp90, the co chaperone p23, and additional, as yet unknown, factors.[143–147] Core particle formation includes the encapsidation of a cellular protein kinase, the identity of which is controversially discussed. Encapsidation occurs only when the polymerase interacts with a specific RNA sequence present at the 5′ end (base 1846 to base 1907) of the HBc mRNA.[141] This signal is termed ε (for encapsidation) and acts predominantly in cis to the polymerase. ε is characterized by a secondary structure consisting of a stem, a bulge, a loop and a non-paired U (see also Fig. 10.9),[265–267] but binding of the polymerase alters the structure of ε[268] and binding to ε is required for activation of the polymerase.[260] However, fusions of ε to heterologous RNAs failed to cause encapsidation. This observation initiated a search for additional sequences required for packaging. Indeed, a second region – termed ε II that is 900 nucleotides 3′ of ε I – was found to be essential at least in avian hepadnaviruses.[269] In addition, this observation may explain why only the pregenomic RNA is encapsidated, although the signal sequence ε is present on the 3′ ends of all hepadnaviral RNAs.

### *Initiation of reverse transcription*

In HBV-expressing cells genome maturation (e.g. re-

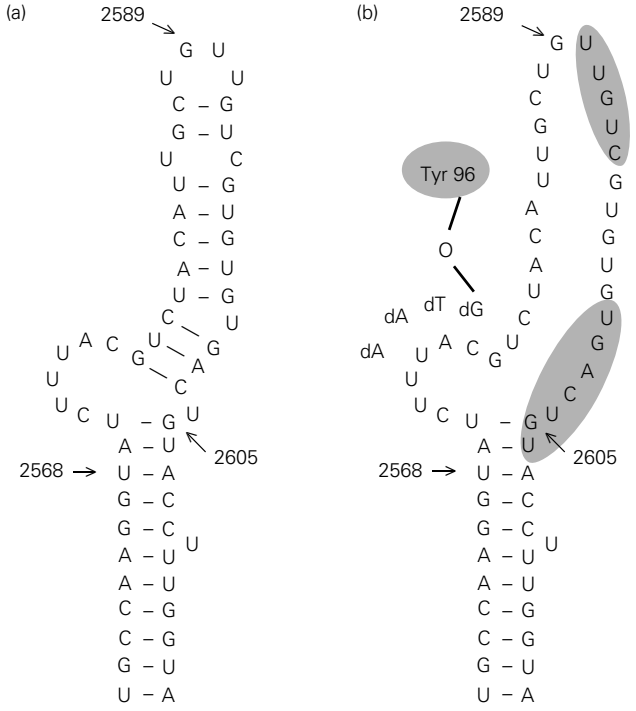

**Figure 10.8** Structure of the DHBV ε as the free form (a) and after binding of the polymerase (b) (modified from Beck and Nassal[268]). Sites of ε interacting with the polymerase are shown as grey shadows. The priming of the DHBV DNA minus-strand starts within the bulge region in the 5′ terminal ε. Priming is initiated by covalent linkage of the first nucleotide with Tyr96 of the DHBV polymerase. After synthesis of the first four deoxynucleotides, the polymerase-oligonucleotide complex switches to DR1 (see Fig. 10.8).

verse transcription to minus-strand DNA and plus-strand DNA synthesis) is a tightly coupled event and seems to occur exclusively within the core particles. However, expression of an active DHBV polymerase in a cell-free system showed that in these systems the first steps of DNA synthesis may occur in the absence of core protein. Using this system, it could be shown that minus-strand DNA synthesis starts in the bulge of the ε-signal. In contrast to that of retroviruses, hepadnavirus replication is initiated *de novo*, i.e. without a nucleic acid primer. Instead, the –OH group of a tyrosine in the amino-terminal domain of the polymerase (Tyr 96 in DHBV,[270] Tyr 63 in HBV[41]) is used for formation of a phosphodiester linkage to the first nucleotide. Due to this mode of initiation, the polymerase becomes and remains covalently linked to the DNA minus-strand.

### *Elongation of DNA minus-strand*

After synthesis of the first four nucleotides within the bulge (DHBV), the polymerase together with its covalently bound nucleotides dissociates from its template and re-anneals with a complementary sequence in the DR1 close to the 3′ end, which was previously named signal for reverse transcription (see Plate 10.1b [found between p. 786–7] and Fig. 10.8). Experiments on the expression of the HBV polymerase confirmed this initiation model for the human hepatitis B virus,[271] although the homology between the bulge and DR1 in all human HBV genomes is restricted to three nucleotides. Because there are many sequences complementary to the three or four initial bases of the minus-DNA strand within the hepadnavirus genome, an additional process must be involved in correct transfer of the polymerase nucleotide complex. Using mutagenesis analysis, a sequence element designated phi located upstream of the 3′ DR1 sequence was identified that is complementary to ε and is important for efficient viral replication. It was hypothesized that this element brings the 3' DR1 sequence into proximity with the three nucleotide primer synthesized at the bulge of ε.[272]

Minus-strand DNA synthesis continues after priming and translocation to the 3′ terminal DR1 of the pregenomic RNA. From mapping the 3′ end of the minus-DNA strand, it appears that this strand nearly coincides with the 5′ end of the pregenomic RNA. Thus, the 3′ end of the minus-DNA strand is specified by 'run off', when the polymerase reaches the end of its RNA template, resulting in a terminal redundancy of the minus-DNA strand of 8–10 nucleotides.

### *RNase H and priming of the DNA plus-strand*

All reverse transcriptases are associated with an RNase H activity, which cleaves the RNA of RNA–DNA hybrids into oligoribonucleotides. Mutational inactivation of the RNase H domain in the HBV polymerase results in a block of DNA plus-strand strand synthesis.[273] However, the RNase H domain of HBV polymerase is not able to cleave the last RNA nucleotides, bound to minus-strand DNA. Thus, an 18-base-long capped RNA fragment from the 5′ end of the pregenome is generated. This fragment dissociates by unknown reasons from its 5′ terminal DR1 in the DNA minus-strand and is translocated to DR2. Here, it functions as a primer for the DNA plus-strand. The DNA begins with the last base of DR2[274,275] and continues towards the 5′ end on the minus DNA strand. Here, the plus-DNA strand synthesis crosses the discontinuity at the 3′ and 5′ ends of the minus-DNA strand leading to a circular DNA genome. Obviously, the specific primer translocation and the circularization processes are complex. In addition to the donor and acceptor sequences, three other *cis*-acting sequences, named 3E, M and 5E, contribute to both processes. By disrupting base-pairing between 3E and M3, and between 5E and M5, evidence was obtained that the ends of the minus-strand template are juxtaposed

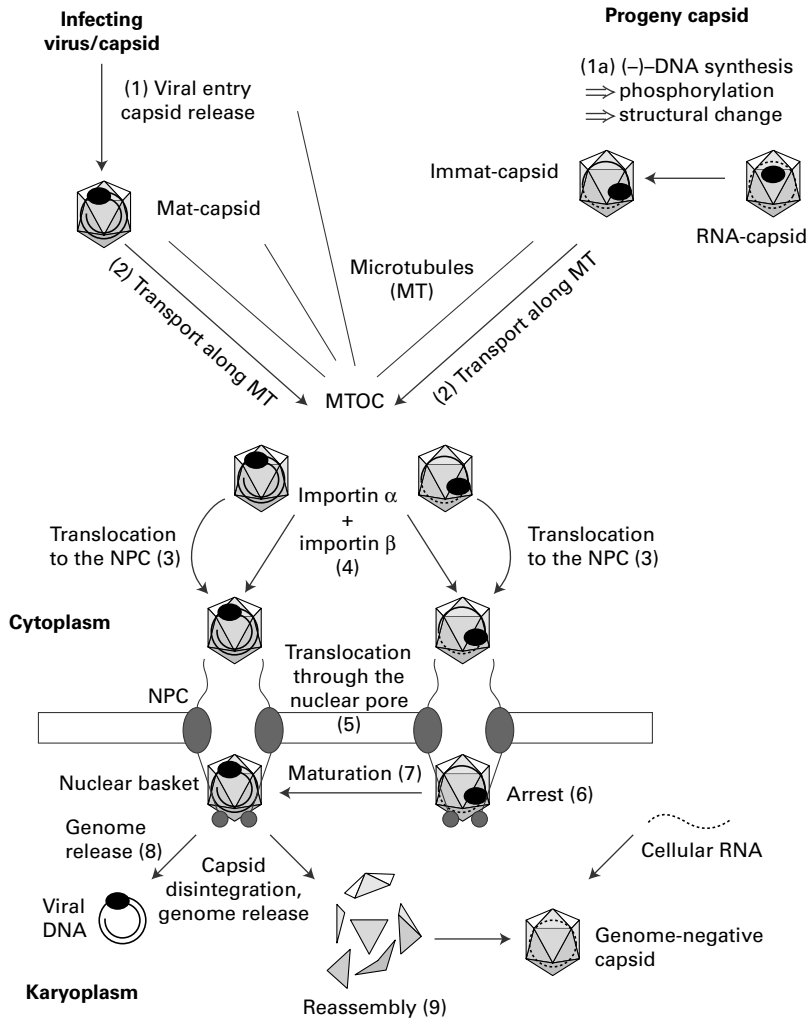

**Figure 10.9** Intracellular transport of HBV capsid and genome. Infection starts with the release of the capsid from the surface proteins (1). The capsid is transported though the cytoplasm towards the microtubules organizing centre (MTOC) using the cellular microtubule network (2), followed by translocation to the cytosolic side of the nuclear pore (3). It exposes nuclear localization signals (NLS) on its surface, allowing the binding of importin β via the importin α adaptor protein (4). Importin β mediates the transport through the nuclear pore into the nuclear basket (5). There, the capsids disassemble and genome becomes released (8). The core proteins can reassemble to capsids (9). At least a part of the newly formed capsids contain cellular RNA. Cytosolic progeny capsids have to undergo phosphorylation of core proteins to induce a conformational change (1a). As infecting capsids, they are actively transported towards the nuclear pore (2, 3). The conformational change allows the binding of importin α and β and the transport into the nuclear basket (4, 5). If the genome maturation has not finished at that time, the capsid remains arrested within the basket (6) and genome maturation can proceed (7). As with the infecting capsids, disassembly and genome release occurs (8).

via base-pairing to facilitate the two template switches during plus-strand DNA synthesis.[276] However, a small terminal redundancy (5′r and 3′r) on the ends of the minus-strand DNA has also been shown to be important, but not sufficient, for circularization.[277,278]

### *Re-entry of mature HBV DNA to the nucleus*

Tuttleman *et al*.[174] showed that the amplification of cccDNA in DHBV-infected primary hepatocytes occurs after the cells have lost their susceptibility for viral uptake. These data were confirmed in the non-susceptible, HBV genome-carrying cell line HepG2.2.15, indicating also that nuclear transport of the genome is not linked to viral uptake. These observations were surprising as they described the first time that a progeny viral particle 'reinfects' a cell without having left the cell. Beside hepadnaviruses, this internal amplification has only been described for other pararetreoviruses such as caulimoviruses and potentially for foamyviruses. In all other viral studied infections, the entry pathway of an incoming virus is strictly separated from the exit pathway of the progeny virion. It must be assumed that in hepadnaviruses this strategy plays an important role in establishment of infection. Early in infection, when viral surface proteins are not yet significantly synthesized, the entry of progeny genomes into the nucleus results in accumulation of the cccDNA.

However, due to the lack of a suitable infection system all data on the nuclear transport were obtained in artificial systems such as the digitonin-permeabilized cells. These experiments show that the progeny capsids harbour the nuclear transport competence and mediate the transport of the progeny genome into the nucleus (Fig. 10.6). Interestingly, exposure of the nuclear localization signal – present on the C-terminus of the core proteins – is associated with phosphorylation of the core proteins.[115] Release of the genome from the capsids was linked to genome maturation, implying a tight regulation.[115] In fact, a defined order of genome maturation, localization and release appears to be essential. If the genome was released outside the nucleus it could not

be transported into the karyoplasms, thus not allowing transcription and further genome multiplication. A premature genome release before genome maturation is finished would prevent synthesis of replication-competent viral DNA as the polymerase depends on the presence of the core proteins for plus-strand DNA synthesis.[110]

Hepadnaviral cccDNA in the nucleus is subject to degradation, with a half-life of 35–57 days *in vivo*.[279] Thus, the pool of intranuclear HBV genomes has to be permanently restored to ensure viral persistence.

### *Envelopment of core particles*

After establishment of infection and sufficient surface protein synthesis, mature core particles are primarily targeted to form progeny virion instead of increasing the pool of intracellular cccDNA. Both pathways overlap as determined for DHBV mutants being incompetent for virion secretion. In these mutants intranuclear cccDNA accumulated up to 50-fold over the natural copy number.[280]

The assembly of core particles occurs in the cytosol, but after assembly and genome maturation HBc protein seems to exhibit an affinity for intracellular membranes, which contain inserted LHBs molecules.[95] It has been shown that significant minus-strand DNA synthesis must have occurred before encapsidation of the core particles.[281] It is presently unsolved whether the conformation change of the particles during genome maturation, which is implied by this observation, is the same as is responsible for exposure of the nuclear localization signal.

For secretion of enveloped virions, an excess of SHBs protein is necessary.[68,282] It appears that the envelope is formed by mixed aggregates of LHBs, MHBs and SHBs, but MHBs seems to be dispensable. For secretion, virions and accompanying HBs particles move from the ER via the Golgi apparatus to the cell surface.[283] During this migration within transport vesicles, the HBs protein is further modified similar to normal cellular secreted proteins. The glycoside side chains of the HBs proteins are trimmed and modified. Covalent disulfide bridges are formed within and between HBc or HBs subunits. It appears that the release of virions and HBs particles from secretory vesicles does not require any specific signal and follows the constitutive pathway of secretion. However, secretion requires trimming of the immature N-linked glycan bound to the HBs protein. Inhibition of that trimming by the glucosidase I inhibitor *N*-butyldesoxynojirimycin also inhibits the appearance of HBV particles in the supernatant of transfected HBV-producing cell lines.[284] The secretion of HBs particles is not as strongly inhibited, probably as a result of the lower contents of glycoside in HBs proteins.

Somewhere between envelopment of core particles and secretion, part of the LHBs molecules is refolded in the pre-S domain from the internal face of the envelope to the surface. Low pH, as it occurs before secretion in the trans-Golgi network seems to favour this refolding, because low pH also induced the *in vitro* appearance of additional pre-S1 epitopes on the surface of HBV particles.[85]

Human hepatoma cell lines such as HepG2 and Huh7 express a suitable ratio of all HBV proteins to allow for virion assembly and secretion. Immortalized mouse hepatocyte cultures[285] are also able to produce HBV. However, *in vivo* not all hepatocytes may be able to express all HBV proteins in a suitable ratio. Thus, in histological specimens from persistently infected liver, only a few cells contain HBV DNA, HBcAg and HBsAg, whereas many cells contain HBsAg or HBcAg alone.

# Chapter 11
# Epidemiology

Daniel Lavanchy

Worldwide, hepatitis B virus (HBV) is the most common among those hepatitis viruses that cause chronic infections of the liver in humans and represents a global public health problem. In 2000, according to WHO estimates, there were over 5.2 million cases of acute hepatitis B infection. Chronic hepatitis caused by HBV may progress to cirrhosis and death from liver failure, and chronic HBV infection is the major cause of hepatocellular carcinoma (HCC) worldwide.[1,2]

Acute hepatitis B usually runs a self-limited course in adult subjects, with most patients recovering completely. Fulminant hepatitis occurs in 1–2% of acute infections, resulting in the death of most of these patients.

About 15–40% of chronically infected subjects will develop complications, leading to an estimated 520 000–1 200 000 deaths each year due to acute and chronic hepatitis, cirrhosis and liver cancer. HCC prevalence is known to vary widely among the world population, and those areas with higher prevalence of viral infection present the highest HCC rates.[3–8] HBV causes 60–80% of the world's HCCs,[9,10] one of the major three causes of death in Africa, Asia and the Pacific Rim.[11] The incidence of HCC has increased worldwide and nowadays it constitutes the sixth most frequent cancer, representing around 5% of all cancers worldwide.[10,12–15] HBV has been classified by the International Agency for Research on Cancer as carcinogenic to humans.[10] The risk of developing HCC is increased, although currently not precisely quantified, when HBV infection occurs in combination with alcohol intake or co-infection with hepatitis C (HCV), hepatitis delta (HDV) or human immunodeficiency virus (HIV).[16–19]

## Burden of the disease

The economic burden of HBV infection is substantial because of the high morbidity and mortality associated with HBV infection. Even in the early stages of chronic HBV infection, before the onset of advanced liver disease, health-care costs of patients with chronic HBV infection are increased. Costs then escalate with increasing severity of illness. The economic burden should also reflect the loss of productivity due to acute and chronic disease. Such data are lacking in most countries, but particularly in developing countries.

In the USA, it was estimated that HBV-related liver disease accounted for an average of US$ 4000 in patients with compensated liver disease, increasing to more than US$ 20 000 per year as liver function decompensated. Liver transplantation was estimated at a cost of approximately US$ 90 000.[20–23]

The economic burden of hepatitis B in Germany was investigated in a small cohort, and it was estimated that the total HBV-related costs for the country exceeded DM 1200 million (approximately US$ 800) in 1997.[24]

In South Korea the total annual societal cost was estimated to be slightly below US$ 1 billion. The direct costs (prevention and disease-related), amounting to almost US$ 700 million, were equivalent to 3.2% of the South Korean national health-care expenditure for 1997.[25]

Thus, medical costs, in the few countries where they have been evaluated, showed a very substantial burden to society. Due to the lack of data in most countries with higher endemicity for HBV, national cost evaluation studies should be conducted.

## Global distribution of HBV infection

More than 2 billion people have been infected worldwide and, of these, 360 million suffer from chronic HBV infection. The incidence of HBV infection and patterns of transmission vary greatly throughout the world in different population subgroups. It is influenced primarily by the predominant age at which infection occurs. Prevalences of anti-HBs and anti-HBc are much higher than those of chronic carriers – hepatitis B surface antigen (HBsAg)-positives – in all populations. Endemicity of infection is considered high in those parts of the world where at least 8% of the population is HBsAg-positive. In these areas, 70–90% of the population generally have serological evidence of previous HBV infection[26] (Fig. 11.1). Almost all infections occur during either the perinatal period or early in childhood, a fact that accounts for the high rates of chronic HBV infection in these pop-

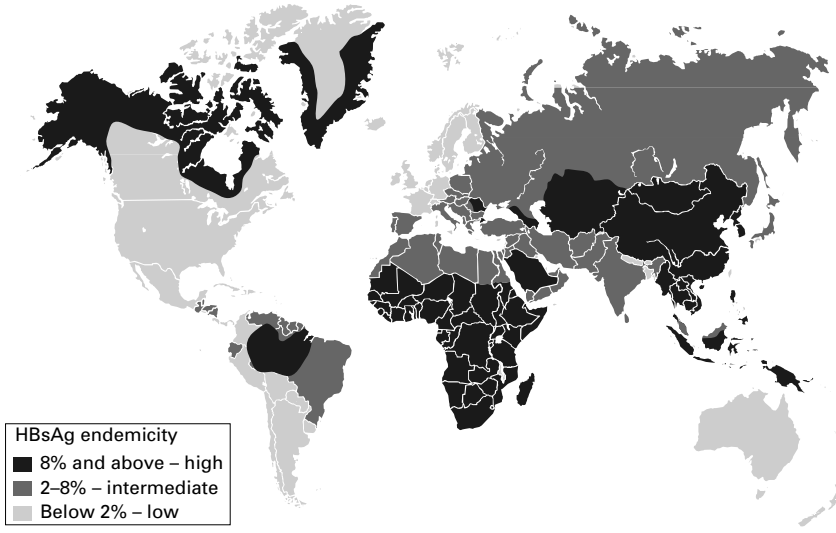

**Figure 11.1** Global prevalence of HBsAg.[26]

ulations. Risk of HBV infection continues after the first 5 years of life, but its eventual contribution to the high rate of chronic infection is less significant.[3]

In high endemic areas such as Asia, sub-Saharan Africa and the Pacific, carrier rates for HBsAg range from 8% to 25% and anti-HBs prevalences from 60% to 85%. Thus, exposure to HBV in high endemic areas, measured serologically, may approach 100%.[27,28]

In areas of the world with an intermediate pattern of HBV infection (eastern and central Europe, the Middle East, the Indian subcontinent and the Amazon basin), the prevalence of HBsAg positivity ranges from 1% to 8%, serological evidence of past infection is found in 10–60% of the population and the lifetime risk of becoming infected with HBV is estimated to be 20–60%.[29,30] In these areas mixed patterns of infant, early childhood and adult transmission prevail.[30]

In most developed parts of the world, the prevalence of chronic HBV infection is <1%, and the overall infection rate is 5–7%.[29]

Overall, approximately 45% of the global population live in areas of high chronic HBV prevalence.[13,28]

## Africa

Sub-Saharan Africa represents a high endemic area for HBV, some countries being among those with the highest prevalence of HBV infection in the world (>8%). This has been explained by a high rate of perinatal and horizontal transmission among children, which in turn has been attributed to promiscuity. Compared with neonatal infection, contamination before the age of 5 but after birth is associated with a rate of chronic infection that is somewhat lower (40–70%), but with a higher proportion of chronic active hepatitis, cirrhosis and HCC among children and young adults.[31,32]

## Americas

In the low prevalence area of North America, the lifetime risk of infection is <20%, and the infection is acquired primarily in adulthood. In most of North America, the epidemiological aspects and public health implications of HBV infection are similar to those in north-western Europe and Australia in terms of prevalence of chronic HBV infection (about 0.2%). The incidence of acute hepatitis B is decreasing as a result of immunization campaigns (routine infant or adolescent immunization) and implementation of measures for controlling HIV infection, transmission through sexual contacts and injection drug use.[32,33] Within these areas most infections occur among adult populations at high risk, including injection drug users, persons with multiple heterosexual partners, men who have sex with men (MSM), and health-care workers. Although the proportion of infant and early childhood infections is low, they can account for a disproportionately high number of chronic HBV infections.[34,35]

The US Centers for Disease Control and Prevention (CDC) estimates that in the United States about 80 000 persons become infected with HBV each year. New infections result in 8400–19 000 hospital admissions annually and in 140–320 deaths from fulminant hepatitis. About 5000 people die every year from liver disease caused by HBV infection.[35,36] There are 1–1.25 million chronic carriers in the United States, many of whom are immigrants from high or moderate prevalence areas. The overall age-adjusted incidence rates of HCC increased from 1.4 per 100 000 in 1975–1977 to 3.0 per 100 000 in 1996–1998. The increase affected most age groups above 40 years, with the greatest increase in the 45–49-year-old age group. White men had the greatest increase (31%) in the time period 1996–1998 compared with 1993–1995. The

incidence of HCC continues to increase rapidly in the United States, with rates increasing the fastest in white men 45–54 years of age. These findings are consistent with a true increase and could be explained by consequences of HBV and HCV acquired during the 1960s and 1970s.[37]

For South America, we need more information on prevalence, sources of contamination (nosocomial), immunization programmes and their impact. There are population groups with different epidemiologies that should be taken into consideration when defining prevalences.[38]

## Asia

Many Asian countries are among those with the highest prevalence of chronic HBV infection in the world (>8%). This is due to a high rate of perinatal transmission from HBeAg-positive mothers to their newborns. Perinatal transmission is associated with chronic infection in >90% of infected children and young adults, explaining the high rate of subsequent neonatal transmission. In patients infected at birth, mild to severe chronic hepatitis develops after a 10–30-year lag phase where the viraemia level is high and hepatitis is mild or absent. In these countries, HBV infection is responsible for most cases of HCC, and represents one of the three major causes of death. Routine immunization of neonates has resulted in a dramatic reduction in the incidence of acute hepatitis and HCC in children in those countries where this has been implemented.[39]

## Australia and Oceania

In Australia the epidemiological aspects and public health implications of HBV infection are similar to those in North America and north-western Europe in terms of prevalence of chronic HBV infection (about 0.2%). The epidemiology differs significantly in the population of Australian aborigines.[39] In Oceania, high endemic areas with carrier rates for HBsAg are also found. Although in some countries (e.g. Papua New Guinea, Solomon Islands) infection rates in infants are relatively low, a rapid increase occurs during early childhood.[39]

## Europe

The prevalence of chronic carriers ranges from <0.1% in north-western Europe to 1–5% in southern Europe. The lifetime risk of infection is <20%, and the infection is acquired primarily in adulthood.

In 1996, it was estimated that more than 1 million people acquired acute hepatitis B infections annually in the 51 countries of the European Region. In Western Europe, incidence rates of <6 per 100 000 were reported from all countries of the European Union apart from France (nine per 100 000) and Luxembourg (13 per 100 000).[40] The estimated number of new cases of hepatitis B has been stable at around 1 million per year. In about 90 000 cases, these infections became chronic. Most cases of chronic hepatitis B are related to the so-called wild-type HBV variant.[30,40,41] By 2001, the overall epidemiological picture had changed little, with low prevalence rates of HBsAg positivity in northern and Western Europe and highest rates in the south and east, in particular the Central Asian republics.

In eastern Europe and the newly independent states, the pattern of risk factors for viral hepatitis is changing significantly, but up until the present, few epidemiological studies have investigated the risk factors for infection using cohort or case-control methodologies. The highest reported rates in the countries of central and eastern Europe, about 20 per 100 000, were in Bulgaria (1998), Estonia and Latvia. Higher rates than that were reported from Kazakhstan, Kyrgyzstan, Moldova, the Russian Federation and Uzbekistan.[41]

In southern Europe, the prevalence of chronic infection is intermediate (1–8%). In these countries, >95% of infections are acquired during adulthood in immunocompetent subjects and are therefore followed by resolution in ~95% of cases. Over half the cases of chronic hepatitis B are related to infection with HBeAg-negative variants. In Italy, up until the mid-1970s, hepatitis B morbidity rates were high, mainly attributed to use of unscreened blood, reuse of inadequately sterilized medical equipment, and increase in intravenous drug use. During the 1980s, HBV infection in Italy began to decrease, mainly due to improvements in health-care delivery, better living standards and the 'AIDS effect' contributing to safer sexual practices. The implementation of a national infant immunization programme in the early 1990s led to a further decrease, transforming Italy into a low prevalence country. A similar, although less marked, evolution could also be observed in Greece and Spain.[42,43]

## Migrating populations

Although travel and immigration are not new phenomena, the impact of migration is most often underestimated. Many countries are facing new situations, with migrants arriving on a mass scale only in recent years. Not only are an increasing number of people on the move, but the demography of these populations is changing. Labour demand patterns have induced a highly gender- and age-specific demography. For the most part, migration populations are highly unstructured, and full access to these populations is often impossible. However, understanding that hepatitis B infection is a highly prevalent disease in some parts of the world is critical to providing the adequate health-care services needed.

**Figure 11.2** HBV genotypes: global distribution (W. Gerlich, personal communication, 2003).

Special migrating populations are infants and young children being adopted, in relation to the fact that international adoption has become increasingly common in recent years. This phenomenon only really started in the second half of the 20th Century. Statistics show that the trend towards international adoption is on the rise. In the United States, for instance, there were 4864 international adoptions in 1979 and 16 000 in 1998. Many children adopted from overseas come from areas where HBV infection is common. Adopted children come often from eastern and south Asia, Africa, South America, and more recently from eastern Europe. In these regions the prevalence of HBsAg ranges from 2% to 15%. Thus, the adopted children have a much higher carrier rate than the general population in most of the countries of adoption, and the figures for hepatitis B infection are alarming within the scope of international adoption.[44–47] Families considering inter-country adoption should be made aware of the risks that the child could be a chronic HBV carrier.

## Epidemiology of hepatitis B serotypes and genotypes

HBV shows substantial genetic heterogeneity. Four serotypes of the HBsAg called subtypes (adw, ayw, adr and ayr) of HBV have been defined by two mutually exclusive determinant pairs, d/y and w/r, and a common determinant a. By subdivision of the four major subtypes in the mid-1970s, nine different subtypes were identified. They show some distinct geographic distributions.[48–56]

Sequencing of viral genomes has now become the major tool used for descriptive virology, and sequence data are now used to reconstruct the phylogenetic history of viruses and to delimit genetic subtypes. Genetic analysis has allowed us to classify HBV into seven distinct genotypes (A–G) that have different geographical distributions (Fig. 11.2), and associations with different risk groups for infection. Genotype A is predominantly found in north-western Europe, North America and central Africa, genotypes B and C are found predominantly in eastern and south-eastern Asia including China and Japan, genotype D is mainly found in the Mediterranean area, genotype E is predominant in western Africa, and the most divergent genotype F is found exclusively among indigenous populations in Central and South America.[57,58] Genotype G has been identified in a few samples in the USA and France. Worldwide genotypes B, C and D are predominant, with an estimated 240 million subjects infected with genotype B/C, and 40 million infected with genotype D. Genotype A has infected approximately 3 million, and genotype E 20 million individuals. The clinical significance of genotypes has not yet been fully evaluated. Some recent data suggest that associations between certain genotypes and HBeAg seroconversions, viral mutations, severity of liver disease and response to treatment may exist. Recent studies from Asia have indicated that HBV genotype B is associated with earlier HBeAg seroconversion than genotype C, thus most likely explaining the less progressive disease in patients with genotype B.[59,60] In the USA, where one study found all genotypes to be heterogeneously distributed among the country, the only significant factors related to genotype epidemiology were ethnicity and place of birth, indicating that population dynamics are an influential causal factor of genotypic distribution.[49–51,53,56,61–65]

## Impact of vaccination on HBV prevalence and liver disease

Data on the decrease of prevalence of HBV markers are accumulating in countries where routine hepatitis B

vaccination programmes were implemented. A decline of incidence of acute cases of disease in paediatric age groups is not easy to demonstrate because hepatitis B is rarely symptomatic in infants and children.[66] Thus, the baseline level of incidence is usually already low before routine immunization. In addition, HBV-related mortality is seen mainly in adult age. However, there are areas with such a high endemicity of infection that it is possible to document the impact of vaccination also by mortality rates.

The impact of mass hepatitis B immunization on the chronic consequences of infection could be demonstrated first in Taiwan. During the 15 years following introduction of mass vaccination, the average mortality from fulminant hepatitis in infants changed from 5.36/100 000 in 1975–1984 (prior to mass vaccination) to 1.71/100 000 in 1985–1998.[67] In parallel, HBsAg prevalence in the population of those under 15 year of age changed from 9.8% (1984) to 0.7% (1999),[68] and in children aged 6–14 years, the incidence of primary liver cancer progressively declined from 0.7/100 000 in the period 1981–1986 to 0.57/100 000 in 1986–1990, and to 0.36/100 000 in 1990–1996.[69,70]

Proof of the decreasing incidence of acute hepatitis B after vaccination is available in Europe from Italy, the first industrialized country to introduce routine immunization in a double cohort of subjects, i.e. infants and 12-year-old adolescents. Data from the Integrated System of Surveillance on Acute Viral Hepatitis (SEIEVA) indicate that during the period 1991–1999, the number of new cases of hepatitis B dropped by about 40%, compared with data from the 1988–1991 period.[42,71] However, the overall incidence of acute hepatitis B was already declining before the introduction of routine vaccination, as it changed from 12 to 5/100 000 between 1985 and 1991, but the decline connected with the improvement of hygienic and living conditions would not have led to such a dramatic reduction in viral circulation without a programme of universal vaccination.[72] As a matter of fact, the incidence in the age group at highest risk (15–24 years) was halved from 1991 to 1994 (12 and 6/100 000, respectively) and continued to decrease thereafter. In Tuscany, a 49% decline of reported cases in the same age group was registered between 1992 and 1996,[73,74] and in a highly endemic area in southern Italy (Afragola), a decline of the incidence from 63/100 000 before implementation of the immunization programme to 3/100 000 in 1997, 15 years after its implementation was reported, and the prevalence of HBsAg dropped from 13.4% in 1978 to 3.7% in 1997 (from 6.8% to 0.7% in children and adolescents).[73] At the present time, the level of acute hepatitis B infection is at an all-time low. However, there are still new infections occurring and there is also a shift in the prevalence of HBsAg-positive subjects towards more advanced age groups. If hepatitis B vaccination coverage rates are maintained at their current levels, elimination of HBV transmission in Italy could become a reality within the next few decades.

In Alaska (an area of traditionally high endemicity), where a programme of vaccination of all infants plus catch-up of susceptibles was initiated in 1983, a 10-year follow-up showed zero HBsAg prevalence in Native Alaskan children aged <10 years, while 16% of those aged 11–30 years were chronically infected.[75]

In Bulgaria, the universal vaccination of neonates introduced in 1991 rapidly reached over 70% coverage. In 1992, a drop of incidence of hepatitis B in infants reached 5.6/100 000 vs. values of 25–35/100 000 during the 1980s.[76]

In South Africa, the prevalence of HBV carriers in 3-year-old children was 12.8% in the pre-immunization years.[77] After 5 years of implementation of HBV vaccination in the framework of the WHO Expanded Programme of Immunization (EPI), none of about 600 vaccinated children showed HBsAg reactivity.[78]

By preventing infections in children through universal immunization programmes against HBV, the number of HBeAg-positive persons declines rapidly over time, because of the inherent clearance of HBeAg in older persons, and this will lead to an ongoing and significant change in the epidemiology of hepatitis B in all those countries where a universal hepatitis B immunization programme has been implemented.

## Transmission of HBV

The incubation period of HBV is long, ranging from 45 to 160 days (average 120). The virus is found in highest concentrations in blood and serous exudates. Percutaneous or mucous membrane exposures to HBV in infectious blood or serum-derived body fluids account for virtually all HBV infections in humans.[44,79,80]

Although HBsAg has been detected in a wide variety of body fluids, only serum, semen and saliva have been demonstrated to be infectious,[81,82] while breast milk and urine remain controversial. The presence of HBeAg in serum correlates with higher titres of HBV and greater infectivity.[83–85] However, HBV strains that have mutations in the precore region of the viral genome that prevent expression of HBeAg (HBeAg-negative/anti-HBeAg-positive variants) also have been associated with transmission.[86]

Infection by faeces, urine, tears, breast milk, bile or pancreatic juice has never been demonstrated even though HBsAg or HBV particles have been detected in such fluids.[87–89] The possibility of transmission by blood-feeding arthropods has been a concern but has never been proven. The hypothesis of bedbug transmission

was tested in the Gambia, where a controlled trial of bedbug elimination in several villages failed to reduce the risk of HBV infection.[90]

## Person-to-person spread

Percutaneous exposures that have resulted in HBV transmission include transfusion of blood or blood products,[91–94] contaminated equipment used for therapeutic injections and other health-care-related procedures,[95–98] injection drug use,[99–105] and needle sticks or other injuries from sharp instruments sustained by hospital personnel.[106,107] In addition, occasional outbreaks of hepatitis B have been associated with tattooing and acupuncture.[108,109] Because HBV is stable on environmental surfaces for >7 days,[110] indirect inoculation of HBV can also occur via inanimate objects. No infections have been demonstrated in susceptible persons orally exposed to HBsAg-positive saliva, although transmission to animals by subcutaneous inoculation of saliva has been demonstrated.[81,82,111,112]

Person-to-person spread of HBV can occur in settings involving non-sexual interpersonal contact over a long period of time, such as among household contacts of a chronically infected person.[113–116] The precise mechanisms of transmission are unknown. However, frequent interpersonal contact of non-intact skin or mucous membranes with blood-containing secretions or perhaps saliva are the most likely modes of transmission.[117] Because of the extremely high concentration of virus in the blood, the number of virions in even very small amounts of blood or body fluids can be quite high. In addition, HBsAg contamination of surfaces is widespread in homes of chronically infected persons,[117] and HBV remains infectious for long periods of time under ambient conditions.

## Sexual transmission

Transmission of HBV from persons with acute or chronic hepatitis B to their sexual partners is an important source of infection,[79,102] and HBsAg-positive adults engaging in high-risk sexual activity are at high risk of transmitting HBV.[118,119] However, most persons with chronic HBV infection are not aware that they are infected. These silent carriers are the most likely source of infection for persons with multiple sexual partners.

In most developed countries, including those in northern and Western Europe, most (80–85%) acute infections of hepatitis B occur among young adults, engaging in high-risk unprotected sexual activity and injection drug use.[120–124]

Historically, men who have sex with men (MSM) were one of the groups at highest risk for HBV infection. Infection in this risk group has been associated with receptive anal intercourse, increased numbers of sexual partners, and number of years of sexual activity (70% of homosexual men were infected after 5 years of sexual activity).[79] Similar factors have been associated with an increased risk of HBV infection among heterosexual men and women, including number of sexual partners, number of years of sexual activity, and a history of other sexually transmitted diseases.[79,125]

## Horizontal and vertical transmission

The risk of perinatal HBV transmission has been well described. This risk is greatest for infants born to women who are HBeAg-positive and ranges from 70% to 90% at 6 months of age. About 90% of these children remain chronically infected.[126] The risk of perinatal infection among infants born to HBeAg-negative mothers ranges from 10% to 40%, with 40–70% of these infected infants remaining chronically infected.[126,127] Children born to HBsAg-positive mothers who do not become infected during the perinatal period remain at high risk of infection during early childhood.[127–132]

A curious, but as yet not fully explained, observation is that perinatal transmission is much more common in Asia than in Africa. The routes of transmission for early childhood infections in Africa are not clearly understood, and there may be significant local variability. In a study of a rural Senegalese community, the prevalence of HBV markers was about 25% at the age of 3 years and increased rapidly after 4 years of age. Even when mothers in Africa are HBeAg-positive, however, their babies do not become HBsAg-positive until 6 months to 1 year of age, whereas in Asia exposed babies tend to become HBsAg-positive by 3 months after birth.[133]

In low HBV endemic countries, a substantial number of children become infected with HBV, many of whom belong to families that have migrated from high HBV endemic countries.[44] As >90% of childhood HBV infections are asymptomatic, the true incidence of childhood disease is not accurately represented by most surveillance data, which in general reflect reported cases of clinically apparent disease.

## Transmission by unsafe medical practices

Transmission occurs through contaminated injection equipment and through inadequately sterilized medical instruments and remains a significant problem because of the difficulty in obtaining disposable needles and syringes and the lack of means to adequately sterilize reusable equipment.[134–136] It was estimated that 8–16 million of new HBV infections may result from unsafe injections each year.[135] In developed countries, episodes of HBV transmission from one patient to another in health-care settings also have been reported.[95,96,134,137–139] In most

cases, these transmissions resulted from non-compliance with recommended infection control practices that were designed to prevent cross-contamination of medical equipment and devices.

In some countries, high HBV endemicity is often connected to the use of non-sterile injection practices. A study in the Republic of Moldova showed that nosocomial transmission was a major risk factor for hepatitis B infection and a study in Kazakhstan in 1998 confirmed this, showing that 52% of acute hepatitis B infections were associated with medical injections. In a study performed in Russia (Moscow) significant associations with invasive manipulations and illicit drug use during the previous 6 months preceding infection with HBV were found. For non-drug users, admission to hospital, tattooing and multiple sexual partners carried an attributable risk of between 3% and 12%.[140]

### Health-care workers

HBV transmission from infected health-care workers (HCWs) to patients is relatively uncommon, but has occurred, especially during exposure-prone procedures, such as invasive surgical, obstetrical or dental procedures.[107,141]

Although HBV infection was recognized as a frequent occupational hazard among persons working in laboratories or exposed to blood while caring for patients,[107] hepatitis B vaccination of HCWs and its wide use, particularly in younger generations of HCWs and in medical and nursing students, determined a clear decline in the incidence of HBV in HCWs.[142] A problem of coverage still exists in older HCWs, who are less compliant with vaccination.[143] Most of the reported cases occurred before hepatitis B vaccination was widely used and before universal infection control precautions were implemented.[144] These mostly involved infected surgeons or dentists who transmitted during the performance of invasive procedures. However, other health-care providers also have been implicated in HBV transmission to patients.[107] The risk of transmission of HBV from HCW to patient during invasive surgical procedures was estimated at values of 2400 per million,[145] much higher than that for HCV and HIV.

In order to prevent HCW–patient transmission, there is consensus that HBeAg-positive HBV carriers should not perform exposure-prone surgery or other treatments at risk of injury for the operator. These personnel should be assigned to a type of work with minimal risk of transmission.

In the long-term perspective, the growing implementation of universal vaccination programmes and the continuing active offer of immunization to HCWs in many countries should diminish the prevalence of HBV carriers in patients and HCWs, thus making hepatitis B transmission in medical settings an uncommon event.[146]

### Transmission of HBV via transfusions and haemodialysis

Transmission of HBV via transfusion of blood and plasma-derived products has been eliminated in most countries through donor screening for HBsAg and viral inactivation procedures, and the introduction in some countries of HBV DNA nucleic acid amplification techniques using mini-pools has further reduced the risk.[147–150]

HBV transmission among haemodialysis patients is consistently associated with the presence of a chronically infected patient, failure to dialyse the infected patient in a separate room using dedicated equipment and staff, and failure to vaccinate patients against hepatitis B. Contaminated environmental surfaces have been a major source of HBV transmission among chronic haemodialysis patients.[92,95,96,151,152]

## HBV and co-infections

Evidence has been generated that HCV co-infection and/or co-infection with HIV are clinically and virologically important co-factors. HBV-positive patients co-infected with HIV tend to have a milder liver disease, but the overall morbidity and mortality seem to be higher than in patients infected with HIV alone. Patients co-infected with HCV tend also to have more severe liver disease and more commonly occurring HCC in comparison with patients having either infection alone.[153,154]

## Disease associations with HBV

The most serious diseases associated with chronic HBV infection affect the liver. However, some uncommon extrahepatic manifestations are caused by immune complexes of hepatitis B antigens and antibodies.[155] The most common ones include chronic membranoproliferative glomerulonephritis and polyarteritis.[156]

## Alcohol and HBV

Alcohol is hepatotoxic and may exacerbate HBV-related liver damage.[157] HCV infection and alcohol consumption appear to be more closely associated with liver damage than HBV infection and alcohol consumption. Chronic alcohol consumption is clearly associated with the development of cirrhosis. Persons chronically infected with HBV and who drink alcohol regularly might be expected to be at higher risk of both cirrhosis and HCC than either HBV carriers who do not drink or drinkers

who are not infected with HBV. Japanese HBsAg-positive blood donors who were moderate or heavy drinkers were at a fivefold to eightfold greater risk of developing HCC than non-drinkers.[158] Other studies have shown either a high, weak or no association.[5,8,159–162]

## Aflatoxin and HBV

Aflatoxins are fungal toxins that commonly contaminate maize, groundnuts and other crops. Aflatoxin B1 plays an important part in modifying the risk of liver cancer associated with hepatitis B. Several studies have shown a strong interaction of chronic HBV infection with aflatoxin B1 exposure and HCC. In some areas of high exposure to aflatoxin, HCCs have revealed a frequent mutation in the p53 tumour suppressor gene in primary liver cancers.[163,164] HBV and aflatoxin B1 may synergistically induce the p53 gene transversion from A G to T at codon 249. The presence of aflatoxin metabolites in urinary excretions increases the risk of HCC about fourfold.[165] Chronic HBV infection increased risk of HCC about seven times, but persons who both excreted aflatoxin B1 metabolites and were HBV carriers had a 30–60 times higher risk than HBV-uninfected, aflatoxin B1-unexposed persons.[164,166,167]

## Conclusions

At the beginning of the third millennium, hepatitis B remains a major public health problem globally. This fact is related to both the continuing occurrence of frequent new infections and to the presence of a large reservoir of persons who are chronically infected, who may develop severe and fatal complications of chronic liver disease. Cirrhosis, HCC, or both, represent a large burden for health-care systems.

Hepatitis B and all the complications resulting from it, as well HDV and its complications, are globally preventable by hepatitis B vaccination, and therefore elimination of HBV transmission and of new acute and chronic infections is a feasible goal. To achieve this, implementation of childhood vaccination programmes against hepatitis B need to be extended to all countries. As of 2002, 154 countries had a national immunization policy.[168]

For the 360 million subjects already suffering from chronic HBV infection, only antiviral treatment can provide help. The currently licensed treatments are expensive, and therefore not accessible to the great majority. Providing safe and effective treatment to those already suffering from the sequelae of chronic HBV infection will reduce the burden of HBV-related morbidity and mortality, but will require significant and coordinated efforts at an international level.

# Chapter 12
# Avihepadnaviridae

Allison R Jilbert, Stephen A Locarnini

Members of the Hepadnaviridae family are primarily hepatotrophic, contain relaxed circular (RC) double-stranded (DS) DNA genomes and have a unique method of replication that involves reverse transcription of a greater than genome length RNA. There are two genera within the Hepadnavirus family: the orthohepadnavirus genus that includes viruses infecting mammals and the avihepadnavirus genus including viruses that infect avian species.

The orthohepadnavirus genus includes the human hepatitis B virus (HBV), as well as a number of naturally occurring HBV strains isolated from non-human primates including chimpanzees, orang-utans, gibbons[1–3] as well as the woolly monkey hepatitis B virus (WMHBV).[4] In addition to the human and non-primate strains of HBV, the orthohepadnavirus genus includes the woodchuck hepatitis virus (WHV) from eastern woodchucks;[5] ground squirrel hepatitis virus (GSHV) from Beechy ground squirrels;[6] and arctic squirrel hepatitis virus (ASHV).[7] The orthohepadnavirus genus is phylogenetically classified into seven HBV genotypes, A–G, with an overall sequence homology of 92%.[8] The non-human primate strains of HBV are distinct from genotypes A–G. HBV strains isolated from chimpanzees are most closely related to the HBV genotype G[8] and have an overall homology to human HBV of >94%.[1] However, with the exception of the WMHV, this difference is not great enough to assign these primate isolates as separate species. The non-primate strains, WHV, GSHV and ASHV, are all assigned as separate species and share 70%, 55% and 63% genome homology with HBV.

The avihepadnavirus genus includes the duck hepatitis B virus (DHBV) isolated from Pekin ducks (*Anas domesticus*),[9] heron hepatitis B virus (HHBV) from grey herons (*Ardea cinerae*),[10] Ross goose hepatitis virus (RGHV; GeneBank DHBV-RGM 95589) from Ross Geese (*Anser rossii*), stork hepatitis B virus (STHBV) from white storks (*Ciconia ciconia*),[11] snow goose hepatitis B virus (SGHBV) from snow geese (*Anser caerulescens*)[12] and the Australian maned duck, (MDHBV) and grey teal (GTHBV) hepatitis B viruses (R.J. Dixon, personal communication). The genomes of a number of avihepadnaviruses including the Australian strain of DHBV have been cloned and sequenced from serum[13–15] and have been shown to be infectious.[12–14,16]

The avihepadnaviruses have been classified phylogenetically into 'Chinese' and 'Western' DHBV strains as well as four highly distinct lineages that include the SGHBV, RGHV, STHBV and HHBV.[12,14,17] Nucleotide sequence divergence within the 'Chinese' and 'Western' strains is 5.99 and 3.35%, while divergence between the strains is 9.8%.[17] The SGHBV is the next closest member of the genus to DHBV, varying by 11–13%,[12] while RGHV varies by 17.3–19.1%[14] and STHBV and HHBV vary by 22.2–23.6%[11,12,14] (Fig. 12.1). The larger evolutionary distance between HHBV and DHBV may reflect their distinct host ranges, as HHBV infects only grey herons and not ducks,[10,18] and may have resulted from co-evolution of each virus in its respective host.

All members of the Hepadnaviridae family share unique structural and genomic features including similar virion size and ultrastructure, with an envelope surrounding an icosahedral nucleocapsid composed of core protein containing a RC DNA genome with similar size, structure and organization. A comparison of the physical features, genomes and encoded proteins of HBV, WHV, GSHV and DHBV is included in Table 12.1.[5,6,9,19–25] HBV and DHBV share only 40% nucleotide similarity, while, as explained above, genomic nucleotide sequences are more similar among the members of each genus.

Members of the two genera were originally thought to encode a different number of genes, with the mammalian viruses having a fourth open reading frame (ORF), encoding the X protein, that appeared to be lacking in the original DHBV isolates.[23] However, it was subsequently reported that avihepadnaviridae strains including HHBV[10,26] and later DHBV,[19] also have an X-ORF. In the case of DHBV, the X protein is produced from an unconventional start codon.[19] Unlike the X protein of the orthohepadnaviruses, the X-ORF of DHBV was found to be non-essential for replication *in vivo*.[27] In addition to the X-ORF, hepadnaviruses also have an S-ORF, C-ORF and P-ORF, encoding envelope, core and polymerase proteins (Fig. 12.2).[28]

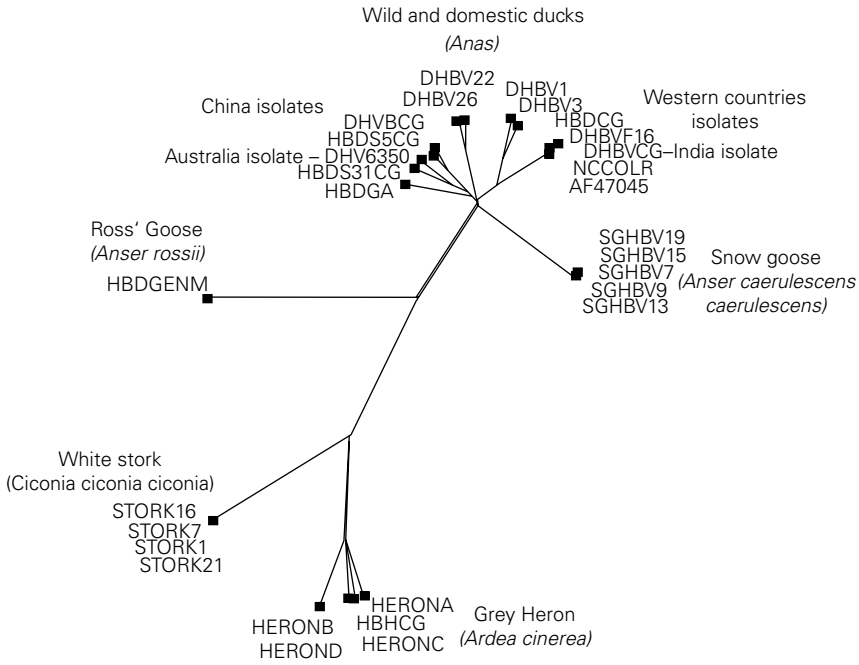

**Figure 12.1** Phylogenetic relationship of avian hepadnaviruses, inferred from the full-length (3018–3027 nt) sequences listed by NCBI number. From Pult *et al.*[11]

Differences in virion structure and the production of non-infectious surface antigen particles exist between the two genera. The mammalian viruses produce 22-nm diameter surface antigen spheres and filaments, while the avian viruses produce pleomorphic, generally spherical surface antigen particles ranging in diameter from 35 to 60 nm and filaments are not produced (Table 12.1). There are also antigenic differences between the two genera. The mammalian viruses show cross-reactivity between epitopes on their core and envelope proteins,[22,25] but not with epitopes of the avian viruses.

Finally, hepadnaviruses all have a narrow host range, which is usually limited to each species. For example, HBV only infects higher primates including humans,

**Table 12.1** Comparison of the different members of the Hepadnaviridae family

| Physical characteristics | Hepadnaviral members | | | |
|---|---|---|---|---|
| | HBV | WHV | GSHV | DHBV |
| **Virion** | | | | |
| Diameter (nm) | 42[5] | 45[5] | 47[6] | 40–45[9] |

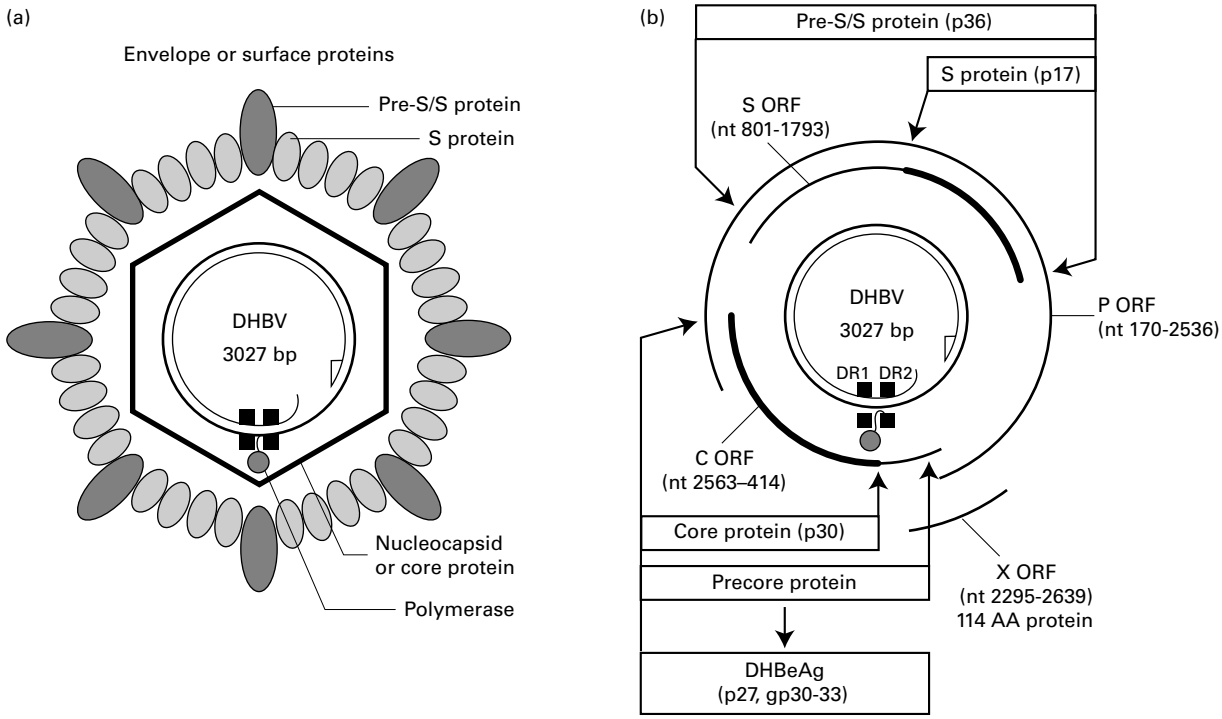

**Figure 12.2** The structure of the DHBV virion (a) and relaxed circular (RC) DNA genome (b), based on the Australian strain of DHBV (14) (DHV6350). (a) DHBV virion showing the viral envelope proteins, pre-S/S and S, the viral nucleocapsid comprised of DHBcAg and containing the RC viral DNA genome and viral polymerase. (b) The inner circles represent the two strands of the DHBV genome, negative (–) and positive (+); the positions of the two 12 nt DR sequences, DR1 (nt 2541–2552) and DR2 (nt 2483–2494) within the 69 nt cohesive overlap region are indicated by closed boxes; and the viral polymerase protein covalently attached to the 5′ end of the negative (–) DNA strand and the polyadenylation signal sequence (nt 2778–2783) are shown. The positive-strand has an 18 nt RNA primer attached to its 5′ end. In virions, the negative-strand is complete, while the positive-strand is less than full length. (Positive-strand completion occurs during initiation of new rounds of infection.) The four overlapping ORFs all present on the negative (–) strand (with production of + sense mRNA) are shown as open arrows with their coordinates and protein products indicated. Modified from Jilbert and Kotlarski.[28]

chimpanzees and gibbons.[1,3] DHBV infection has been found to occur naturally in domestic flocks of ducks and geese but not in other anseriforme species.[29,30] DHBV has also been experimentally transmitted to geese.[29,31,32]

As HBV does not infect non-primate laboratory animals, the discovery of other animal hepadnaviruses has led to the development of alternative systems for studying pathogenesis and replication as well as antiviral therapy. In particular, studies of the WHV and DHBV systems have resulted in important observations that have enhanced our understanding of the replication strategy, natural history and pathogenesis of hepatitis B.

## Replication strategy of avian hepadnaviruses in hepatocytes

The DHBV model was essential in determining that hepadnaviruses replicate via reverse transcription of an RNA intermediate[33] and has also proved valuable in the study of the early events of the hepadnavirus life-cycle.

### Viral attachment and entry into the hepatocyte

Hepadnavirus infection is species-specific and the main cell type infected is the hepatocyte. The steps involved in DHBV infection of a single cell are shown in Fig. 12.3.[28] The species and cell specificity of hepadnavirus infection are determined by the presence of receptors required for virus binding and entry. Cell surface receptors on primary duck hepatocytes have been shown to bind DHBV particles in a species-specific manner,[34] and receptor binding is thought to occur via peptides encoded by the large viral envelope protein. Receptor binding is followed by cell entry via endocytosis.

Recent studies have determined that the ubiquitous protein carboxypeptidase D is capable of binding DHBsAg particles with high affinity.[35] This glycoprotein is found on both internal and surface membranes of the cell. However, transfection of cells with DNA expressing carboxypeptidase D does not confer the ability to be infected with DHBV, suggesting that other co-receptors or mechanisms may be operating.[36] An additional

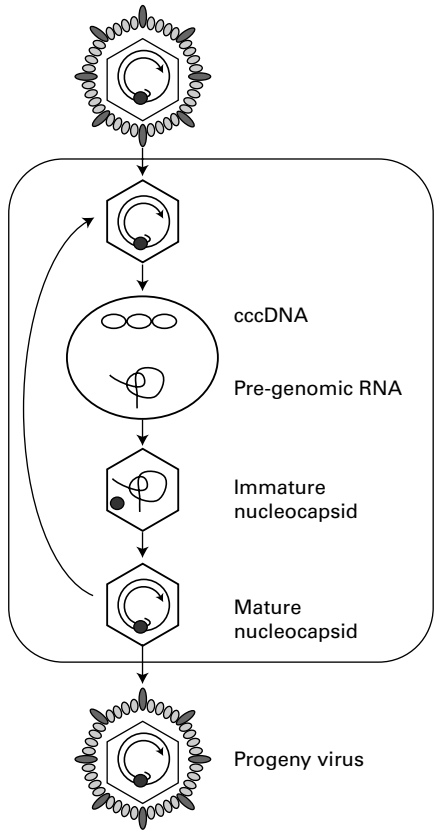

**Figure 12.3** DHBV infection of a single cell. The DHBV enters the cell by receptor-mediated endocytosis and uncoats in the cytoplasm. Virion DNA is translocated to the nucleus, where it is repaired to form cccDNA. cccDNA is then organized into nucleosomes and forms a viral mini-chromosome. Transcription of the DHBV genome produces messenger RNAs that are polyadenylated. The viral core and polymerase proteins are translated in the cytoplasm. The envelope proteins (including p36) are translated in association with the ER (endoplasmic reticulum). The pregenome and polymerase protein are encapsidated in the core particle and viral DNA synthesis occurs in the cytoplasm. Negative- and positive-strand DNA is generated by the viral polymerase. The core particles can be used by two different pathways. The core particles can associate with the p36 and bud into the ER and be secreted from the cell as virions. Alternatively, the viral genomes in the core structure can be translocated to the nucleus via an intracellular conversion pathway to replenish the pool of viral cccDNA. From Jilbert and Kotlarski.[28]

binding protein, glycine decarboxylase, with a size of 120 kDa has been identified.[37,38] Cellular expression of carboxypeptidase D is restricted to the liver, kidney and pancreas, which are the three major organs supporting DHBV replication. These proteins are potential components of the DHBV receptor complex and probably have a role in determining DHBV organ tropism. Several groups using lysosomal-tropic agents have studied the penetration and uncoating of the virus. DHBV uptake is thought to occur by endocytosis in a pH-independent manner.[39]

## Generation of a transcriptionally active hepadnavirus template

Liver cells have a slow turnover in the healthy state, and hepadnavirus infection thus requires a mechanism by which the genome passes through nuclear pores. Phosphorylated HBV nucleocapsids have been shown to bind to the nuclear pore complex (NPC), leading to exposure of a nuclear localization signal (NLS) on the surface of the capsids.[40–42] The NLS is then bound by importin α followed by binding of importin β, allowing translocation of the total complex into the nuclear basket on the nuclear side of the pore. NPCs have been shown to transport particles with a diameter of 39 nm,[43] and HBV capsids can be imported in an intact form through the nuclear pore into the nuclear basket[44] followed by release of the RC viral DNA and capsid protein into the nucleoplasm.

Several modifications of the infecting RC viral genome must be made before transcription can occur. The single-stranded (SS) DNA region of the hepadnavirus genome must be converted to DS DNA. It is known that the endogenous viral DNA polymerase present in the nucleocapsid can complete the synthesis of this region of DNA *in vitro*.[45] In addition to the synthesis of DNA, removal of the terminal protein and oligoribonucleotide attached to the 5′ ends of the viral DNA strands and ligation of the nicks in the RC DNA must occur to generate covalently closed circular DNA (cccDNA) genome. The viral cccDNA is then organized into nucleosomes[46] to form a viral mini-chromosome[32,47] (Fig. 12.3). In DHBV-infected ducks cccDNA has been detected by Southern blot hybridization within 6 hours of virus inoculation, indicating that conversion of RC to cccDNA occurs early in the replication cycle[48] (Jilbert *et al*., unpublished observations). cccDNA provides the transcriptional template for hepadnavirus infection and is present in multiple copies in the nucleus of each infected cell. This intracellular amplification of cccDNA occurs late in the infection process as a result of transport of RC DNA containing nucleocapsids to the nucleus (Fig. 12.3, also see below).

## Transcription of the avian hepadnavirus genomes

Transcription of hepadnavirus RNA from the cccDNA template occurs in the nucleus of the cell using host cell RNA polymerase II. In contrast to cellular mRNA, hepadnavirus mRNAs are exported to the cytoplasm in an unspliced form. Like cellular mRNAs, the hepadnavirus mRNAs are of positive orientation, possess a 5′ cap and are polyadenylated at their 3′ end. The HBV

and DHBV genomes contain a single polyadenylation signal (TATAAA in HBV, AATAAA in DHBV) and have a common 3′ poly A tail.

The avian hepadnaviruses have four ORFs (Fig. 12.2) and produce three major RNA transcripts,[49] which are transcribed from three distinct promoter regions. The core promoter is used to produce the 3.5-kb RNAs, which are terminally redundant and polyadenylated. A second promoter controls the synthesis of the pre-S envelope mRNA and a third, downstream promoter, synthesis of the S envelope protein mRNA. The DHBV envelope mRNAs are 2.3 and 2.1 kb in length and are polyadenylated at the same site as the pregenomic RNA.[50] The viral envelope mRNAs initiate 1100–1400 nucleotides downstream of the core promoter.[51,52] An mRNA species for the DHBV X protein has not yet been described.

Transcription of the greater than genome length pregenomic RNA, is strongly dependent on a *cis*-acting element at the 5′ end of the RNA, which has been called *pet* (positive effector of transactivation).[50] This element suppresses premature termination during the first circuit of the genome by RNA polymerase II. In addition, a negative effector of transcription (*net*) has been identified upstream of the envelope promoter region.[53] The *net* region and polyadenylation signal are essential for transcription termination and polyadenylation. The presence of *pet* allows transcription complexes to read through *net*, permitting production of the greater than genome length pregenome.[53] Once produced, pregenomic RNA is translated in the cytoplasm to produce the polymerase and core proteins and, as described below, is also encapsidated and used as the template for reverse transcription.

The DHBV genome has only one identified enhancer sequence.[51,52] This sequence binds hepatocyte-adipocyte nuclear transcription factor C/EBP, hepatocyte nuclear factor 1 (HNF1), and F3, which resembles the ubiquitous factor EF-C and is essential for full activity.[54] There are also three sites around the enhancer that bind hepatocyte nuclear factor 3 (HNF3) and three other sites that appear to bind GATA factors.[55]

Comparative analysis of HBV and DHBV sequences and transcription studies has shown that similar nuclear binding factors bind to the enhancers of both viruses, but the organization of these binding sites is different. However, in both cases, the result is that efficient transcription of the complete set of viral mRNAs is highly liver-specific.

## Replication of hepadnaviruses

Hepadnavirus replication takes place in the cytoplasm of the cell within nucleocapsids composed of viral core protein (Fig. 12.3). Pregenomic RNA and viral polymerase are packaged together into the nucleocapsids due to binding of polymerase to an RNA packaging signal, epsilon (ε) present within pregenomic RNA (Fig. 12.4a).[56] Once packaged, pregenomic RNA is used by the viral polymerase as the template for DHBV DNA synthesis.[33,57] The negative-strand of DNA is first produced by reverse transcription (Fig. 12.4a–d) followed by production of the positive-strand of DNA (Fig. 12.4e–f).

Pregenomic RNA contains a number of *cis*-acting sequences important for reverse transcription. For DHBV, these include the packaging signals, epsilon and region II,[58–60] the direct repeats, DR1 and DR2,[61,62] and three *cis*-acting sequences 5E, M and 3E.[63] Extensive studies of the role of 5E, M and 3E have shown that they function by base-pairing to each other and contribute to primer translocation and circularization of the genome.[63,64] These results suggest that within DHBV nucleocapsids the ends of the negative-strand of DNA are base-paired, and that this facilitates the template switches that occur during positive-strand DNA synthesis (see below).[64–67]

Two types of replication are identified for hepadnaviruses, legitimate and illegitimate. During legitimate DNA replication (Fig. 12.4a–f), three or four nucleotides in a bulge of the RNA packaging signal, ε, which folds into a stem loop structure, serve as the template for the priming of reverse transcription.[68,69] In the DHBV genome the sequence is UUAC[70] and in the HBV genome it is UUC.[71] Priming of reverse transcription from this site results in production of a complimentary three or four nucleotide DNA strand (Fig. 12.4b)[70] that is covalently bound to the amino-terminal region of the viral polymerase via a tyr residue.[72,73] The polymerase protein remains covalently bound to the RC DNA genome at this site throughout replication and is bound to the RC DNA genome found in virions.

The three or four nucleotide DNA strand and the polymerase then dissociate from the RNA template and re-anneal with complementary sequences of the copy of DR1 at the 3′ end of the pregenome. DNA synthesis then continues towards the 5′ end of the pregenome RNA and generates a short terminal redundancy of approximately eight to nine nucleotides of DNA. During the process of reverse transcription the RNase H activity of the polymerase digests the pregenome RNA template, leaving an 18 nucleotide RNA sequence at the 5′ end of the pregenome, including the 5′ cap (Fig. 12.4e). This capped RNA serves as the primer for positive-strand DNA synthesis.[61] Typically, the primer is first translocated from the end of the newly synthesized minus DNA strand to the DR2 sequence located, for DHBV 69 nt from the (226 nt in HBV), from the 5′ end of the negative-strand DNA (Fig. 12.4b, c), where it serves as a primer for the positive DNA strand synthesis. Synthesis then proceeds from the primer at DR2 to the end of the negative-strand. The eight to nine nucleotide redundancy in the negative DNA strand permits the transfer of synthesis to the 3′

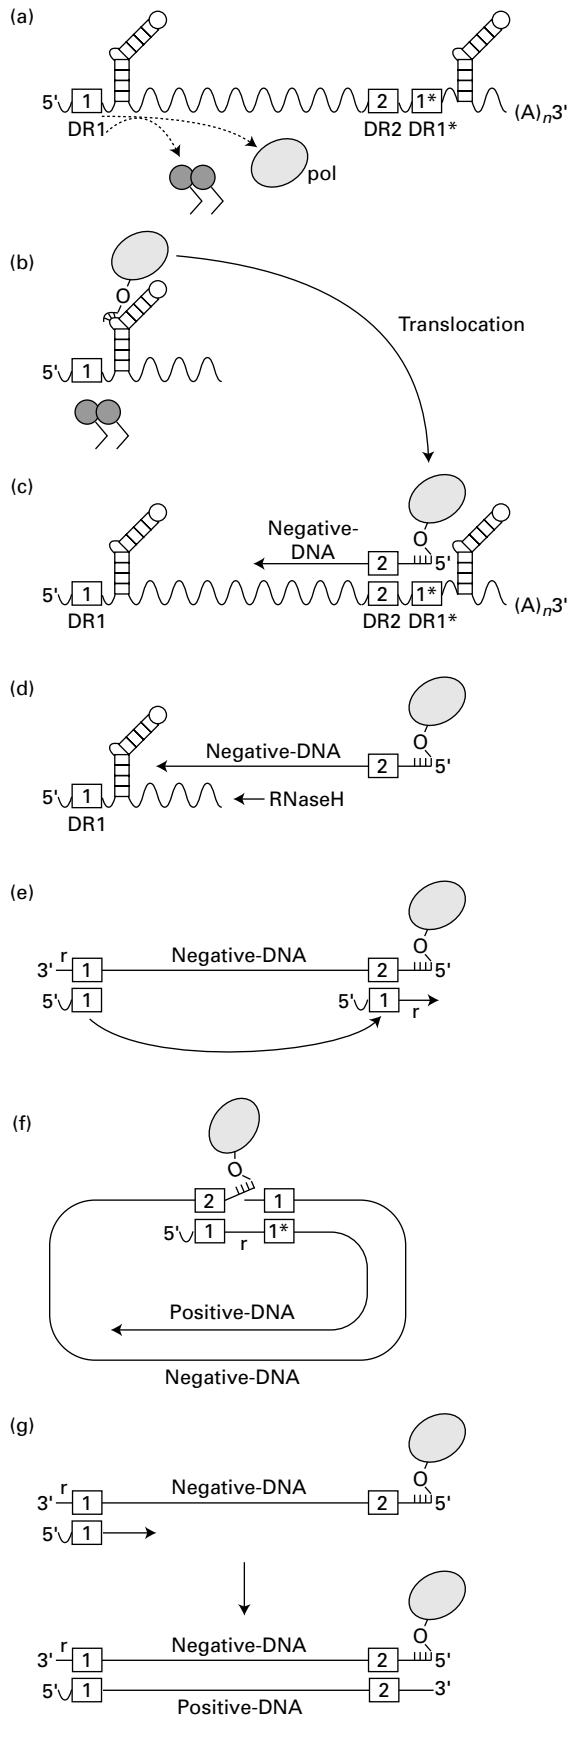

**Figure 12.4** Hepadnavirus replication strategy. (a) The wavy line represents the 3.6-kb longer than genomic length pregenomic RNA, which also serves as mRNA for both the core and polymerase proteins. The encapsidation signal, epsilon (ε) (nt 2566–2622) which is present at both ends of the genome is shown as a symbolic hairpin, and the direct repeat elements DR1, DR2 and DR1* are shown as boxes. (b) Binding of polymerase protein to the 5′ ε and (1) subsequent addition of core protein dimers and hence nucleocapsid assembly, and (2) initiation of synthesis of four DNA nt using the bulge region of ε as template and Tyr-96 of poymerasel as primer. (c) The polymerase–oligonucleotide complex is then translocated to DR1* to initiate synthesis of the negative-strand of DNA that is extended to the 5' end of the RNA pregenome. (d) The RNA template is degraded by the RNase H activity of the polymerase protein, except for a short oligonucleotide at the 5' end containing the DR1 sequence. (e) The 18 nt RNA segment is then transferred to DR2 and used as a primer for synthesis of the positive-strand DNA. (f) Due to an 8 nt terminal redundancy, r, the 3' end of the positive-strand DNA can use the 3' end of negative-strand DNA to circularize the genome and continue positive-strand synthesis. (g) An alternative (illegitimate) replication pathway of positive-strand synthesis where translocation of the 18 nt capped RNA primer to DR2 does not occur but rather positive-strand DNA synthesis is primed *in situ*. Elongation of the positive-strand then proceeds, resulting in formation of a DSL molecule with the 18 nt primer present in an RNA:DNA duplex at the 3′ end of the negative strand. From Jilbert *et al*.[56]

end of the minus DNA strand (Fig. 12.4e, f). This generates a circular genome that, upon further extension of the positive DNA strand, generates the RC DS hepadnavirus genome found in the virion.

Illegitimate replication, in contrast, results from *in situ* priming of positive-strand synthesis without translocation of the 18 nt RNA primer; that is, from the 3′ end of the negative-strand (Fig. 12.4g). This leads to the formation of DS linear (DSL) rather than RC viral genomes. Formation of these DSL genomes occurs at a frequency of about 5–10%.[74] When nucleocapsids with linear DNA are transported to the nucleus, they can undergo illegitimate recombination at their ends to form cccDNA.[74,75] As nucleotides are lost in this process, the resultant cccDNA is often defective in the ability to support virus replication, although some viral proteins may be produced.

Illegitimate DNA replication of hepadnaviruses occurs infrequently. However, mutations that reduce the homology between DRI and DR2 can prevent primer translocation and increase the frequency of *in situ* priming.[76,77] DSL DNA formed due to *in situ* priming has been shown to have a much higher probability than RC DNA of integrating into host DNA during initiation of DHBV infections.[78]

### Assembly of hepadnavirus virions and subviral particles

The DHBV surface antigen ORF has two AUG codons and encodes two forms of DHBV surface antigen, the DHBV Pre-S/S (37 kDa) and S (17 kDa) proteins. The pre-S/S protein contains an additional 163 amino acids (aa) amino-terminal extension in addition to the 167 aa of the DHBV S protein. The amino-terminal extension in the pre-S/S protein contains the receptor binding site[18] and has two alternate transmembrane topologies.[79] In the first topographical form the amino-terminal extension is translocated across the ER membrane, exposing the receptor binding site on the exterior of the virion and resulting in formation of infectious virions. Only 50% of pre-S/S molecules have translocated amino-termini, thus mature DHBV virions contain mixed internal/external pre-S/S topologies, including a partially translocated or intermediate form.[79]

Both the pre-S/S and S proteins contain signal sequences that direct their translocation into the ER and are transmembrane proteins with up to five transmembrane domains. Studies of transmembrane domain 1 (TM1), located within the common carboxy-terminal region of both the S and pre-S/S proteins, have shown it to be essential for stability of the S protein and for particle assembly.[80] The TM1 protein is also involved in fusion of virus particles with infected cells. Recent studies have indicated that some pre-S/S molecules are spring-loaded and undergo a major conformational change analogous to fusion activation.[81] These studies showed that the conformational change exposed TM1 to the virion surface, allowing virions to bind to cell membranes, suggesting that the TM1 of pre-S/S is a fusion peptide. The TM1 domain, common to both envelope proteins, thus has a different functional role in pre-S/S and S and thus a different structural arrangement on the assembled particle.

The envelope proteins have the ability to assemble subviral particles that bud into the lumen of the ER and the Golgi compartments. This auto-assembly process results in the production of a large excess of subviral particles compared with virions in the serum of viraemic individuals. The final step in the assembly of the virions involves the association of the nucleocapsid with viral envelope proteins at the ER membrane. Enveloped nucleocapsids are deposited into the ER lumen, and the particles are secreted via the constitutive secretory pathway.

The DHBV e antigen (DHBeAg) is a secretory protein that is produced from the translational product of the longest of the 3.5-kb viral RNAs.[82,83] It is generated from a precursor polypeptide that contains a signal peptide, which targets this polypeptide to the ER. It is modified by cellular proteases and secreted as a 27-kDa unglycosylated and 30- or 33-kDa glycosylated protein.[82]

### Maintenance of the nuclear covalently closed circular hepadnaviral DNA pool

Cells supporting HBV replication have been shown to contain ~10–50 copies of cccDNA/cell.[84] Similarly, WHV- and DHBV-infected cells contain 10–50 and 6–30 copies of cccDNA per cell, respectively, and up to 500 or more copies of single- and double-stranded replicative intermediates in the cytoplasm.[15,85–87] The copy number of viral cccDNA has been demonstrated, for DHBV at least, to be regulated by the pre-S/S.[88] Viral cccDNA can be produced from the infecting virion, and also from genomes that are produced via the reverse transcriptase pathway and are transported into the nucleus.[15,87,88] Thus, mature intracellular nucleocapsids containing RC DNA proceed along one of two alternative pathways. Early in the infection process, the newly replicated virion DNA within mature nucleocapsids is delivered to the nucleus, resulting in amplification of cccDNA. Later in the infection process, production of the pre-S/S inhibits viral cccDNA amplification, redirecting viral nucleocapsids into envelope virus particles that are exported from the cell. Importantly, hepadnaviral cccDNA appears to be a major viral replicative DNA species that is resistant to inhibition by conventional antiviral agents[89,90] (see below). This reflects the fact that it does not itself replicate, except via the reverse transcription pathway, and functions solely as a template for viral RNA synthesis.

## Pathogenesis of avian hepadnaviral infections

### Transmission and outcome of infection

The predominant route for the natural transmission of hepadnaviruses varies significantly between the mammalian and avian hepadnaviruses. Mammalian hepadnaviruses are transmitted via parenteral contact with body fluids, such as blood and lymph.[91] Transmission also occurs via perinatal exposure of infants to carrier mothers, which typically results in persistent infection of the infant.[91] In contrast, avian hepadnaviruses are primarily transmitted *in ovo* where persistent infection develops at a frequency of 100%.[85,92–94]

The ability of individual ducks to resolve DHBV infection is linked to the age of the duck at the time of inoculation and the dose of inoculated virus.[95] Titration of stocks of the Australian strain of DHBV in newly hatched ducks (1–3 days old) has shown that it is possible to establish persistent infection by inoculation of pooled serum from congenitally infected ducks containing the equivalent of one virus genome. This result

indicates not only that newly hatched ducks are highly susceptible to the development of persistent infection, but that a 1:1 ratio of infectious viral particles to DNA genomes occurs in congenitally infected duck serum.[96] Similar infectivity experiments have been performed in Australian ducks infected with both the German DHBV 3 strain[19] and the USA strain DHBV16,[23] and similarly high ratios of infectious particles to DNA genomes have been demonstrated.[27,97]

In older ducks, the outcome of infection is also linked to the dose of virus inoculated. For example, inoculation of $1 \times 10^6$ genomes of DHBV into 14-day-old ducks leads to a persistent infection, while inoculation of $4 \times 10^4$ genomes results in transient infection.[95] After 4–6 weeks of age, it is harder, although possible, to establish persistent DHBV infection. In one study in 4-month-old ducks, one of three animals inoculated with infectious serum containing $2 \times 10^{11}$ DHBV genomes developed persistent infection, while all animals inoculated with serum containing $10^3$, $10^6$ and $10^9$ DHBV genomes had transient infection.[95] The failure to develop persistent infection in older ducks is not due to a loss of receptors or to an inability to infect hepatocytes in the liver, as the ducks receiving $2 \times 10^{11}$ genomes had DHBV infection in >95% of hepatocytes at days 6, 9 and 12 after inoculation.[95] In contrast, it is thought that older ducks have an increased ability to generate effective immune responses, resulting in production of virus neutralizing antibodies and cytotoxic T lymphocytes that lead to resolution of DHBV infection (reviewed in Jilbert and Kotlarski[28]).

Characterization of the DHBV model has enabled some basic questions about the biology of hepadnavirus to be asked, including the kinetics of growth in the liver, with the idea that the prolonged incubation period reported for HBV infection might be due to slow virus spread. Instead, DHBV infection in young ducks spread rapidly throughout the liver with a doubling time of 16 hours, resulting in full infection of the liver from a single virus particle within 4 weeks.[96] The rate of spread of DHBV in the liver of 3-day-old ducks infected with $1.5 \times 10^3$ $ID_{50}$ of the Australian strain of DHBV is shown in Fig. 12.5.[96] The number of cells expressing DHBV surface and core antigen increase exponentially, due to cell to cell spread of the virus, resulting in infection of >95% of hepatocytes by day 13–15 after infection. The DHBV model has been used in a similar way to study the kinetics of growth and behaviour of viral mutants *in vivo*, including DHBV strains with mutations in the X-ORF[27] and cytopathic mutants of DHBV with specific mutations in the viral pre-S/S protein[97–99] (Meier *et al*., unpublished observations).

Studies of the immune response during DHBV infections have been hampered by the lack of reagents for studying the immune system of the duck. However, recent progress has been made with the development of *in vitro* stimulation assays for detection of viral antigen-specific T-cell responses,[100–102] monoclonal and polyclonal antibodies for duck T-cell markers[103,104] and ELISA assays for DHBV surface antigen and anti-surface and anti-core antibodies (reviewed in Miller *et al*.[102]). The recent cloning of cDNAs for the duck cytokines, interferon (IFN)-$\alpha$[105] and IFN-$\gamma$[106,107] and the duck T-cell markers, including CD3, CD4, CD8, MHC I and II by David Higgins and colleagues at the University of Hong Kong (GenBank AF378704; T-cell surface glycoprotein CD4 precursor mRNA, GenBank AF378701; T-cell antigen CD8 alpha mRNA, GenBank AF378373; MHC class I antigen alpha chain mRNA, GenBank AF393511; MHC class II antigen beta chain mRNA, GenBank AF390589), now make studies of the immune response during DHBV infection highly feasible. In addition to the reagents above, anti-duck CD4 and CD8 monoclonal antibodies are now available (Ursula Schultz, University of Freiburg, unpublished data) to allow further studies.

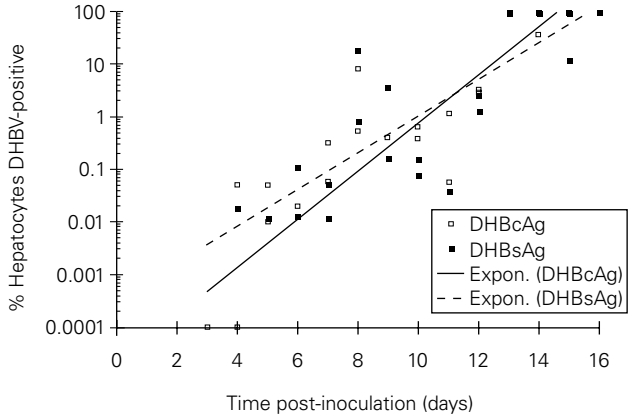

**Figure 12.5** The spread of DHBV infection from cell to cell in the liver of a group of 28, 4-day-old ducklings inoculated intravenously with $1.5 \times 10^3$ $ID_{50}$ of DHBV. DHBV infection was also monitored from days 3 to 16 post-inoculation by immunoperoxidase staining of DHBcAg and DHBsAg in sections of fixed autopsy liver tissue. The percentage of DHBcAg and DHBsAg-positive hepatocytes was determined by cell counts in sections counterstained with haematoxylin and the calculated line of best fit for exponential increase in the number of DHBcAg and DHBsAg-positive hepatocytes is shown. From Jilbert *et al*.[96]

The ability to modify the outcome of DHBV infection and reproducible kinetics of DHBV infection following experimental inoculation have made the DHBV model a valuable and reliable experimental system for studying aspects of acute and chronic hepatitis.[28,85,95,96,102,108,109] Studies are in progress to further define the role of the immune response during the resolution of transient DHBV infection and in assessing the protective and therapeutic efficacy of various vaccine strategies against DHBV infection.

## Pathology of infection

The study of the animal hepadnaviruses has made it possible to determine whether differences in liver pathology following infection are proportional to the amount of viral replication, or are the result of host-specific responses and/or environmental factors.

Acute infection with HBV can be asymptomatic or can result in severe and fatal hepatitis. Recent studies of the resolution phase of transient WHV infection have demonstrated that extensive turnover of hepatocytes occurs with the equivalent of at least one entire liver of hepatocytes being destroyed and regenerated during resolution.[110] Analysis of the levels of integrated WHV DNA indicated that the recovered liver was populated to a large extent by previously infected hepatocytes that had undergone cell division, consistent with the idea that loss of virus infection from hepatocytes required turnover of infected cells.[110]

In agreement with this, resolution of transient WHV infection was also accompanied by histological evidence for activation of Kupffer cells, of marked apoptosis and for a substantial amount of cell death. Remarkably, during resolution the Kupffer cell population in the liver increased from 5–9% (weeks 0–4) to 25–29% of total lobular cells (weeks 8–12). Kupffer cells also increased in size due to the accumulation of PAS-diastase-resistant material. The high apoptotic index and high fraction of PAS-D-positive Kupffer cells supported the idea that a major fraction of hepatocytes had been destroyed by the host immune response (Jilbert *et al*., unpublished data). Preliminary studies of Kupffer cells in the liver of ducks undergoing resolution of DHBV have shown similar levels of Kupffer cell activation, suggesting that cell death is also a significant feature of the resolution of DHBV infection (Jilbert *et al*., unpublished data).

Chronic HBV and WHV infection are associated with various levels of liver disease that can vary from minor inflammation in the liver to severe hepatitis, cirrhosis and, ultimately, hepatocellular carcinoma (HCC). Chronic hepadnaviral infection is associated with the development of HCC in WHV, HBV, GSHV and DHBV infections in descending order of risk.[111]

In contrast, chronic infection with the avian hepadnaviruses including DHBV generally results in a mild hepatitis that does not usually progress to cirrhosis or HCC.[29,112] This type of infection is similar to the 'healthy' carrier status of humans infected with HBV.

The failure to detect HCC in avian species may be linked to the timing and mode of transmission of these viruses, as they are usually transmitted vertically by *in ovo* transmission, resulting in congenital infection with immune tolerance and an absence of liver disease.[29,85,112] In support of this idea, experimental infection of 4-month-old ducks with DHBV leads to the development of chronic DHBV infections with mild and marked liver disease,[95] and these animals may have a greater chance of developing HCC. The ability of avian species to develop HCC may also be affected by their shorter lifespan. Chronic infection of Pekin ducks has been followed longitudinally for many years without the development of tumours.[113–116] HCC has only been found to occur in ducks from a single province in China,[112,117,118] where environmental aflatoxin exposure may have been prevalent. In summary, pathogenesis does not appear to correlate directly with the amount of virus replication but rather, with the host immune response to the infection. Environmental factors also appear to play a role, particularly in the development of HCC.

## Extrahepatic DHBV infection

Hepadnaviruses primarily replicate and cause cellular injury in the liver. A large number of studies have provided evidence for DHBV infection in extrahepatic sites as well.[9,119] Despite the large number of studies performed, the significance of extrahepatic viral replication to infection outcome remains unclear.

Most studies of extrahepatic DHBV infection have been based on the *in situ* detection of viral proteins, DNA and RNA replicative intermediates, and the natural history of hepadnaviral infection of extrahepatic sites has been best described in the DHBV model *in vivo*.[112,120–122] Embryonic studies of DHBV replication have identified that endodermal yolk sac cells support virus replication before hepatocytes.[123] This endodermal cell layer is oncogenetically and functionally related to the liver. Furthermore, pancreatic endocrine and exocrine cells, kidney tubule cells and glomeruli have also been shown to support viral replication in duck embryos.[85,124]

A systematic study of the course of viraemia and tissue tropism in ducks congenitally infected and experimentally infected with DHBV was performed for 6 months.[122] During this study, experimentally infected ducklings had detectable virus infection in the endocrine and exocrine pancreas. Over time, the number of infected acinar cells declined. However, there was a corresponding increase in the number of pancreatic islet cells that expressed DHBV DNA and DHBsAg. Earlier studies by Halpern *et al*.[119,125,126] had found that DHBV DNA infection was present in both α-cells (glucagon-secreting) and β-cells (insulin-producing), with the former having a high percentage of cells expressing viral antigens.

DHBV infection has been demonstrated in kidney tubules[119] and some glomeruli.[119,120,122,127] Viral DNA was found in foci of adjacent glomeruli[120] and proximal tubules[119,120] using the technique of *in situ* hybridization.

Viral antigen accumulation in glomeruli may in part be bound within immune complexes or due to the excessive antigenic burden produced by chronic infection with the respective hepadnavirus.

Small clusters of DHBV antigen-positive cells were detected in adrenal glands of young. These cells were identified on the basis of histological criteria and found to be adrenal cortical cells.[125] However, no evidence was obtained for DNA replication in the adrenal gland. The pancreatic islet cells and the cells of the adrenal gland secrete hormones involved in the regulation of carbohydrate metabolism and are susceptible to DHBV infection.[128] The implications of this are presently unknown, and further investigations are required.

DHBV DNA is not usually found in the spleen of chronically infected ducks but has been observed during acute infection,[121,129] specifically in splenic mononuclear cells.[129] The distribution of DHBsAg in the spleen was found to correlate well with the presence of DHBV DNA, although a proportion of splenic red pulp cells, which were shown to contain lower levels of DHBV DNA by *in situ* hybridization, were negative for DHBsAg. Only viral DS DNA has been found within germinal cells of the spleen of ducks and humans.[129] The DS nature of the viral DNA in spleen cells may also be related to the age of the ducks examined. Earlier studies had noted an age-associated transition from SS to DS DHBV DNA in the spleen of infected ducks.[121]

Within the liver, DHBV replication has also been found to occur in a population of cells other than hepatocytes. Bile duct epithelial cells have been reported to contain DHBV proteins and DNA.[85] DHBV replication has been convincingly demonstrated using primary cultures of bile duct epithelial (IBDE) cells isolated from ducklings. The primary IBDE cells formed duct-like structures of multi-layered IBDE cells, which were identified as bile duct cells using the anti-keratin marker, CAM 5.2, and were negative for duck albumin. Primary IBDE cells were shown to be susceptible to DHBV infection with production of DHBV cccDNA, replicative intermediates and viral surface and core proteins. These cells might form a reservoir for DHBV infection in the liver and are a clear example of DHBV replication in cells other than hepatocytes.

## Development of antihepadnaviral agents

The mechanisms that determine the final outcome of the interaction between HBV and its host are multifactorial. As chronic HBV infection can cause serious liver damage, elimination of persistent infection before the development of cirrhosis, liver failure and/or malignancy is an important clinical therapeutic strategy.[91] Thus, the primary goal of antiviral therapy is to eradicate HBV infection from the host and thereby prevent the consequences of persistent infection, namely chronic liver disease and its further clinical progression.[130]

### The experimental model of DHBV

The relatively low response rate to the existing approved antiviral therapies for the treatment of chronic HBV infection clearly supports the necessity for the ongoing development of alternative therapeutic regimens.[130] As all hepadnaviruses share a common replication strategy, animal models such as DHBV have provided useful preclinical systems for the development of novel agents or improved treatment protocols. Two major classes of therapeutic agents are currently used for the treatment of chronic HBV: immune modulating agents (cytokines such as IFN-α) and antiviral agents (such as nucleoside analogues). More recently, these agents are also being trialled in various combination strategies.

The use of the DHBV model of hepatitis B in the assessment and development of therapeutic agents and protocols has proved particularly useful for the purine nucleoside analogues such as ganciclovir,[89,90,131] penciclovir,[132] adefovir (PMEA),[133–135] entecavir (ETV)[136,137] and FLG,[138,139] as well as the pyrimidine analogues including emtricitabine (FTC),[140] an agent very similar in antiviral profile to lamivudine,[141] clevudine (L-FMAU) (Aguesse-Germon) and β-L-Fd4C[141] (see Table 12.2)[51,86,89,90,131–133,135,137–140,142–155] (reviewed in Shaw and Locarnini.[153]). Such detailed studies in the duck model have highlighted the value and reinforce the need for extensive preclinical testing of an agent before it enters phase I/II clinical trials. In this way, both predictable and unpredictable toxicity should be avoided.[89]

Early attempts to screen potential anti-hepadnaviral compounds measured antiviral efficacy by the amount of endogenous viral DNA polymerase activity or viral surface antigen in serum. This approach had limited applications and did not attempt to define intrahepatic effects of the agent on the overall hepadnaviral replication. Present antiviral evaluations *in vivo* have become much more sophisticated and typically include a detailed intrahepatic viral protein and nucleic acid analysis,[92] pharmacokinetics[90] and drug toxicity assessments[151] as part of the standard evaluation protocol (Table 12.2).

Because of the limited success achieved with monotherapy, several different approaches and new protective strategies and treatments for persistent HBV infection are being developed by combining an antiviral treatment with a nucleoside analogue to reduce viral load, and vaccination with DNA vaccines expressing the DHBV antigens. A recent combination study of antiviral and DNA vaccine study has used ETV treatment and found reduced levels of viral replication and antigen expression in the liver and serum.[136] However, the

**Table 12.2** Antiviral compounds tested for activity against chronic DHBV infection *in vivo**

| Compound | Viral assay | Comment | Ref. no. |
|---|---|---|---|
| Phosphonoformate | DNA (S,L) | Treatment reduced viral DNA levels in serum and liver in a dose-dependent manner | 154 |
| Adenine arabinoside (ara-A) | DNA (S,L) | Dose-dependent inhibition of viral DNA in the serum and liver. Higher doses than given in human studies were required to demonstrate an antiviral effect. cccDNA levels in the liver were unaffected by therapy | 147 |
| Dideoxycytidine | DNA (S,L) | Reduction in serum DNA and DNA polymerase activity and >90% reduction in DHBV DNA in the liver. Some antiviral activity was sustained after therapy had ceased | 71 |
| Azothymidine (AZT) | DNA (S,L) | No activity | 145 |
| Ganciclovir | DNA (S,L) | Reduction in serum and liver DHBV DNA levels. No effect on viral cccDNA in the liver | 90 |
| | Viral proteins (S,L) | Reduction in viral envelope and core proteins in hepatocytes. No reduction in serum antigenaemia | 89 |
| Cyclobut-A, Cyclobut-G, AZT | DNA (S) | The purine analogues reduced serum DHBV DNA levels. AZT has no activity | 152 |
| Dideoxyadenosine (ddA)/ dideoxydiamino purine | DNA (S) | Dideoxydiaminopurine reduced serum DHBV DNA more effectively than ddA | 149 |
| 2′CDG | DNA (S,L) core protein (L) | Virus production was inhibited >50-fold. Viral DNA in the liver was reduced, including the viral cccDNA, by >70%. The number of infected hepatocytes declined after 3 months of therapy | 144,151 |
| FTC | DNA (S,L) viral proteins (L) | FTC inhibited viral DNA replication in the serum and the liver. Viral cccDNA was reduced by >50%. A high proportion of hepatocytes remained infected at the end of treatment | 140 |
| PMEA (adefovir) | DNA (S) | PMEA reduced serum viral DNA levels during treatment, but relapse occurred in the follow-up period. No effect on cccDNA. Reduction of replication in bile duct epithelial cells | 133, 135, 146 |
| Penciclovir/famciclovir | DNA (S,L) | Penciclovir, and its orally active form famciclovir, inhibited viral replication in the liver and virus secretion into the serum. No effect on viral cccDNA levels after 12 days of treatment;[51] however, PCV therapy reduced cccDNA levels by >50% after 4 weeks[143] | 133, 151, 156 |
| Entecavir (ETV) | DNA (S,L) | Very potent inhibitor of replication. cccDNA reduced but not eliminated | 137 |
| L-FMAU (Clevudine) | DNA (S,L) | Potent inhibitor of replication | 148 |
| FLG (Fluoroguanosine) | DNA (S,L) | Potent inhibitor of replication | 138,139 |
| β-L-Fd4C | DNA (S,L) | Potent inhibitor of replication. Minimal effect on cccDNA | 141 |

*The viral products were detected either in serum (S) or in the liver (L). Modified from Luscombe and Locarnini,[131] with permission and Shaw and Locarnini.[153].

administration of five doses of DNA vaccine expressing the DHBV S, pre-S/S and core antigens did not prevent the rebound of DHBV infection after withdrawal of the drug or lead to significant long-term effects on DHBV infection. Similar findings were observed with the combination approach of adefovir (ADV) plus DNA vaccination, except that more of a sustained antiviral effect was achieved.[156]

In attempts to enhance the immune response to DNA vaccines, approaches used by others for eliciting cell-mediated immune responses are being tested in ducks. These include whole-cell DNA vaccines using primary duck embryonic fibroblasts (PDEF) expressing DHBcAg, an internal antigen of the virus, and DNA vaccine prime, followed by fowlpox virus boosts (Miller and Jilbert, unpublished data).

## Challenges for development of therapies for chronic HBV: the role of cccDNA inhibitors and animal model testing

From the results of such testing as discussed above and outlined in Table 12.2, the most important observation found to date is that conventional antiviral therapy has a minimal effect on the intrahepatic viral cccDNA levels as well as viral RNA production.[157–159] Complete inhibition of viral polymerase activity by a nucleoside analogue should prevent replenishment of the cccDNA pool by blocking synthesis of its RC DNA precursor. However, the resistance of chronic HBV infection to treatment with nucleoside and nucleotide analogues such as lamivudine and adefovir indicates that the cccDNA pool in infected cells is relatively stable. If production of new

virions could be completely blocked, cccDNA should eventually be eliminated as a result of either death of infected hepatocytes or intracellular decay. The lifespan of infected hepatocytes appears to be variable, depending on the severity of liver disease, and intracellular turnover of cccDNA is probably similarly variable.

The presence of functional hepadnaviral mini-chromosomes in hepatocyte nuclei is essential for viral replication and establishment of persistence. Therefore, their complete elimination is necessary in order to affect a lasting cure. Because it is replicated via an RNA intermediate, viral cccDNA is not directly affected by deoxynucleos(t)ide analogue inhibitors of DNA polymerase activity. These inhibitors are only virustatic. The long *in vivo* half-life of cccDNA during chronic infection and low viral replication fidelity make it likely that drug-resistant virus will emerge before cccDNA is completely depleted.

One approach has been to attempt to destabilize cccDNA and prevent its formation by treatment with compounds that either interact directly with viral cccDNA or that inhibit specific enzymes required for its formation and processing. The first group includes intercalators and compounds that bind to DNA. The second are mostly inhibitors of topoisomerases, the enzymes that catalyse interconversion of DNA topoisomers by introducing transient single- or double-strand breaks via formation of covalently enzyme-DNA intermediates. Stabilization of topoisomerase-DNA 'cleavable complexes' by inhibitors and cross-linking agents blocks progress of polymerases, ultimately causing permanent strand breakage and has been shown to work as a 'proof of principle' in primary duck hepatocytes infected with duck HBV.[160] Compounds shown to have antiviral activity included adriamycin, tenoposide and camptothecin, which have been used clinically as anti-cancer drugs, but which are clearly too non-specific and too toxic to be used long-term in patients with chronic HBV. An alternative approach might involve the use of a new generation of antineoplastic drugs that interfere with histone and DNA modification.[160–163] Another extension of this approach is to use combinations of conventional nucleoside analogue therapy with topoisomerase inhibitors[164] as well as antiviral cytokines.[165] These studies indicated that the recalcitrant nature of the cccDNA molecule as an antiviral target could at least be partly reversed and should act as a stimulus for further studies in the duck model. Whether or not these compounds have clinically useful antiviral activity awaits evaluation, but their use in animal models such as the DHBV model will ultimately generate useful information about the structure and function of hepadnaviral mini-chromosomes that could eventually lead to their therapeutic elimination and 'cure' of chronic HBV.

# Chapter 13
# Woodchuck hepatitis virus

Michael Roggendorf, Michael Lu

## Introduction

The Eastern woodchuck (*Marmota marmota*) is naturally infected by woodchuck hepatitis virus (WHV) which was discovered in 1978.[1] WHV was found to be closely related to hepatitis B virus (HBV)[2] and classified as a member of the genus orthohepadnavirus, family Hepadnaviridae. However, these viruses differ in several aspects, e.g. regulation of transcription.[3] The family Hepadnaviridae was still growing in recent years.[4,5] Infections of woodchucks with WHV have been shown to be endemic in the mid-Atlantic states of the USA, e.g. Delaware, Maryland, Pennsylvania, whereas in the states of New York and New England woodchucks are rarely infected with WHV. The molecular characterization of WHV and experimental infection of woodchucks with WHV has been of value in modelling several aspects of hepadnaviral infection in humans. Many questions of hepadnaviral infection have been addressed in this model, e.g. natural course of infection,[6–9] immunopathogenesis,[9–15] host and viral factors associated with development of chronicity,[15–17] development of hepatocellular carcinoma (HCC),[18,19] and rise and significance of viral mutants in acute and chronic infections.[20–28] From a medical point of view, the woodchuck model has been used to develop new strategies for prevention of infection[29,30] and therapy of chronic hepadnaviral infection including: nucleoside analogues,[31–45] non-nucleoside analogues,[46] therapeutic vaccination[47–50] and gene therapeutic approaches for treatment of HCC.[51] Liver transplantation has recently been established for woodchucks to study early events in reinfection and adoptive immune transfer.[52,53] Previous reviews have covered the natural history of WHV infection,[54] aetiology of HCC,[19] antiviral treatment by nucleoside analogues[55–57] and pathogenesis of hepadnaviral infection.[9] Lately, significant progress has been made in this model of hepadnavirus natural infection, which demonstrates that non-cytotoxic and cytolytic antiviral immune responses are needed for elimination of the virus from hepatocytes or to at least control viral replication. This review therefore focuses on the recent development of tools to study humoral and cellular immune responses to WHV and the immunopathogenesis of WHV infection, prevention of infection by protein and DNA vaccines and immunomodulatory approaches to treat chronic WHV infection. These new insights into the immune response to WHV will enable the development of new strategies to treat chronic hepatitis B virus (HBV) infection.

## New tools to characterize the immune response to WHV

The woodchuck is an ideal model for hepadnavirus infection in humans, as WHV infection in woodchucks results in a number of different outcomes which are similar to HBV infection in humans, ranging from a subclinical or acute transient infection to chronic infection progressing to HCC. Unfortunately, at present no inbred animals are available to standardize infection experiments. For an understanding of the underlying mechanisms responsible for different outcomes of infection, detailed *in vivo* studies on humoral and cellular immune responses to WHV are required. Assays for antigen and antibody detection have been available for many years.[58] However, until recently little information about the cellular immune system was available.

### Characterization of virus-specific T cells in the woodchuck

For many years, studies on the cellular immune response to WHV were hampered by the lack of effective proliferation assays for peripheral blood mononuclear cells (PBMCs). Thymidine uptake by woodchuck PBMCs stimulated by mitogens or specific WHV proteins was very low compared with other cell systems such as mouse or human, although mitogen clearly induced blast formation of woodchuck cells, as confirmed by microscopic examination. Based on these negative results reported so far the experimental conditions were re-evaluated to measure antigen-induced PBMC proliferation.[59] The lack of incorporation of [$^3$H]-thymidine into cellular DNA by PBMCs was due to the absence of expression of thymi-

dine kinase (TK) gene in the woodchuck lymphocytes. However, the TK gene is present in the woodchuck genome and is probably expressed in other cell types.[60] Transfection of woodchuck cells with mouse TK gene demonstrates that TK1 is transcribed and a functional TK protein can be expressed.[60] Using 2[$^3$H]-adenine as an alternative labelled nucleoside, we could demonstrate a significant incorporation into cellular DNA and partially RNA in proliferating PBMCs.[10] In addition to 2[$^3$H]-adenine, a non-radioactive proliferation assay for woodchuck PBMCs using 5-bromo-2′-deoxyuridine (BrdU) as thymidine analogue was established.[61] However, measurement of PBMC proliferation induced by mitogens and WHV core protein (WHcAg) by the incorporation of BrdU was less sensitive than the assay using 2[$^3$H]-adenine. Another alternative assay to determine T-cell proliferation was established by measuring secretion of interleukin (IL)-2 of activated T cells.[47,62] In this assay, woodchuck IL-2 secreted in supernatants from stimulated PBMCs was tested in an IL-2-dependent murine cell line, CTLL-2, indicating a cross-reactivity of mouse and woodchuck IL-2. Viral proteins for *in vitro* stimulations were obtained by purification of WHsAg from plasma and recombinant WHcAg in *Escherichia coli*. Using overlapping and non-overlapping peptides derived from WHcAg, a number of T-cell epitopes on WHcAg could be identified (see below). These modified and optimized proliferation assays made it possible to perform studies on T-cell immune response, specifically to WHV proteins in acute and chronic infection and immunized woodchucks.[61] It remained to be proven that stimulated T cells are actually CD4-positive T-helper cells because of the lack of specific antibody to the woodchuck homologue of CD4. A cross-reacting anti-CD3 antibody from swine binds to these cells.[10,11] It can be assumed that proliferating CD3-positive T cells correspond to the T-helper cell population which expand under similar experimental conditions in the mouse system. Despite many efforts, demonstration of cytotoxic T cells has not been achieved for the woodchuck model. Using DNA vaccination in mice with plasmids expressing WHcAg, specific CTLs to WHcAg could be demonstrated in the mouse model (Isogawa *et al*., unpublished results).

## Cloning and characterization of components of the woodchuck immune system

In recent years, a number of cytokines and surface markers of immune cells have been characterized. Proteins related to immune response such as antigen processing (TAP-1, TAP-2) and presentation, e.g. major histocompatibility complex (MHC) class I and class II, proteins involved in signal transduction, and cell surface markers like CD3, CD4 and CD8 present in cells of the immune system have been cloned and sequenced. In Table 13.1, the components of the woodchuck immune system characterized at the molecular level so far are summarized.[15,29,63–69] In general, cDNA fragments were amplified by reverse transcription polymerase chain reaction (RT-PCR) with RNA from woodchuck lymphocytes. Primers were designed according to aligned sequences and chosen from regions well conserved among human and other mammalian species.

### *Cytokines*

The complete coding sequences of tumour necrosis factor-α (TNF-α),[63,67] interferon-α (IFN-α),[66] IFN-γ,[63] IL-6,[63] IL-10,[23] IL-12[29] and IL-15,[15] GMCSF,[68] lymphotoxin-α (LT-α) and -β (LT-β)[67] were obtained. Partial sequences of IL-2, IL-4, Fas ligand[69] and others were cloned. The

length and homology of woodchuck cytokines to human and mouse cytokines are given in Table 13.1. In general, the woodchuck genes are more closely related to human than to mouse counterparts. The structure of woodchuck cytokines as compared to human cytokines seems to be well conserved, e.g. the comparison of woodchuck TNF-α to the human sequence demonstrates that two cysteine residues, cys69 and cys101, that are known to be involved in an intermolecular disulfide bridge are conserved. Other amino acid residues like leu29, arg32, ala143 and ser145, which were found to be important for receptor binding of the human protein, are also conserved in the woodchuck TNF-α.[63] For IFN-α it could also be shown that four cysteine residues which form intramolecular disulfide bridges are conserved.[66]

TNF-α, IFN-α, IFN-γ, IL-12 and LT-α have been tested for their biological activities. The entire open reading frame (ORF) of IFN-α was cloned under control of the cytomegalovirus (CMV) promoter into the expression vector PVIJ.[66] Supernatants of HeLa cells transfected with this construct protected woodchuck cells from vesicular stomatitis virus (VSV)-induced cytopathic effect (CPE). The biological action of IFN-α was also demonstrated by induction of expression at MxA-protein. Finally, the biological activity of IFN-α was tested in WHV-infected woodchuck hepatocytes. Woodchuck IFN-α reduced WHV surface antigen expression in a dose-dependent fashion.[66]

The biological activity of TNF-α and LT-α was tested in a cytotoxicity assay using woodchuck A2 cells. The specific activities for both woodchuck cytokines TNF-α and LT-α were significantly higher in woodchuck cells than in mouse L9 to 9B and human HepG2 cells.[23,63]

We expressed recombinant woodchuck IFN-γ (wIFN-γ) in *Escherichia coli* and mammalian cells. wIFN-γ protected woodchuck cells against infection with murine encephalomyocarditis virus in a species-specific manner. It upregulated the mRNA level of the woodchuck major histocompatibility complex class I (*Mamo-I*) heavy chain in permanent woodchuck WH12/6 cells and regulated differentially the gene expression.[65] However, the level of the replication intermediates and specific RNAs of WHV in persistently WHV-infected primary woodchuck hepatocytes did not change despite treatment with 1000 U of wIFN-γ per mL or with a combination of wIFN-γ and wTNF-α (Fig. 13.1). Rabbit antibodies to wIFN-γ were able to block biological activity of IFN-γ.

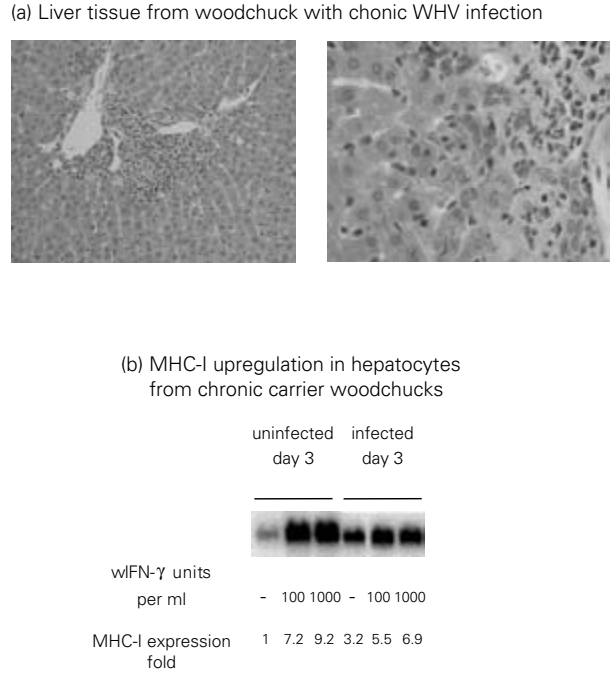

**Figure 13.1** (a) The persistent viral infection leads to infiltration of lymphocytes into the liver. Recent studies showed clearly that the intrahepatic production of wIFN-γ continuously occurs in chronic carriers and leads to stimulation of cellular gene expression. (b) MHC-I expression in response to the stimulation with IFN-γ. The woodchuck MHC-I cDNA is expressed only at a low level in naïve hepatocytes (uninfected), but showed an enhanced expression in hepatocytes derived from chronically infected liver (infected). The expression of MHC-I increased up to 9.2-fold with treatment with IFN-γ at a concentration of 100 or 1000 units/mL in cultures. Notably, the expression of MHC-I in infected hepatocytes did increase only slightly after stimulation with IFN-γ.

## Intrahepatic expression of wIFN-α and -γ in chronic WHV infection

wIFN-α and -γ were cloned into adenoviral vectors for gene therapeutic approaches to treat chronic WHV infection.[57,70,71] *In vitro* transduction of woodchuck hepatocytes with adenoviral vector resulted in secretion of biologically active cytokines. In subsequent experiments, both vectors have been used to treat chronic WHV infection *in vivo*. The transduction of livers of WHV carriers with HD-AdwIFNα or HD-AdwIFNγ induced levels of biologically active IFN, which could be measured in the sera of these animals. Expression of wIFN-α in the liver significantly reduced intrahepatic WHV replication and WHV-DNA in sera. However, transduction with HD-wIFNγ reduced WHV replicative intermediates only slightly. The data demonstrate for the first time the successful HD-Ad-vector-mediated transfer of genes for IFN-α and IFN-γ *in vivo* and timely limited reduction of WHV replication by wIFN-α, but not by wIFN-γ.[70] Similar experiments with a second generation of adenoviral vector expressing wIFN-γ and wTNF-α reduced WHV core-positive hepatocytes and cccDNA. However, this may be due to the immune response to the vector.[57]

## Cell surface markers

Characterization of T-cell markers is a prerequisite to define T-cell subpopulations and to functionally analyze

these cells in the course of acute and chronic infection. By designing primers chosen from regions conserved among humans and other mammalian species, fragments of CD3, CD8 and the complete sequence of CD4 have been cloned (Table 13.2).[15,28,69,72–75] The complete coding region of woodchuck CD4 has a length of 1365 bp encoding a protein of 455 amino acids (aa) (Fiedler, unpublished results). The cDNAs of woodchuck CD28 and cytotoxic T-lymphocyte-associated antigen 4 (CTLA-4) have been cloned and sequenced.[74] These two molecules are known to play important roles in the regulation of T-cell activation by delivering the co-stimulation signals. Woodchuck CD28 showed a similarity of 70–80% to its mammalian homologues according to the deduced amino acid sequences. Woodchuck CTLA-4 has a higher similarity of 74% to the corresponding mammalian CTLA-4 molecules. The strict conservation of critical amino acid residues like cysteine and asparagine residues in woodchuck CD28 and CTLA-4 suggests that both molecules may structurally resemble their human or mouse homologues. A hexapeptide motif, MYPPPY, which has been supposed to be essential for the interaction with CD80, is present in both woodchuck CD28 and CTLA-4.[74]

Sequence information of woodchuck CD3, CD4 and CD8[77] has been used to determine the kinetic of influx of T cells into the liver. Either sequences of wIFN or wTNF-α were suitable to determine cytokine expression during the incubation period and acute or chronic WHV infection.[7,77,78] In week 2 post-infection, an influx of CD3+ lymphocytes could be observed and reached higher levels before and during the recovery phase. The peak level of CD4+ and CD8+ T cells coincided with recovery. Monoclonal or polyclonal antibodies to CD3+, CD4+ and CD8+ of woodchuck are not available yet. One monoclonal antibody to the conserved region of CD3 from swine was found to cross-react with woodchuck lymphocytes. The antibody was used to identify T cells in the liver during acute and chronic WHV infection. During transient infection, T cells can accumulate in the liver and reach up to two-thirds the total number of liver cells.[7]

## MHC class I

The full-length cDNAs of woodchuck *Mamo-I* genes were cloned using cellular mRNA isolated from peripheral blood mononuclear cells and liver tissues of woodchucks.[79] DNA sequence analysis of *Mamo-I* cDNAs revealed that the coding regions of *Mamo-I* genes were about 1080 bp long, encoding 359 amino acid residues.[74] The deduced amino acid sequences of *Mamo-I* showed structural features like leader, α1, α2, α3, transmembrane and cytoplasmic domains, similar to their homologues in humans and other mammals. Analysis of five full-length clones from unrelated woodchucks indicated a polymorphism within the α1 and α2 domains of *Mamo-I* heavy chain and a high conservation within the α3 and the transmembrane/cytoplasmic domains. Amino acid residues of the α2 and α3 domains, which are supposed to be involved in the binding of MHC class I to CD8 molecule, were largely conserved among

*Mamo-I* genes. Phylogenetic comparison of woodchuck MHC class I genes to other mammals indicated a close evolutionary relationship between woodchuck and squirrel MHC class I.[74] Among these 14 alleles identified so far, *Mamo-A**01 and *Mamo-A**09 were of the highest frequency of about 21.5% and 14.5%, respectively.

To prove the allelic nature of *Mamo-I* genes by classical genetics, like the segregation analysis, allelic diversity of *Mamo-I* in two three-generation woodchuck families consisting of 15 members was analyzed. Alleles were identified by the sequencing of *Mamo-I* genes and immunoblotting of *Mamo-I* proteins after one-dimensional isoelectric focusing (1D-IEF). A typical Mendelian segregation of *Mamo-I* genes and antigens was observed in the families studied.[56] Our study established *Mamo-A* as a classical MHC class I locus by the polymorphic and allelic nature of *Mamo-I* gene in the woodchuck. Full-length cDNA of *Mamo-I* has been transfected to mouse p815 cells and peptides bound to MHC-I were eluted from the transfected p815 cells and analyzed. The potential anchor sequence of eluted peptides has been identified for *Mamo-I* (Stephanovic, unpublished results). This information will be used to generate peptides of WHcAg and WHsAg, which are potential epitopes for CTL in woodchuck with the *Mamo-I* allele.

MHC class II sequence has also been identified. The putative protein has 266 aa and typical domains like signal peptide $P_1$Domain, $\beta_2$Domain, transmembrane and cytosolic domain. So far, 14 alleles have been identified. One of these has a high frequency of 69% in our woodchuck cohort. The overall homology of MHC clade II of woodchuck is 87% to the human analogous DRB (S. Viazov, unpublished results).

## Characterization of T-cell response during the incubation period and acute phase of WHV infection

Currently, the major issue in the pathogenesis of hepadnavirus infection is how the immune system contributes to the elimination of the virus from the liver and which viral and/or host factors determine the recovery or chronic outcome after an acute phase of hepadnavirus infection. There is controversial discussion on the contribution of cytokines secreted by natural killer (NK) cells, T-helper cells and cytotoxic T cells for downregulation of hepadnavirus replication at an early stage of acute infection.[80,81] At a later time-point of acute infection cytolytic function of CTLs seems to be responsible for elimination of infected hepatocytes and for the ultimate recovery from HBV infection.[82,83]

In several studies, the course of WHV infection after experimental infection has been investigated either intravenously or subcutaneously. After inoculation of adult woodchucks with a medium titre of WHV ($10^5$–$10^8$), viraemia can be detected at week 2.[16] Maximal titres of WHV are observed in the serum during weeks 6–8. WHsAg and anti-WHc are detected in weeks 3–5 and 4–6, respectively (Fig. 13.2). Inoculation of low titre WHV resulted in a very short and late viraemia in some animals. The only marker of infection was seroconversion to anti-HBc 8–10 weeks after inoculation. In neonatal subcutaneous infections, viraemia seems to be delayed as compared with intravenous infection of adult animals.[16] Low titre infection of neonate woodchucks is also associated with lower carrier rate.[6] Highest levels of WHV DNA always precede the peak of succinyl hydrogenase (SDH), which is a good marker of hepatocyte

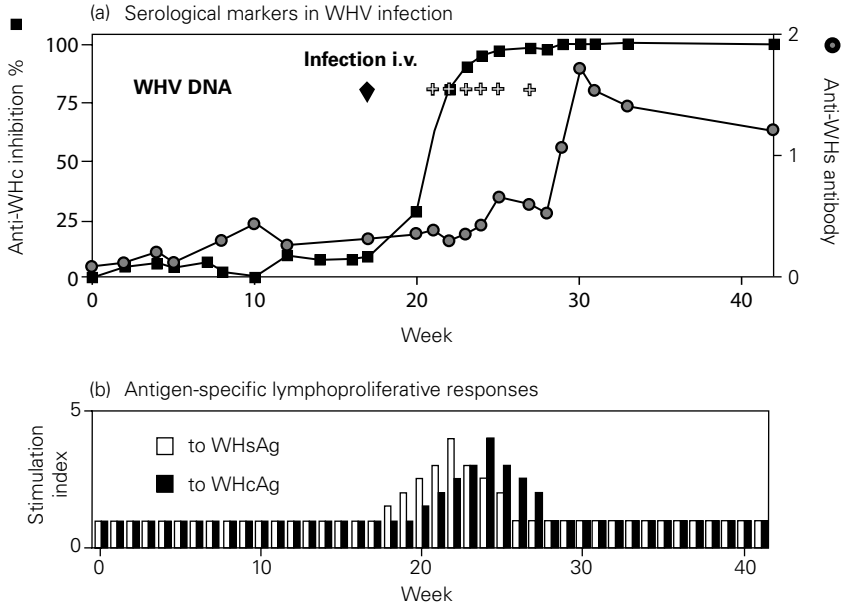

**Figure 13.2** Experimental infection of woodchucks. (a) Experimental infection of woodchucks is initiated by intravenous injection of WHV. The WHV infection can be monitored by detection of WHV DNA using spot-blot hybridization and detection of WHsAg by using specific ELISA antibodies to WHcAg and WHsAg. (b) The lymphoproliferative response to the WHV proteins is usually measurable during the viraemic phase. The WHsAg-specific response appears early in the course of infection, while the response to WHcAg peaks later and is coincident with the appearance of anti-WHsAg.

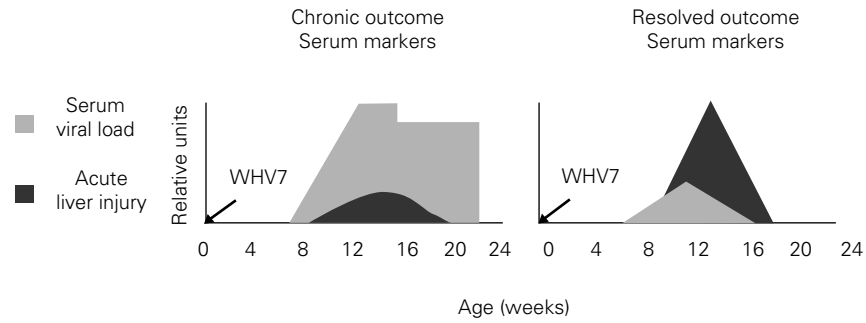

**Figure 13.3** Schematic diagram of relation of serum viral load (based on WHV and WHsAg) and liver injury response (based on succinyl hydrogenase, SDH) to outcome of neonatal WHV infection.

lysis (Fig. 13.3).[11] It has been demonstrated that influx of CD8-positive T cells in the liver of woodchucks reaches maximal levels when viral DNA replication and expression of core protein are already reduced,[7,84,85] similar to the situation during HBV infection in chimpanzees and patients. These findings indicate that non-cytolytic mechanisms are involved in downregulation of WHV replication, and most probably CTLs are responsible for elimination of infected hepatocytes, as shown in chimpanzees,[86,87] transgenic mice[83] and patients.[88]

The problem of elimination of virus without lysis of the majority of infected hepatocytes in a very short time window has been elucidated in a recent study by Summers *et al*.[78] They used the presence of viral DNA sequences uniquely integrated into the DNA of a small fraction of infected hepatocytes as genetic markers for the population of infected cells to follow the fate of the infected cells during viral clearance. They found that after recovery from the infection, there was no discernible reduction in the number of copies of integrated viral DNA in the liver, indicating that the uninfected cells of a recovered liver were derived primarily from infected cells.

## T-helper response in acute and chronic WHV infection

Experimental infections of woodchuck provide the opportunity to study the detailed kinetics of WHV-specific T-helper cells during the early incubation phase in the peripheral blood and the liver. This has not yet been tested in chimpanzees and humans. The strength of T-helper response may be important for the clinical outcomes of infection (see below). The establishment of methods to determine T-cell proliferation[8,11,59,61] has made it possible in recent years to monitor the dynamics of T-cell response to WHsAg, WHcAg and derived peptides after experimental infection during the incubation period, acute and chronic disease under well defined conditions in detail. The response of woodchuck T cells to WHsAg recombinant WHcAg and WHcAg-derived peptides was monitored by 2[$^3$H]-adenine assay, which had a higher sensitivity than that assay using BrDU incorporation.

The first T-cell responses against WHsAg were detected 3 weeks after WHV inoculation (Fig. 13.2). The maximum T-cell responses to WHsAg occurred when WHsAg was detected in serum and decreased upon seroconversion to anti-HBs. The development of anti-WHs, which is regarded as a virus neutralizing antibody, was associated with the elimination of WHsAg from the serum. These findings suggest that T-helper cell responses to WHsAg occur very early in the infection before liver damage takes place, as shown by the presence of normal SDH levels in the serum. The T-helper cell response to recombinant WHV core protein was seen in week 4, generally 1 week later than HBsAg-specific T-cell responses. In independent experiments, CD4-positive T cells were detected in the liver at week 3.[7] However, it has not been determined whether these cells were specific to WHV epitopes. Similar to the early response in the WHV-infected woodchucks, an early CD4+ T-cell response could be observed during the incubation period in a limited number of patients.[88] In chimpanzee experiments, the application of anti-CD4 antibodies at week 6 did not alter the course of infection. The interpretation of this has been that T-helper cells are no longer needed after week 6. However, elimination of CD8+ T cells through a specific antibody results in a prolonged viraemia in these chimpanzees. The virus was eliminated after rebound of specific CD8+ T cells, indicating that specific CD8+ T cells are essential for virus elimination.[86,87]

## Mapping of T-helper epitopes

The T-cell responses to the peptides derived from WHcAg measured in different studies indicate that at least 10 different epitopes located throughout the entire core protein are recognized in woodchucks. Different subsets of WHc epitopes were recognized by different animals (at least four in each animal) during acute self-limited infection.[12] The large number of epitopes may be explained by the fact that outbred animals were used in these studies which might have had different alleles

of MHC class II. Some peptides, on the other hand, like peptide 97–110 (100%), 110–119 (86%), 112–131 (55%) and 1–20 (53%), were recognized by the majority of woodchucks with acute self-limiting infection, which strengthens previous findings that some immunodominant epitopes may be promiscuous (Fig. 13.4). The importance of the immune response to the epitope 97–110 has been demonstrated in subsequent experiments. Woodchucks immunized four times with this peptide showed a specific T-cell response and were protected from WHV infection, as no WHV DNA was detectable in serum and liver. We observed a specific and increasing T-cell response to peptide 97–110 and rWHcAg following immunization. The predominant T-cell response to WHV antigens during immunization and after challenge suggests that protection was primarily based on the cellular response (Th cells and/or CTLs). Likewise, immunization of mice with peptides derived from the nucleoprotein of lymphocytic choriomeningitis virus resulted in protection without detectable virus neutralizing antibodies.[89,90] Further experiments are needed to elucidate the mechanism of protection. Animals that developed chronic infection showed only a weak T-cell response. The majority of them were unable to recognize peptide 97–110, but developed T-cell response to other epitopes which are present at a low frequency in animals with acute resolving WHV infection. The appropriate immune response during the incubation period of WHV infection has to be considered as the critical period of virus–host interaction. Further studies are needed to characterize virus-specific CD8+ T cells in the woodchuck system in the peripheral blood and the liver to determine their contribution to elimination of virus replication and WHV-infected cells with cccDNA.

## Failure of appropriate immune response in the incubation period and early acute infection results in chronic carriership

In chronic HBV/WHV carriers, only weak or no T-helper responses are detected. The question arises whether the chronic outcome of hepadnaviral infection is related to failure to mount an early T-helper response or to loss of T cells during the acute phase.

Studies on the early immunological events following HBV infection in humans are usually limited due to the time interval between infection and onset of clinical symptoms. Only very small numbers of patients could be tested so far.[88] As the majority of these cases represent self-limiting courses, there are only few opportunities to examine the T-cell response in the acute phase associated with subsequent development of chronic HBV infection. The question whether chronic outcome is associated with an absent or suboptimal

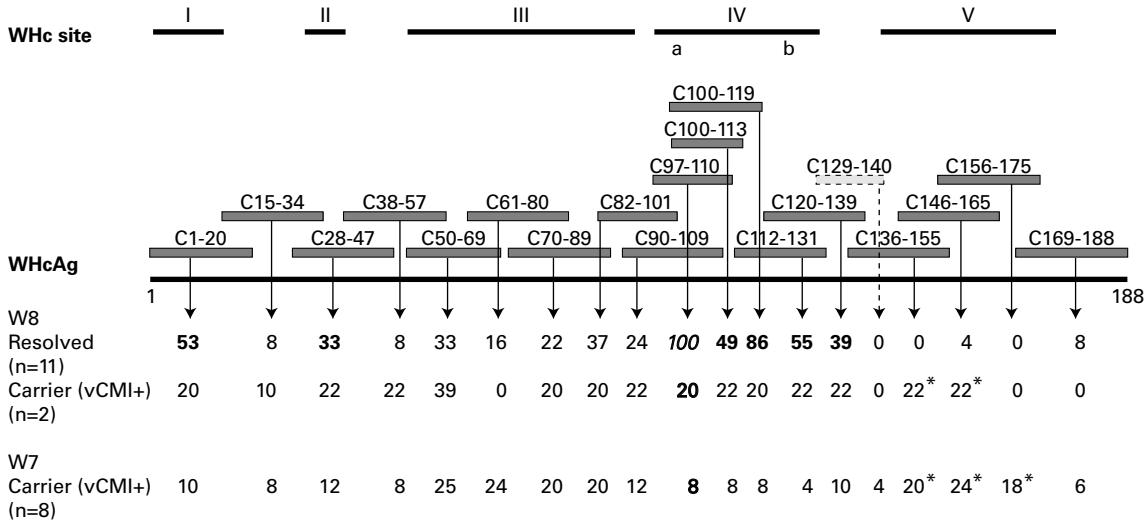

**Figure 13.4** Summary of specific lymphoproliferative responses to WHcAg-derived peptides in woodchucks with resolved WHV infection and in carriers with positive acute phase lymphoproliferative responses.[12] Values for the strain W8 and W7 outcome categories were expressed relative to the most frequently recognized WHcAg peptide, C97–110, in the resolved strain W8 infection group (i.e. 51% in Table 13.3 was set at 100%, italic, here). Other values were calculated accordingly. Sites I–V were demarcated on the basis of differential and similar response frequencies for the present groups of neonatally infected woodchucks and also on other published information. In site IV, a and b represent at least two non-overlapping epitopes, one of which (C97–110) has been shown previously to be protective in experimental challenge studies. Sites I, II and IV appeared to be preferred recognition sites for woodchucks with resolved infections (bold numbers). Site III appeared to be recognized similarly in both outcome groups. Site V may be recognized preferentially by neonatal carriers (numbers are marked with an asterisk).

**Table 13.3** Percentage of neonate woodchucks responding to and frequency of PBMC samples positive to WHV antigens and WHc

| Outcome of infection | % of woodchucks responding to | | | | % of PBMC samples positive to | | | |
|---|---|---|---|---|---|---|---|---|
| | rWHcAg | WHsAg | rWHxAg | C97-110 | rWHcAg | WHsAg | rWHxAg | C97-110 |
| Resolved | 100 (11/11) | 82 (9/11) | 91 (10/11) | 100 (11/11) | 59 (32/54) | 34 (18/53) | 34 (17/50) | 51 (28/55) |
| Chronic | 39 (9/23) | 22 (5/23) | 26 (6/23) | 17 (4/23) | 6 (16/262) | 3 (6/242) | 4 (10/242) | 2 (5/265) |

Data from Menne *et al*.[12] Eleven woodchucks recovered from infection and 23 developed chronic hepatitis.

cellular immune response during the incubation period or early acute infection has been addressed in the woodchuck. WHV infection of neonate woodchucks led to the development of a high carrier rate. The rate of chronic outcome depends on age at time of infection, viral strain and viral titre of inoculum. WHV strains W8 and W7 are closely related and differ from each other by a few positions on their genomes.[91] They have identical precore and core proteins, identical small and middle surface proteins, and there are only two amino acid substitutions in each of the X-protein and pre-S1 region of the envelope protein and nine amino acid substitutions in the polymerase protein. Inoculation of neonatal woodchucks with strain W8 resulted in 11 resolved infections and four chronic carriers out of 15 infected woodchuck neonates.[12] In a second experiment, neonates were infected with strain W7, which consistently produces higher rates of chronicity. Inoculation of 19 neonatal woodchucks with strain W7 produced 19 chronic carriers. The reasons why the strains produce differing chronicity rates are not known. Infection of neonates and subsequent monitoring of cellular immune response may provide information as to whether animals that developed chronic disease show initial lack of immune response or weak immune response as compared with animals which resolve WHV infection. Wang *et al*.[14] found that woodchucks which resolved infection had lower titres of WHV DNA in serum than animals developing chronic infection (Fig. 13.3). Woodchuck with acute resolving infections had a robust acute phase T-cell response against WHV antigens, to WHcAg (100%), WHsAg (82%) and WHX protein (91%) (Table 13.3). They recognize at least four epitopes in three distinct regions of WHcAg, including the protective epitope C 97 to 110.[12] T-helper response in neonates was seen significantly later than in experimentally infected adult animals. This finding may be explained by the different route of infection. Neonates were infected subcutaneously with $10^5$ particles from adults which were infected intravenously with $10^{10}$ particles. The chronicity may be interpreted as an outcome of neonatal WHV infection which resulted from a complete or partial deficiency of primary T-cell response to WHV proteins; 56% of carriers appeared to be unresponsive altogether to WHV antigens during the early stage of acute WHV infection. This indicates unequivocally that acute phase T-cell response is required for resolution of acute infection. Failure to respond to specific viral proteins was not due to some general unresponsiveness of PBMC, as PBMC samples from such carriers responded normally to mitogens in a similar manner to woodchucks in which infection was resolved or uninfected control woodchucks. Suppressing T-helper cells by cyclosporin during the incubation period of WHV infection resulted in a high WHV carrier rate.[92,93] This underlines the importance of functional T-helper cells for appropriate immune response.

The lack of significant T-cell responses in carriers could be the result of an early induction of tolerance. Possible mechanisms for early tolerance may include complete or partial deletion of virus-specific T-helper cells, partial deletion of such cells to below the level of detection in the *in vitro* proliferation assay, clonal energy, clonal exhaustion due to rapid increase in viral load or an abnormally high level of T-cell apoptosis. Absent or incomplete early T-cell response was associated with increasing viral load and with the onset of chronic infection (Fig. 13.3). It is remarkable that a WHcAg-derived peptide C 97–110 was recognized in all animals with acute-resolving infection but not by animals developing chronic infection, indicating that the T-cell response to this epitope is relevant for clearance of viral infection. In the animals that became carriers, only 17% recognized peptides C 97–110, whereas 100% of animals with resolved infection showed a T-cell response in 100% (Fig. 13.3). In humans only a small number of patients could be systematically analyzed for T-helper response in the incubation pe-

riod. However, these data indicate that patients who developed a chronic infection also have an impaired primary T-helper response.

## Development of prophylactic and therapeutic vaccines in the woodchuck model

Many efforts have been made to improve the current vaccine against hepatitis B with respect to the enlarging humoral and cellular immune response to reduce the number of revaccinations required for low and non-responders and expand time intervals for revaccination. HBV vaccines that are used in humans are subunit vaccines consisting of 22-nm empty subviral particles composed of the envelope proteins of HBV. Despite the existence of a safe and efficient vaccine to prevent infection with HBV in humans, DNA-based vaccines have been evaluated and might be used for preventive or therapeutic vaccination in the future.

The need for new types of prophylactic vaccines against HBV is not only a priority in the developed countries, but efforts are also being made to improve health care in other less developed countries. In contrast, therapeutic vaccines against chronic HBV infection are of general interest, as regards both the basic science and clinical use. Through the progress on the characterization of the woodchuck immune system and the development of specific immunological assays, the woodchuck model became an informative animal model for vaccine development. Among the new types of vaccines, genetic vaccines based on purified plasmid DNA provide a series of new features in contrast to classical protein vaccines and seem to be the most promising candidates for future development.[94,95] The woodchuck is an excellent model in which to assess prototype prophylactic or therapeutic vaccines, as efficacy can be tested by challenge experiments or viral elimination in chronic carriers, respectively.

### DNA vaccines against WHV infection

DNA immunization is a powerful method to induce protective immune responses to viral infection, particularly with the option to induce cellular immune responses.[94,95]Plasmids expressing HBsAg or HBcAg are able to induce specific antibody and CTL responses to HBsAg or HBcAg in mice, respectively.[96–98] In addition, results of DNA immunization in chimpanzee and duck models have demonstrated that DNA vaccines prime the specific immune responses and lead to control of HBV infection.[99,100]

In woodchucks, DNA vaccines are able to prime the immune response to WHcAg and WHsAg and confer protection against WHV challenge.[30] Similar to immunizations with HBcAg and HBsAg, the intramuscular injection of plasmids expressing WHcAg and WHsAg (pWHcIm and pWHsIm) induced specific anti-WHcAg and anti-WHsAg antibodies in mice, respectively, with the dominance of an IgG2a subtype. However, despite the high immunogenicity of WHcAg, 1 mg of plasmids expressing WHcAg were necessary to induce a low, transient anti-WHcAg antibody response in woodchucks. After three immunizations, woodchucks developed specific humoral and cellular immune responses to WHcAg, but still at a low level. Woodchucks that received three immunizations with 1 mg of pWHcIm remained negative for markers of WHV replication after virus challenge, whereas unimmunized or pcDNA3-immunized woodchucks developed acute WHV infection. Anti-WHsAg antibodies became detectable in week 5 after challenge. Apparently, the WHV replication was efficiently suppressed by DNA-primed immune responses. This could be interpreted in such a way that the immune responses to WHcAg did not prevent the infection of hepatocytes by input viruses but limited the virus spread. Thus, woodchucks became positive for anti-WHsAg in response to WHsAg produced by infected hepatocytes. Similarly, woodchucks that received immunizations with 1 mg pWHsIm per injection did not develop a measurable anti-WHsAg response but were protected against the subsequent virus challenge. An anamnestic anti-WHsAg response developed in week 2 after virus challenge, while no significant anti-WHcAg antibody response was measured in these woodchucks.[30] Altogether, immunization with plasmids expressing WHcAg and WHsAg induced protective immune response in woodchucks.

A disadvantage of DNA vaccination is the need for large amounts of plasmid DNA to induce adequate immune responses in humans or large animals. Thus, we explored the option of using IFN-γ as molecular adjuvant and evaluated the potential of a single, low-dose DNA vaccination by co-delivery of the expression vectors pWHcIm for WHcAg and pWIFN-γ for woodchuck IFN-γ.[101] Animals were immunized with 10 μg pWHcIm only, or with pWHcIm and pWIFN-γ using a gene gun. These experiments demonstrated clearly that only the animals vaccinated with pWHcIm combined with pWIFN-γ developed a significant proliferative response against WHcAg and were protected against virus challenge. Two out of three animals vaccinated with pWHcIm only were negative for WHV DNA by dot-blot analysis, but positive by PCR after challenge, indicating that a single-shot intradermal immunization using 10 μg of pWHcIm reduced viraemia but did not protect all animals. In a similar experiment, IL-12, a potent inducer of IFN-γ-production, has been shown to enhance the protective immunity induced by DNA vaccine.[29] All vaccine

studies to prevent WHV infection are summarized in Table 13.4.[10,29,30,102,103]

An interesting approach is to fuse bioactive domains like L-selectin and cytotoxic T-lymphocyte-associated protein 4 (CTLA-4) to an antigen. Such fusion antigens may be expressed *in vivo* and directed to the immune cells by the specific bioactive domain, and therefore possess a great potential to induce and modulate antigen-specific immune responses. In a new study, this approach was tested for the immunomodulation against hepadnaviral infection in the woodchuck model (Lu *et al.*, unpublished observations). Plasmids expressing the nucleocapsid protein (WHcAg) and e antigen (WHeAg) of WHV only, or in fusion to the extracellular domain of the woodchuck CTLA-4 and CD28, were constructed. Their ability to induce a specific immune response to WHcAg was tested by immunization of mice. While immunization with plasmids expressing WHeAg or WHcAg only led to a specific antibody response with IgG2a as the dominant IgG subtype, fusions of WHcAg to the woodchuck CTLA-4 and CD28 induced an antibody response with both IgG1 and IgG2a at comparable levels. Furthermore, the specific IgG1 to WHcAg/WHeAg was developed after just a single immunization with the CTLA-4-WHcAg fusion antigen. Moreover, woodchucks were immunized with plasmids expressing WHeAg or CTLA-4-WHcAg fusion antigen and then challenged with WHV. Results of these experiments indicate that the protective efficacy of this plasmid vaccination was demonstrated.

DNA vaccines against hepatitis D virus were tested in chronically WHV-infected woodchucks. However, immunizations with HDV p24 antigen did not protect the woodchuck against virus challenge.[70,75]

## Therapeutic vaccination against chronic hepatitis B in the woodchuck model

To date, several attempts to stimulate the specific immune response to HBV to reach control over HBV in chronic carriers have been undertaken but showed only limited success.[104–108] Woodchucks with chronic WHV infection provide excellent opportunities to test the effectiveness of new options for therapeutic vaccinations (see Table 13.5).[49,50,58,109]

**Table 13.5** Therapeutic vaccinations

| Vaccines | Application | Outcome | Reference |
|---|---|---|---|
| WHsAg and Th-peptide | Intramuscular | Transient anti-WHs antibody response<br>Two woodchucks died | Hervas-Stubbs *et al.* (1997)[109] |
| WHsAg in adjuvant | Intramuscular | Antibodies to the pre-S region of WHsAg | Lu *et al.* (2003)[49] |
| WHsAg in combination with L-FMAU | Intramuscular | Stimulation of T-cell responses to WHV proteins, anti-WHs antibody response | Menne *et al.* (2002)[50] |
| WHsAg-anti-WHs immune complex and DNA vaccines in combination with lamivudine | Intramuscular | Stimulation of anti-WHs antibody and suppression of WHV titre | Lu (unpublished results) |
| WHcAg | Intramuscular | Viral elimination in one of six animals | Roggendorf and Tolle (1995)[58] |

No antiviral effects were achieved in chronically WHV-infected woodchucks during the early immunization trials with WHcAg only or in combination with famciclovir.[58] In subsequent experiments, a T-helper cell determinant peptide FISEAIIHVLHSR encompassing amino acids 106–118 from sperm whale myoglobin (termed FIS) was added to the vaccine preparation, in an attempt to circumvent the T-cell unresponsiveness to WHV proteins.[47,109] This approach was promising, as a combined immunization with HBsAg and FIS induced anti-HBsAg in SJL/J mice, a non-responder strain to immunization with HBsAg.[109] Indeed, PBMCs from FIS-immunized woodchucks produced IL-2 upon restimulation with FIS *in vitro* IL-2. Seven chronic WHV carrier woodchucks immunized with WHsAg in combination with FIS produced anti-WHsAg.[109] However, two woodchucks developed high titres of anti-WHsAg and suffered severe liver damage. Thus, foreign T-helper cell determinant peptides might provide help to overcome the deficiency of specific T-cell responses to viral proteins in chronic carriers.

In another immunization experiment, we treated a group of chronically WHV-infected woodchucks with plasma-derived WHsAg adsorbed to aluminium salt with monophosphoryl lipid A.[49] Anti-WHsAg antibodies were detected in all immunized woodchucks and persisted for a time period of up to 2 years after immunization. The major portion of anti-WHsAg antibodies was directed to the WHV pre-S region. However, neither WHV DNA nor WHsAg titres in immunized woodchucks changed significantly. Sequence analysis of the WHV pre-S and S genes of WHV isolates from these woodchucks showed that no WHV mutants emerged after the induction of anti-WHsAg/anti-WHpreS antibodies. These results indicate that immunization with WHsAg could partially induce specific B-cell responses to WHV proteins in chronically WHV-infected woodchucks. However, additional components for the stimulation of T-cell responses are necessary to achieve therapeutic effects against chronic hepatitis B.

The high replication level of hepadnaviruses in chronic carriers may maintain the immunotolerance to viral proteins. The T-cell response to HBV was successfully restored in patients treated with lamivudine or IFN-α. Thus, a reduction of the viral load by antiviral treatments may enhance the effect of therapeutic vaccines. Recently, Menne *et al*. reported that a combination of an antiviral treatment and immunization with WHsAg induces WHV-specific lymphoproliferation in chronic carriers.[110] For the antiviral treatment against HBV, a potent drug (L-FMAU) was applied for 8 months and led to a dramatic decrease of viraemia. Although subsequent immunization with WHsAg led to lymphoproliferative responses to WHV proteins in both treated and untreated woodchucks, the antiviral treatment led to a broader spectrum of specific T-cell responses to different WHV proteins core and X-proteins. Immunization with WHsAg consistently induced a low level of anti-WHsAg in chronic carrier woodchuck. This finding provides hints as to the usefulness of a combination of antiviral treatment and immunizations.

A novel prototype therapeutic vaccine was developed by Wen and co-workers.[108] Therapeutic vaccination using an antigen–antibody complex has been successfully tested in transgenic mice and is now under clinic phase I evaluation. In the woodchuck model, a combination of antiviral treatment with lamivudine and therapeutic vaccination with DNA vaccines or antigen–antibody complexes was carried out to evaluate their efficacy (Lu *et al*., unpublished observations). Ten woodchucks chronically infected with WHV were treated with 15 mg of lamivudine per day for 4 months. Six weeks after the start of lamivudine treatment, one group of woodchucks was immunized with pWHsIm, a plasmid expressing WHsAg, and a second group with WHsAg-anti-WHsAg complex and pWHsIm. Two woodchucks treated with lamivudine only served as controls. Blood samples were taken every 2 weeks and tested for WHV DNA, anti-WHsAg and lymphoproliferative responses to WHV antigens. The treatment with lamivudine led to a marginal decrease of WHV DNA concentrations in woodchucks. Immunization with pWHsIm did not lead to any change in the carrier status in woodchucks. Interestingly, three woodchucks immunized with WHsAg–anti-WHs complexes and pWHsIm developed anti-WHs antibodies and showed a further decrease of serum WHV DNA and WHsAg concentrations. The anti-WHs antibody persisted in two woodchucks for a period of 8 weeks. These results indicate that immunization with antigen–antibody complexes is an effective treatment against chronic HBV infection.

## What we learnt from the woodchuck model

In recent years, the immune control of hepadnaviral infection has been studied intensively in animal models.[7,82,86,87] Particularly, the HBV-specific immune T-cell response was analyzed in the transgenic mouse model.[80,81] In addition, immune transfer and immunization experiments in the mouse model provided interesting results, indicating the important role of antiviral cytokines IFN-γ and TNF-α as major mediators of the antiviral action of specific CTLs. Several findings in the animal models support the direct antiviral activity of cytokines, as follows. (1) In experimentally infected chimpanzees and woodchucks, decline of replication of WHV/HBV has been observed prior to cell destruction as determined by elevated transaminases. (2) There is a direct correlation of intrahepatic expression of increased levels of

IFN-γ and reduction of viral replication. (3) In the transgenic mouse model, antibodies to IFN-γ can completely abolish reduction of replication of HBV DNA. (4) Elimination of IFN-γ producing the specific CTLs by an anti-CD8 antibody is correlated to persistent replication until CD8+ cells reappear at later time-points. These findings led to the hypothesis that cytokines suppress viral replication as a first step of viral clearance, and on the other hand chronic HBV/WHV infection may be caused by a low expression of cytokines like IFN-γ. This hypothesis raises the question as to whether direct application or *in vivo* induction of cytokines could actually be used for the therapy of chronic HBV infection.

Our experiments in the woodchuck model with chronic virus infections revealed some aspects that had not yet been considered in the interpretations of the results from the transgenic mouse model.

It is not surprising that inflammatory cytokines including IFN-γ are expressed in liver tissues of chronically WHV-infected woodchucks. A number of IFN-stimulated genes were shown to be induced in liver tissues. The expression of IFN-γ expressed in this context is, however, not sufficient to terminate WHV infection. It remains to be investigated whether the IFN-γ expression contributes at all to limitation of WHV replication during the chronic course of WHV infection.

The results of therapeutic use of the cytokine wIFN-γ in the woodchuck model are rather disappointing. wIFN-γ was applied to WHV-infected primary woodchuck hepatocytes, but showed no significant antiviral effect even at cytotoxic concentrations, and no significant suppression of WHV replication was achieved by *in vivo* application by adenoviral vector-mediated expression in the liver. Nevertheless, wIFN-γ has been clearly demonstrated to be biologically active in terms of induction of interferon sensitive gene (ISG) expression in primary hepatocytes and *in vivo*. Taken together, these findings raise the question as to whether an established WHV infection renders hepatocytes strongly resistant to wIFN-γ, indicating that chronic hepadnavirus infection is a result of viral resistance to cytokines or could be due to the changed cellular responsiveness to cytokines.

In the therapeutic approaches, interesting results were generated in the woodchuck model. It became clear that the induction of antibodies to WHsAg is possible in chronically infected individuals. In particular, immunization with immune complexes appears to be an effective method to stimulate antibody responses with antiviral action. These exciting findings raise the hope of developing a useful protocol of immunotherapy for chronic HBV infection.

Thus, future investigations will have the major advantages of the woodchuck model as an authentic model of infection. No other animal model is available that mimics the chronic course of hepadnaviral infection and presents the features in pathogenesis and virus–host interaction in a satisfactory way, as compared with the woodchuck model.

# Chapter 14
# Hepatitis B surface antigen (HBsAg) variants

William F Carman, Mohammad Jazayeri, Ashraf Basuni, Howard C Thomas, Peter Karayiannis

Viruses are under constant selection pressure and as a consequence undergo continual sequence variation (Fig. 14.1). This process has had a number of effects on many genes of the hepatitis B virus (HBV), described here and in Chapter 15. Some of these are clinically relevant.

The anti-HBs (antibody to HBsAg) response following natural infection or after immunization comprises mainly antibodies that recognize the major hydrophilic region (MHR) of the protein. This comprises amino acids (aa) 99–160 that encompass the group-specific 'a' determinant, an epitope recognized by a variety of antibodies. Isolated cases of infection with HBV variants bearing substitutions in this region, which are predicted to escape neutralization (as there is no *in vitro* or *in vivo* model, it is impossible to be certain) by antibody, have been described. There have also been cases of infection that have been missed because of failure of current serological assays to detect some variant forms of HBsAg. Variants that escape neutralization by monoclonal and polyclonal anti-HBs have been selected during immunoprophylaxis against HBV during liver transplantation and in vaccinees receiving passive/active immunization after birth to HBV-infected mothers. Moreover, in recent years, variants resistant to nucleos(t)ide analogues as a result of mutations in the polymerase encoding gene have been described. Such variants may affect the antigenicity of the S gene that encodes HBsAg, as it is overlapped completely by the polymerase open reading frame (ORF).

Here, we describe HBs antigenic variation, possible geographical differences and variation under human-induced selection pressures and its relevance to diagnosis, vaccination and treatment.

## The surface gene and subtypes

A single ORF that occupies more than one-third of the HBV genome encodes the three HBsAg-containing polypeptides. These proteins are highly conserved at the amino acid level, with regions of variability.[1] The

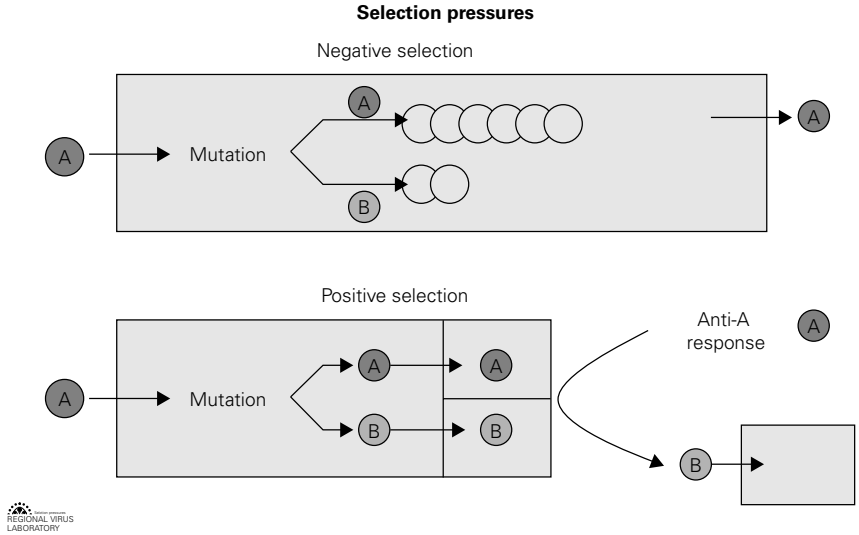

**Figure 14.1** In the top diagram, a virus A mutates randomly to virus B, but virus A out-competes virus B and therefore virus B disappears. In the bottom diagram, viruses A and B replicate equally efficiently, and so go on to infect further cells independently. However, the immune response against virus A (which was pre-existing) destroys cells containing virus A (or viruses derived from cell A are neutralized by the humoral response) so virus B predominates.

domain within pre-S1 (aa 21–47) which is involved in binding to the hepatocyte[2] is highly conserved (see Chapter 10). Based on antibody-peptide binding and chimpanzee inoculation experiments as well as *in vitro* mutagenesis,[3,4] a model was proposed[5] of the antigenic region of the small envelope protein that contained two loops formed by disulfide bridges between cysteines 124/137 and 139/147.[6,7] It is well-documented that the antigenicity of HBsAg is dependent on tertiary structure. The affinity of an anti-HBs-positive human serum for the linear peptide from aa 139 to 147 is higher than for the peptide from aa 124 to 137.[6] If the former peptide is cyclized between the terminal cysteines, affinity is increased.[6] This region, particularly between aa 139 and 147, is highly conserved (Fig. 14.2). Studies using phage epitope libraries[8] indicate that only the second loop is likely to be real, and that the first loop is incorporated within a larger loop from aa 107 to 138. There may also be a small loop between cysteines 121 and 124[8,9] (Fig. 14.3). The importance of the highly conserved cysteines in the S protein to secretion and antigenicity has been discussed elsewhere.[10,11]

Before the sequence of the HBV genome became available, a number of antigenic determinants in HBsAg had been identified. The *a* determinant is common to all strains, but its limits are poorly defined. In the latter case, studies have been based on the use of overlapping peptides, in the absence of *in vitro* or *in vivo* models of neutralization. All subtypes of HBsAg contain the common *a* determinant and are defined using appropriate monospecific antisera (monoclonal antibodies are also available). Geographical variability has most likely come about by population pressure over the millennia, probably under the influence of major histocompatibility complex (MHC) antigen type and other immunogenetic factors (Basuni, unpublished observations).[12] This is further discussed below. There are two pairs of mutually exclusive subtype determinants, *d* and *y*, and *w* and *r*.[13] There are nine subtypes (because there are other sub-subtypic determinants), but the major ones number four (*adw*, *ayw*, *adr*, *ayr*). Rare examples of unusual specificity, such as *adwr* or *adyr*, may be the result of mixed infections. Although there are clear differences in the geographical distribution of the subtypes,[14] there is no obvious correlation between subtype and virulence. The presence of lysine or arginine at aa position 122 confers *d*/*y* specificity: *adw* and *adr* subtypes have lysine at this position, whereas *ayw* and *ayr* have arginine (Fig. 14.2).

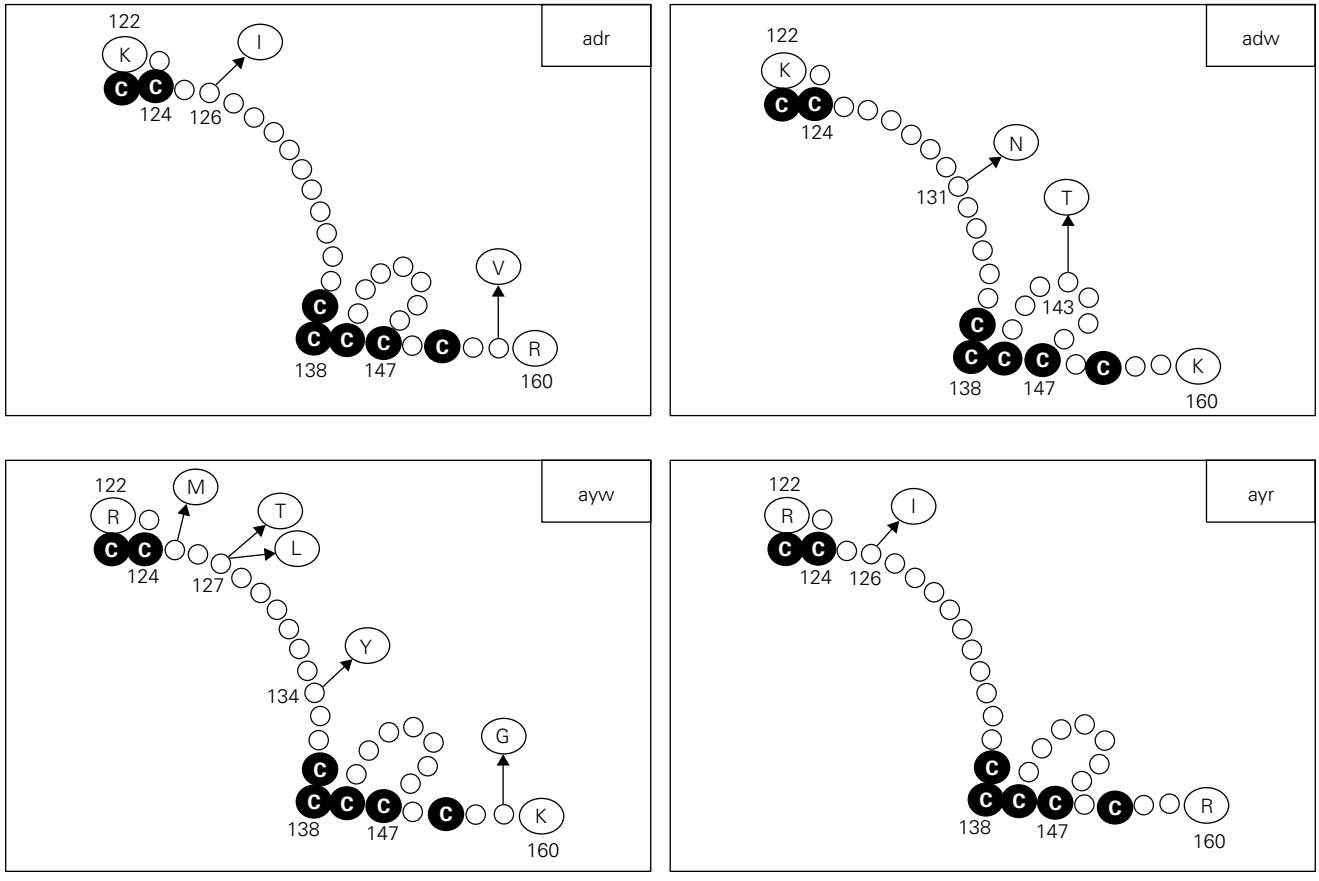

**Figure 14.2** Variability within the four standard subtypes. The two loops of the new model are shown in an expanded format. Well-described variability, which distinguishes each subtype, is indicated. Note that the first loop is less variable than the second.

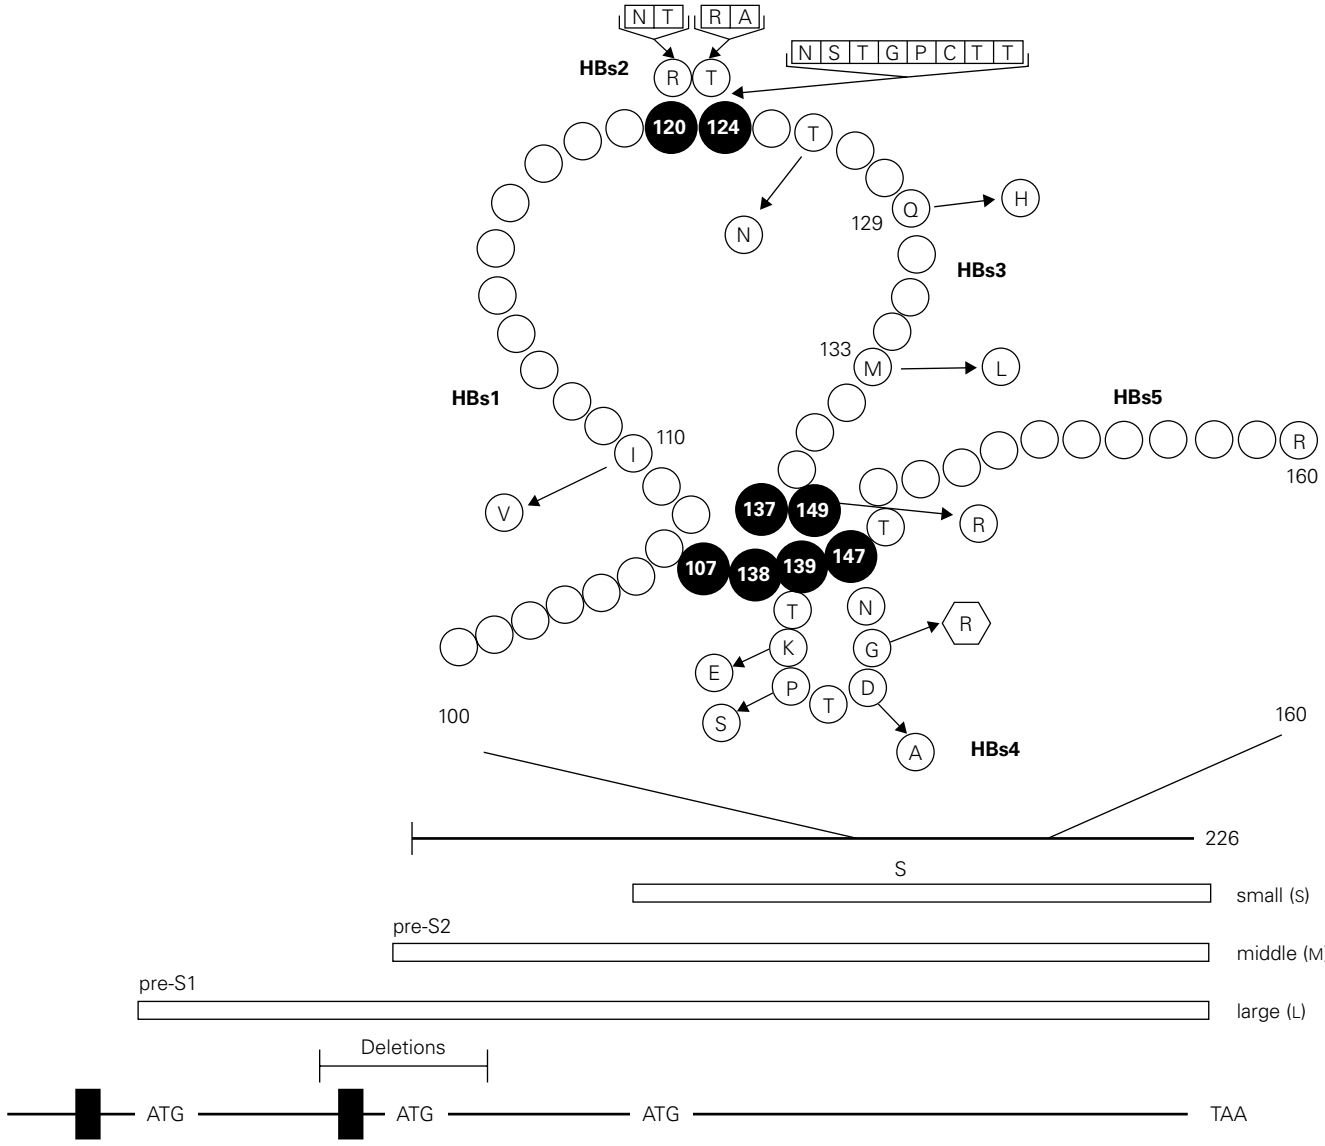

**Figure 14.3** Surface gene antigenecity: variants associated with vaccination, and insertion variants. There are three ATG (initiation codons) and one TAA (stop codon). Thus, three envelope proteins can be translated: L (large), M (middle), and small (S) or HBsAg. The region between aa 100 and 160 (or thereabouts) is termed the major hydrophilic region (MHR); this is found on LS, M and L proteins. Deletions of pre-S1 (between the first and second ATG), which often overlap the pre-S2 (beginning of M protein) ATG lead to biological effects (see text). Two major loops and one minor loop are proposed in the MHR, defined by multiple potential disulfide bridges, between aa 107/137 (or 138), 139/147 (or 149), and 121/124. Reseach workers have suggested that there may be five antigenic regions termed HBs1-5. Vaccination-associated variants are shown in circles. Note that sG145R is by far the commonest, seen in all studies, and that most are clustered into HBs4. Insertions in HBsAg have only been seen in Far East patients and are all between aa 121 and 124.

Similarly, residue 160 seems to be central to *w/r* specificity: *adw* and *ayw* have lysine at this position, whereas *adr* and *ayr* have arginine (Fig. 14.2). In addition, the residues at positions 113 and 134[3] and those at residues 144 and 145[15] constitute subdeterminants of *d/y* specificity. Codon 126 also correlates with *w/r* specificity: *w* isolates have threonine and *r* isolates have isoleucine at this position (Fig. 14.2). Minor subtype specificities have also been defined that correlate with sequence.[15] Mutations at aa positions 120, 143, 144, and 145 can result in poor reactivity with *d/y* subtyping monoclonal antibodies.[15,17] As this specificity is defined by the residue at aa 122, this indicates the discontinuous nature of many of the epitopes in this antigenic region. There are linear and discontinuous B-cell epitopes, and some regions are part of more than one epitope. Subtype-related variation can

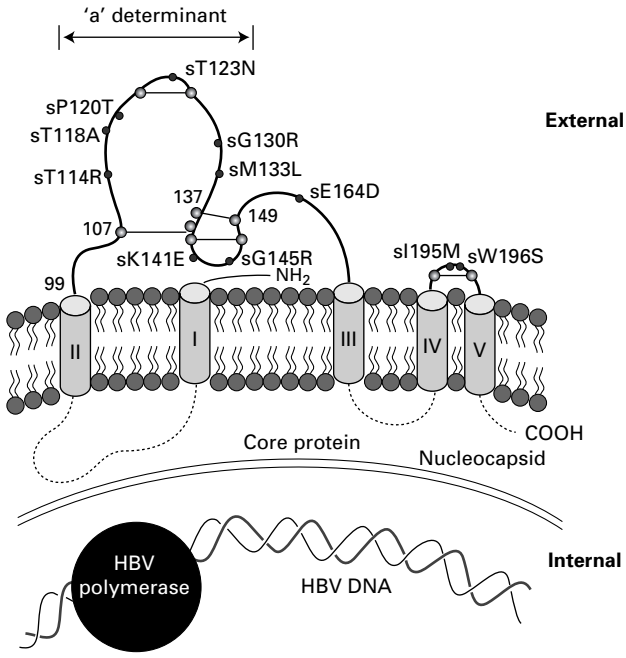

**Figure 14.4** Topology of the major hydrophilic region (MHR) of HBsAg, in relation to the lipid bilayer forming the envelope of the HBV virion. Cysteine residues are shown as shaded circles and disulfide bridges are indicated as thick lines. Alpha-helices traversing the lipid bilayer of the envelope are shown as cylindrical structures. Taken from Torresi.[76]

alter binding of antibodies to regions linearly distant. Because of this interleaved and complex nature of the antigenicity of HBsAg, we will not refer to the *a* determinant herein, but will consider the MHR in its entirety.

Of course, antigenia subtypes have become less important with the advent of cheap large-scale sequencing. Genotypes are now the primary classification of HBV variability. Some subtypes can be found within more than one genotype (Fig. 14.5). Genotypes of HBV are discussed in more detail in many reviews.

## Geographical and ethnic variability

There are a number of viral systems in which the geographical location (and thus ethnic background) of the host has been shown to be linked with specific subtypes or strains of an infectious agent. Human immunodeficiency virus (HIV), hepatitis C virus (HCV), human T-cell lymphoma/leukaemia virus (HTLV) and mumps are all examples. Recent work has expanded on this principle in HBV by examining the inter-relationship between south-east Asian and Pacific Islander sequences. As can be seen in Plate 14.1 (found between p.786–7), the island of Kiribati has predominantly genotype D (of unknown origin), whereas the rest of the Pacific is genotype C. The strains of D that appear on these other islands are related to those in Kiribati. The genotype C sequences in the Pacific are clearly discrete compared with the rest of Asia (Plate 14.2, found between p.786–7). Indeed, they are more diverse as well, implying that genotype C may have arisen in the Pacific and then migrated back to south-east Asian countries. Within the Pacific islands, there are distinct motifs that define the local strain (Plate 14.2 [found between p.786–7] and Table 14.1). It is likely that this represents human migration patterns. Each movement of people from island to island (as tribes moved on in search of better habitats) took with it a distinct strain. Vanuatu, which is relatively isolated, has an almost homogeneous and specific strain of virus.[18]

It is also possible to define genotype and subtype-defining motifs for the core gene (Table 14.2), although the distinction is less marked because of the reduced variability (and therefore options for change) in this gene.

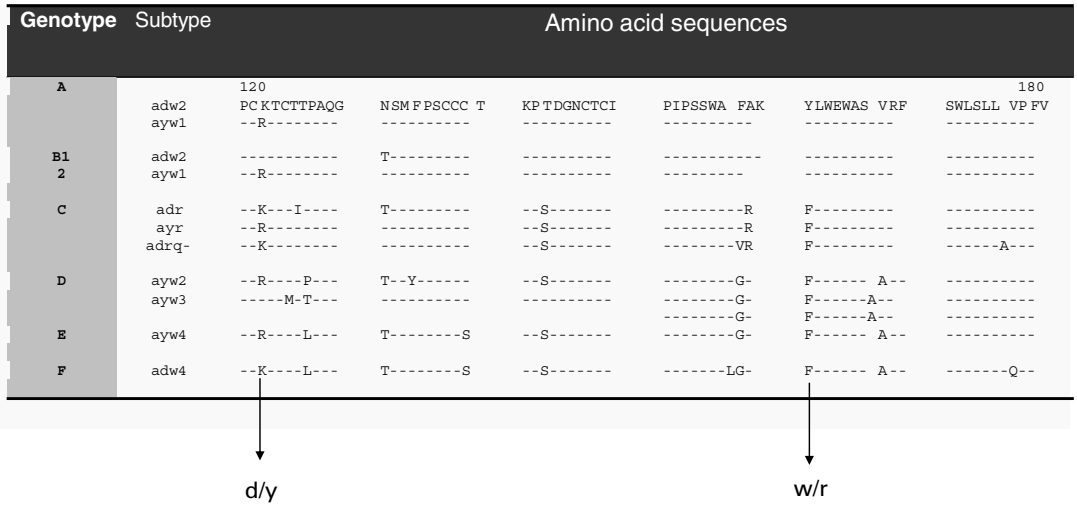

**Figure 14.5** HBV genotypes A–F and allotted subtypes based on S gene variability between amino acid residues 120–180.

**Table 14.1** Surface gene, amino acid and nucleotide differences between prevalent strains in Fiji, Tonga and Vanuatu.

| Amino acid position | Number with each variation | | |
|---|---|---|---|
| 44–47 aa pair | Vanuatu | Fiji | Tonga |
| G/V | 13 | 3 | Nil |
| E/R | 5 | 12 | 8 |
| E/V | 2 | 5 | 12 |
| **Nucleotide position** | **Number with each variation** | | |
| 13 A>G | 1 | 2 | 10 |
| 203 T>C | 2 | 3 | 12 |
| 213 C>T (S) | 12 | 2 | Nil |
| 246 C>A (S) | 4 | 1 | Nil |
| 282 G>A (S) | 1 | 3 | 11 |
| 339 A>C (S) | 3 | Nil | 13 |
| 348 C>A (S) | 1 | 3 | 11 |
| 384 T>A (S) | 13 | 2 | Nil |
| 524 T>C | 14 | 2 | 2 |
| 551 T>C | 1 | 1 | 12 |
| 552A >C (S) | 1 | 3 | 10 |
| 594 G>T or A | 5 (T) | Nil | 1 (A) |

Of especial interest (Table 14.3) is that one can define an amino acid motif which seems to prevail in either Asian or Caucasian peoples, irrespective of the genotype infecting the patient. If confirmed, this would imply that there is extremely strong selection pressure on HBV based on the ethnic background of the person, overriding the 'push' for diversity by the virus. This would most likely be immune-based.

It is of interest to look at sequences in the Asian population of the west coast of the USA. The sequences observed are highly related to the ethnic origin of the person (e.g. China, Singapore, etc.) rather than being distinctive to the USA. This would be in keeping with recent migration patterns and supports the observations on Pacific Islands which represent past migrations. It has become possible to distinguish with some accuracy the origin of a virus which may aid forensic investigation (e.g. outbreak tracing), and would also help to inform public health authorities and vaccination policy on the origins of viruses that are causing chronic hepatitis. For example, in many Western European countries, imported HBV poses a much greater threat than locally acquired infections: this can readily be studied using data to identify the origin of the isolate.

**Table 14.2** The most frequent differences in HBcAg amino acid sequences between genotypes and antigenic subtypes in B and T cell epitopes.

| | | Variant amino acid positions | | | | | | | | |

Specific amino acid motifs are found in specific ethnic backgrounds.

## Variants associated with active immunization

The emergence of variants of HBV can be due to selection pressure associated with extensive immunization in endemic areas,[5,19–25] but at present there is little evidence of this on a population-wide basis. Amino acid substitution within the MHR can allow replication of HBV in vaccinated persons, as much of the antibody induced by current vaccines does not recognize critical changes in this surface antigen domain.[26] These variants are summarized in Fig. 14.3 and Table 14.4. The first published study is instructive. Responses to the plasma-derived vaccine were studied in 1590 subjects, mostly infants from two regions of southern Italy, where the prevalence of HBsAg is >5%.[24] A total of 44 of the vaccinees became HBsAg-positive, 32 with additional markers of HBV replication in the presence of anti-HBs. Sera from several of these cases were investigated further by polymerase chain reaction (PCR) sequencing of the region of the MHR.[5] One case was a child of an HBeAg-positive mother who was given hepatitis B hyperimmune globulin at birth and at 1 month and a course of vaccine at 3, 4 and 9 months. Despite immunoprophylaxis, the child became chronically infected with HBV. HBsAg present at 11 months and at 5 years (when anti-HBs was no longer detectable) showed reduced reactivity with a panel of monoclonal antibodies known to bind to the MHR, although binding to HBsAg from the mother was normal with two of the monoclonal antibodies and only slightly reduced with a third. The sample taken from the child at 5 years had sG145R. The mother had sG145.

Additional studies of the prevention of mother–infant spread using hyperimmune globulin and vaccine showed similar results (Table 14.5). sG145R has been described from Singapore, Japan, United States, Venezuela, India, China and elsewhere.[22,27–34] The mutant is not generally found in the virus population of the mother, but in a US study, it was present as a small minority component in a couple of cases. If it is present, the sG145 virus in the inoculum from the mother may have been neutralized by the hyperimmune globulin, leaving the variant to become established. Recent studies in the United States indicate that 0.8% of infants born to HBV-infected mothers develop persistent infection with the sG145R variant in spite of adequate passive/active vaccination. Because neonatal transmission is responsible for 75% of HBV transmission worldwide, this could result in a significant reservoir of HBV variant infection. While the vertical transmission of HBsAg mutants (in particular sR145) has been observed from mothers to their vaccinated infants, few horizontal transmissions have been reported so far for sG145R[35] and D144A.[36]

Other mutations have been noted in vaccinated children. Amino acid 144 replacement is frequently encountered with or without G145R.[17,37–39] In two siblings from Japan, sT/I126N was selected,[32] but unlike the sG145R cases, this was also seen in the majority (12 of 17) of clones in the mother. The grandmother had a mixture of strains at aa 126 (although no s126N), indicating a slow selection process over three generations. Apart from vaccinated individuals, HBsAg variants have also been reported in blood donors (positive for anti-HBc alone) and after interferon (IFN) therapy.[40] In no case has horizontal transmission of a vaccine-associated variant to a vaccinee been documented, although this must be regarded as a potential problem, as anti-HBs-positive vaccinees may be susceptible to infection. In the ongoing Gambian study, emergence of sK141E has been seen in children from two villages that were infected horizontally.[41] It is not known whether this strain has become predominant or whether, with a higher rate of vaccina-

**Table 14.4** The most frequent medically selected amino acid changes in HBsAg.

| Amino acid position | Wild-type | Mutant | Cause |
|---|---|---|---|
| 120 | P | E-S-T | V-L-HBIG |

tion coverage, it may infect more of the children in these villages. Horizontal spread of variants to previously vaccinated individuals is less probable than vertical spread to a neonate who receives vaccine simultaneously with exposure. Nevertheless, 1560 health-care workers from Sardinia were studied some years after vaccination;[42] 13 were anti-HBc-positive. Of these, nine were available for further study, four were PCR-positive, and one had a dual variant, sI110V and sC149R. The importance of the former is unknown, but mutation of sC149 is known to have major antigenic effects. In many studies, mutations in vaccinated children were preferentially located in the 'a' determinant,[40,43] in contrast to the more randomly located mutations in unvaccinated children.[44] In general, replacement in the presumed second 'a' determinant loop, including amino acid positions 144 and 145, are more often associated with anti-HBs immune pressure than mutations in other epitopic domains of the MHR.[45] On the other hand, second 'a' determinant loop mutations are unusual in the absence of anti-HBs pressure.[46]

Whether mutants of the HBV 'a' determinant may pose a potential threat to immunization programmes is still controversial. Studies on infected vaccinated children with 'protective' anti-HBs titres reveal some with only mutants in the MHR.[44,47,48] The potential for takeover by variants in vaccinated children has been modelled,[49–51] showing that variants could become the dominant viral strains, even in the epidemiological setting of horizontal transmission (Fig. 14.7). In this model, the rate of emergence of vaccine escape mutants (for example sG145R) was predicted by combining previous models under a baseline parameter set, as estimated for the Gambia.[52] This two-strain, age-structured model also incorporated the strong age dependency in the probability of becoming a carrier of HBV.[52] sG145R is most likely to appear in vaccinated individuals, suggesting that sR145 out-competes sG145 best under the selective advantage of being able to evade vaccine-induced immunity. The model assumed that the fitness of sR145, in the absence of vaccination, as measured by the basic reproductive rate ($R_0$),[53] was lower than that of sG145. If the fitness is identical (and there is no reason to believe otherwise), then the following predictions are minimalist. The predictions of the model were robust to uncertainty in the parameter estimations, with the exception of two parameters, for which there is no reliable information. These are the cross-immunity of the HBV vaccine, c (the reduction in protection provided by the vaccine against sR145 as opposed to sG145), and the mutation term, Q (the prob-

**Table 14.5** Incidence of infection and variants in vaccinated infants born to HBeAg-positive mothers

| Country | Vaccine regimen | Incidence of infection (anti-HBc/HBsAg) | Proportion of variants |
|---|---|---|---|
| UK | S vaccine + hyperimmune globulin | 6% | 12% |
| USA | S vaccine + hyperimmune globulin | 9% | 23% |
| Taiwan | S vaccine + hyperimmune globulin | – | 33% |
| Indonesia | S vaccine | 23% | ND |
| Singapore | S vaccine + hyperimmune globulin | 12% | 39% |

ND, not done.

ability that an infectious contact, between a susceptible and an individual infected with s145G, will produce an infection with s145R). Q is obviously a function of the rate at which sG145R mutations arise during viral replication, the number of replicating viruses in an infectious individual, and the number of virions that constitute an infectious dose.

Figure 14.7 plots the time taken for sR145 to numerically out-compete sG145, at different values of c and Q. A notable feature is the time predicted for the emergence of the mutants. This is because, although highly contagious, HBV is not very infectious compared with measles or influenza. The spread of HBV is dependent on chronic infection generating new infections over a long time, so the incidence of new infections is low and the mutant takes decades to spread through the population. This seems to be the case whatever the values of c or Q. However, just because the change in HBV type is slow does not mean the mutants are unimportant. If they are allowed to attain high prevalence, it will also take several decades to eradicate them, even with cross-reactive vaccines, because of the chronic nature of the infection. Chronic infection of children may go undetected for decades while imposing a risk of liver disease and hepatocellular carcinoma (HCC) and the possibility of onward transmission. It is highly relevant that, of the vaccine escape variants so far described, sR145 and 144 are the most persistent and are not lost in favour of standard strains over time. Thus, they may have the capacity to cause chronic hepatitis B in a vaccinated population. This model does not take account of vertical transmission (which is the most common setting of emergence), or of a baseline prevalence in the unvaccinated population (which has been clearly shown). Thus, these predictions fall at the latest point of a range of time periods. However, there is little evidence at this stage that transmission is occurring horizontally, especially among vaccinated individuals. Further, experiments in chimpanzees reveal that 'standard' vaccine is protective against an sG145R inoculum.[54] Other mutations located beyond the MHR[22,29,42,55–57] also show altered viral antigenicity, but they are rare in studies of vaccinated infants. A correlation between HBV subtypes and emergence of variants has been reported in several studies.[19,58–60] Chen and Oon.[61] described a close association of vaccine-related HBsAg mutants with the *adw* subtype in Singapore compared with subtypes *adr, ayw* and *ayr*.

## Variants associated with passive immunization

Patients with end-stage liver disease attributable to HBV often undergo transplantation and are treated with human monoclonal anti-HBs or hyperimmune globulin to prevent infection of the graft. In some cases, HBsAg again becomes detectable in serum, and a number of substitutions have been observed in this virus compared with pretransplantation virus (Fig. 14.8 and Table 14.4).[45,57,62–68] In one reported series of transplantation patients treated with monoclonal antibody,[69] three of six patients exhibited reactivation of HBV in the graft, and the surface gene of the virus was sequenced. sG145R was seen alone in one and as a mixture with sG145 in a second. Other mutants were also present simultaneously as a quasi-species in this patient: sT140S and sC124Y. In the third patient, sC137Y was observed to emerge. It is interesting that loss of cysteines has also been observed after vaccination (see above) and hyperimmune globulin therapy (see later). There are no natural strains of HBV without these cysteines that are proposed to be involved in the loop structure of the MHR. Whether these

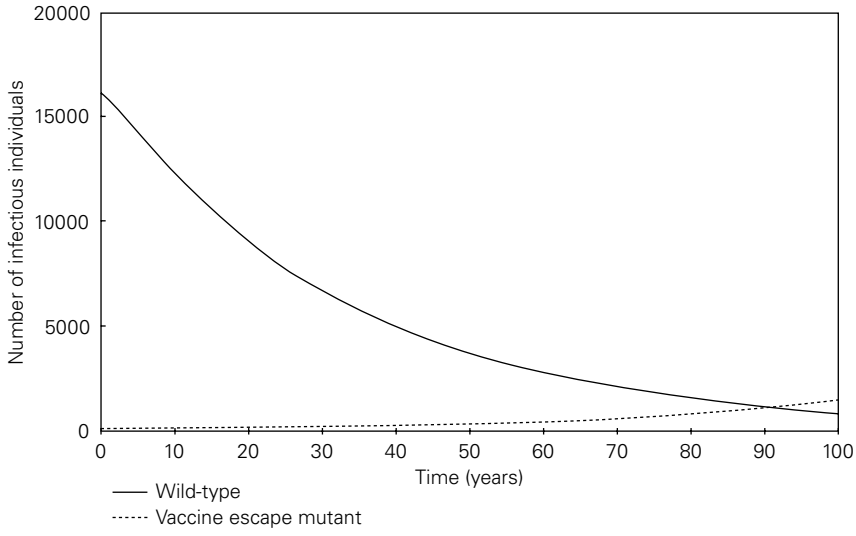

**Figure 14.7** The impact of mass vaccination on the prevalence of standard sequences and vaccine escape variants. The model was run to equilibrium before vaccination and then mass vaccination was simulated with 80% coverage. The number of infectious individuals is plotted on a non-logarithmic scale.

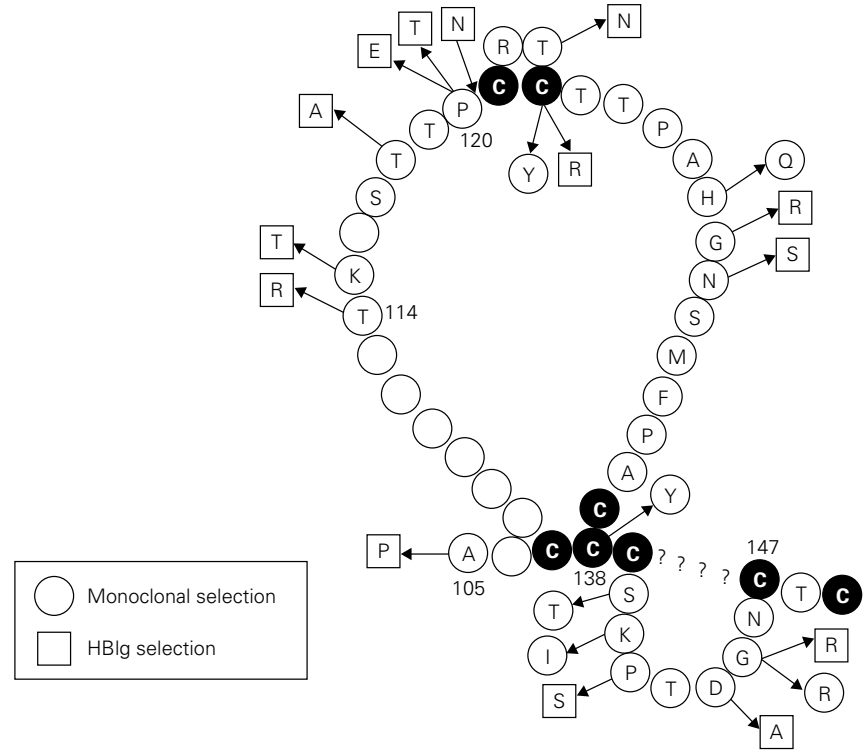

**Figure 14.8** HBsAg mutants selected during monoclonal or polyclonal anti-HBs therapy after liver transplantation. The latest model of the MHR of HBsAg, expanded for clarity, identifies a selection of variants observed in a number of studies. Amino acids in the loops are the 'usual' sequence, and those at the arrowheads are the mutants that emerged.

are independently viable strains was not addressed by this study, and in some cases a premature stop codon was noted in the polymerase ORF.

That monoclonal antibody can select HBsAg mutants is not surprising. However, polyclonal antibody in the form of hyperimmune globulin can also lead to different strains after therapy (Table 14.4).[62,70–73] On the withdrawal of hyperimmune globulin, the mutants are often lost and the wild-type again becomes dominant.[45] Only one study has controlled for immunosuppression in the absence of hyperimmune globulin pressure. sG145R has appeared in four of these five studies, but not in all cases. Hyperimmune globulin does put selection pressure on HBsAg. There is a report on the post-transplant patients who received hyperimmune globulin that mutants persisted despite the withdrawal of hyperimmune globulin administration for 4–5 years.[63] The variants are not present as a minority species before therapy; not all the mutations are within the MHR (although the majority are); within the MHR, they tend to accumulate within and around HBs2 and HBs4, but mainly HBs2.[74] However, there are discrepancies in this story. McNair *et al*.[72] found no changes between pretransplantation and post-transplantation samples in seven treated patients. Immunosuppression alone usually does not lead to HBsAg selection. It is possible to be viraemic in the absence of detectable HBsAg (such a case had loss of a critical cysteine – sC124R). Overall, in one study, 80% of the nucleotide changes led to amino acid changes (implying selection). There is some doubt about the significance of these results because some of the changes seen after therapy were seen before therapy in other patients. Although the data indicate that variant selection is a factor in graft infection, there are probably other factors such as inability to fully neutralize virus in extrahepatic sites. Without an *in vivo* model of neutralization, it will be difficult to ever be sure. Pre-S variants can be lost, but seldom gained, during hyperimmune globulin therapy,[75] implying either that these strains are less replication efficient or that they are viral dead ends.

## Variants associated with anti-viral therapy

As a result of the overlap of the S and P ORFs (Fig. 14.9),[76] HBV isolates with P gene mutations that are selected during the course of antiviral nucleoside analogue therapy may carry altered neutralization epitopes within the HBsAg. The classic lamivudine resistance 'signature mutation' in the HBV polymerase is the substitution of either valine or isoleucine for methionine in the highly conserved tyr-met-asp-asp (YMDD) motif, which comprises part of the active site (domain C) of the viral reverse transcriptase (Fig. 14.9). These YMDD mutations also result in amino acid substitutions in the HBsAg (Table 14.4). The B domain of the HBV polymerase coincides with amino acids 150–175 of HBsAg. This domain contains most of the S gene mutations observed

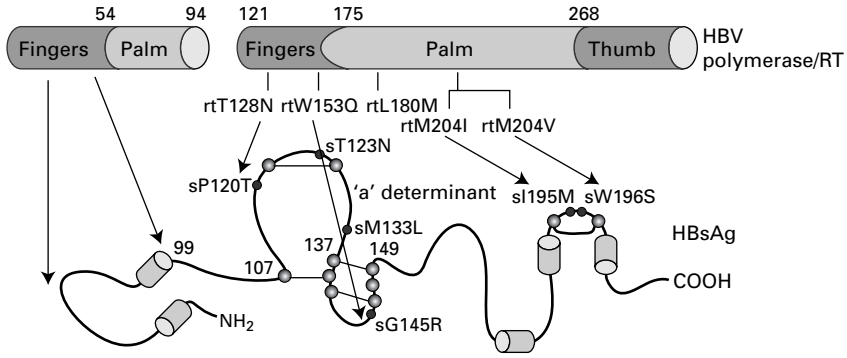

**Figure 14.9** Overlap of the HBV polymerase/RT with the HBsAg protein and the MHR. The HBV polymerase/RT is subdivided into fingers, palm and thumb domains. The vaccine-escaped mutations are shown together with the overlapping lamivudine-associated changes downstream of the 'a' determinant. The positions of key cysteine residues are shown as shaded circles and the important disulfide bridges in the HBsAg protein are indicated as broad lines. Alpha-helices in the HBsAg protein are shown as cylindrical structures. Taken from Torresi.[76]

in the presence of lamivudine[61,66,77–79] (Table 14.4). These drug resistance isolates may have the potential to become vaccine-escape mutants.[76]

Torresi *et al*.[80] investigated the role of lamivudine in selecting HBV mutants with antigenically altered HBsAg protein using pooled individual vaccine sera. They found that vaccine sera had reduced binding to HBsAg mutants selected during lamivudine treatment to a varying degree (Fig. 14.10).[80] In an enzyme immunoassay (EIA), binding of HBsAg mutants was reduced relative to the binding to the wild-type HBsAg (Fig. 14.10a and b). However, the potential of nucleoside analogues to select HBV mutants which reduce the efficacy of the current HBV vaccine has yet to be established. On the other hand, it has been shown that the changes in the S gene overlapped with the P protein have a compensatory effect that increased *in vitro* viral DNA levels in both intracellular replicating HBV core particle and extracellular virus.[81]

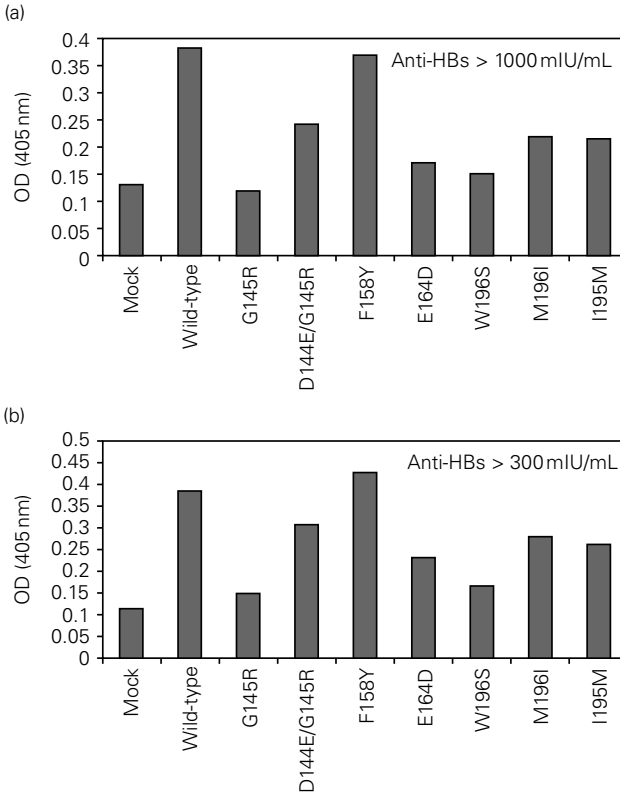

**Figure 14.10** Binding of individual vaccinee sera to wild-type and recombinant yeast-derived HBsAg. Enzyme immunoassay (EIA) plates were coated with 5 µg/ml of recombinant HBsAg and incubated with individual human vaccinee sera. The binding pattern of two representative sera (a and b) to the mutant proteins is shown. Taken from Torresi *et al*.[80]

## Diagnostic problems

A wide variety of commercial assays is available for the detection of HBsAg. Some use polyclonal anti-HBs and others use multiple monoclonal antibodies. Clearly, the sensitivity of an assay to detect a variant is dependent on the anti-HBs used. Thus, it is not surprising that there are examples of variants that cannot be detected by all assays. Clues to their existence are provided when a low-level signal is either not confirmed or is found to give a much higher signal by a second assay. There are accumulating data from Europe, Asia and Africa about HBsAg variants which are not recognized by either monoclonal or polyclonal antibodies specific for wild-type group 'a' determinant, but positive by DNA PCR.[17,30,31,82–85] Table 14.6 provides examples of this situation from a recent series from Papua New Guinea.[42] Sera with isolated anti-HBc (i.e. no HBsAg or anti-HBs) have been known to be infectious. Clearly, there are two possible explanations for lack of HBsAg positivity: a very low level of antigen or an antigenic variant. Of 104 sera from Sardinia with this serological picture, 21 (of the 75 available) were PCR-positive. However, only one of these

S/CO ratio <1 = negative; N/A, not applicable; pAb, polyclonal antibody-based assay. Sequences refer to subtype in parentheses and observed rare or unique variants. (From Carman *et al.*[42] with permission.)

PCR-positive samples had a clinically relevant variant. Other studies have shown that 'a' determinant variants may be responsible for 'anti-HBc only' positive individuals.[37,85,86] Still others can occur in patients who have HBsAg and anti-HBs simultaneously. A good example of the last[87,88] had sD144N, as well as changes at aa 126, 131, and 133. The patient also had a large deletion and other mutations in pre-S1. Another series of cases with co-existing HBs/anti-HBs came from Japan.[46] Five cases had either sR145, sN126 or an eight amino acid insertion in the tight loop between cysteines at 121 and 124. These show that sR145 can occur naturally, which gives it an added importance in an increasingly vaccinated world. However, not all series of HBs/anti-HBs-positive sera have variants to explain this situation. This is perhaps not surprising considering that this antigen and antibody are often complexed, and that detection of one or the other alone merely indicates dominance at that time. Also, with sensitive commercial assays, both can usually be detected, as was the case with the first infected vaccinated neonates.[24] Patients who have cleared their infection by classical criteria (anti-HBc/anti-HBs-positive),[89] usually do not have viraemia by PCR. An exception is within the first year after successful interferon (IFN) therapy.[89] Thus, it must be very unusual for a person to have a variant that is not detectable using standard HBsAg assays in this situation.

As already described, variants are not always simple but can have multiple changes within the MHR. Another good example of a complex variant, which also exemplifies the situation of disparate results in two commercial assays, was a patient who developed fulminant hepatitis B (FHB) after withdrawal of cytotoxic therapy for lymphoma.[20] No anti-HBs was administered, nor was this patient proven to have been vaccinated. He was positive by a polyclonal antibody-based assay but negative by a monoclonal antibody-based assay. sR145 as well as an insertion of N and T between aa 123 and 124 was found. Similar insertions at the same site have been seen in Chinese and Japanese patients.[46,90] Thus, all the insertions have been found in Far Eastern people and all within HBs2. Another example of a complex strain was from an Arabian man who was positive in a polyclonal assay but negative in a monoclonal antibody-based enzyme-linked immunosorbent assay (ELISA). Sequencing revealed sK145 plus other changes at aa 133, 134, 142 and 144. Finally, an example of a complex variant with undetectable HBsAg by a number of commercial and laboratory-based assays has recently been described in an agammaglobulinaemic patient, who had in addition substituted the sybtype determining amino acid at position 122 to isoleucine.[91]

## Antigenic characterization

### Immune escape at B-cell level

Most companies have either assessed their current diagnostic assays or produced new versions in order to better detect a range of variants, both natural and clini-

cally selected. The introduction of sensitive techniques for detection of HBV DNA has highlighted this issue, as a significant proportion of persons can be DNA-positive in the absence of HBsAg. Although currently available HBsAg assays are superior to their predecessors, there is a need for further development with ongoing assessment of assay ability to detect a wide range of HBsAg variants. It is obvious that the ability of an assay to detect a variant depends critically on the choice of anti-HBs used. However, the fundamental difficulty in the *in vitro* characterization of all this variation is that it is difficult to quantify the expressed HBsAg in a way that does not depend on its antigenicity. Several studies compare the sensitivity of modern assays for the detection of HBsAg variants.[65,74,92–96] In a study by Ireland and colleagues,[74] various cloned variants from 13 diagnostically relevant cases of hepatitis B patients were tested by seven commercial diagnostic assays. They compared assay performance of the variants that reacted at a level ≥10% of the standard HBV sequence (Table 14.7).[74] The assays detected between seven and 11 of the variants. In general, they found that the use of a polyclonal antibody in the capture and/or detection phases was associated with higher detection rates; assays 1, 2, 5 and 6 detected 11, 9, 10 and 9 of the 11 variants, respectively. The exception was assay 7 (detected seven variants), which used a sheep polyclonal antibody in the capture phase and mouse monoclonal antibody for detection. Assays 3 and 4, which detected only seven and eight of the variants, respectively, used monoclonal antibody in both capture and detection phases. However, having a similar, if not identical, amount of 'standard' antigen to compare the variant to is crucial for the interpretation of results. Use of an antibody that binds to a common region away from the variant domains being tested is one approach, but how can one be sure that the conformation is not affected? Another approach is to include an epitope tag within HBsAg. Basuni and co-workers developed an epitope tag system for standardization of the number of variant particles, independently of HBsAg antigenicity. An influenza epitope was inserted at both ends and the particle numbers could thus be standardized. Subsequently, the HBsAg was measured after capture by an anti-influenza monoclonal antibody. They found that single epitopes of up to 15 amino acids can be inserted at either end of the HBsAg protein without affecting HBsAg reactivity (Basuni, unpublished data). Counting of particles by electron microscopy is too labour-intensive and variable (Carman, unpublished data). Production in yeast has been successful for studying the role of the cysteines in the MHR.[3,4,10,97] Constructing HBsAg variants, particularly sG145R, in yeast led to markedly reduced binding by monoclonal and polyclonal antibodies,[98,99] indicating that this change alone may be important in the cases of vaccine escape described to date. However, naturally occurring sR145 variants are often detectable with monoclonal antibody-based assays,[74,100] albeit at reduced sensitivity. Whether these cases also had very high levels of serum HBsAg or whether there are antigenic subtleties after expression in yeast is unclear. It appears that variants can have different antigenic expression depending on their genotype/subtype background.

## Immune escape at T-cell level

The humoral response to HBsAg is T-cell-dependent. At least four regions within HBsAg present epitopes for MHC class II restricted $CD4^+$ T cells.[101,102] The effect of HBsAg T-cell epitope variants on the cellular immune response has been studied in individuals vaccinated against HBV by Bauer *et al*.[103] Six of 23 different variants in two HBsAg Th epitopes were shown to be responsible for inadequate T-cell reactivity.

Similarly, the MHC class I-restricted $CD8^+$ CTL response plays a key role in suppressing HBV infection. Schirmbeck *et al*.[104,105] showed that in $H\text{-}2^b$ mice even small changes in amino acid residues within two different CTL epitopes that mimic natural variants of adw2, ayr and adr, completely eliminated the immunogenicity of each epitope.

## Pre-S/S variants and chronic hepatitis

It was mentioned earlier that variants of HBsAg can be selected at or around the time of HBs/anti-HBs se-

**Table 14.7** Number of variants detected by each assay at a level of 10% of the standard HBsAg (GlyY/GlyD)

Taken from Ireland *et al*. [74]

roconversion. Ongoing mutant selection with the development of new anti-HBs populations persists until functional constraints on HBsAg do not allow further mutations. This can also occur after IFN therapy. Loss of proline at aa 142 and sR145 has been observed in patients who successfully cleared HBe and HBs antigens many years earlier. These patients are HBsAg-negative, DNA-positive with elevated transaminases.

Mutations in the pre-S region of the surface ORF have been described in many patients from different countries with chronic hepatitis B or HCC.[22,75,106–111] There is evidence to suggest that these mutants may be found with certain HBV genotypes. They have been more frequently found in genotypes C and/or B than in other genotypes.[107,110,112] Serum HBV DNA is not always detected by nucleic acid hybridization. A plethora of nucleotide substitutions and deletions have been observed in this region. A deletion of 61 amino acid residues from the carboxy-terminal half of the pre-S1 domain and of the promoter for the mRNA for the middle and small envelope proteins has been seen more than once. The authors also presented electron microscopic evidence of aberrant forms of virions. The region of pre-S1 from aa 21 to 47, believed to be responsible for hepatocyte attachment,[2] is always conserved. In most cases, a full-length gene is simultaneously present in serum, implying that complementation is necessary for viability. Pre-S1 deletions can arise after IFN therapy.[113] These probably affect the upstream transcription factor binding sites, explaining the lower production of HBsAg. Furthermore, decreased secretion of encapsidated mutant viral genomes, which could be trans-complemented by co-transfection of the S ORF, has been observed. There is also some *in vitro* evidence that deletions render the virus cytotoxic. Retention of S protein-containing particles in vesicles and relative overexpression of pre-S1 occur.[114] Cytopathic effects of pre-S1 mutants have been shown in several studies with 'ground glass-like' hepatocytes in transgenic mice and in ducks.[115,116] However, ground glass-like appearance also has been shown in samples with pre-S2 mutants.[117] Cells transfected with plasmid constructs bearing these deletion mutations were often destroyed, implying that the effects of these mutations were directly cytotoxic. It is of interest that a case of fibrosing cholestatic hepatitis (FCH) (that is characterized by intracellular retention of viral proteins) has been described (see above) with mutations in the S promoter.[75] There is also an assumption that pre-S1 regulates viral cccDNA levels via negative feedback,[118] redirecting the nucleocapsid into the virion formation pathway.[119] Variations in the pre-S2 region may thus lead to the accumulation of HBcAg in the nucleus, and newly synthesized genomes may be converted into cccDNA, thus increasing viral DNA transcription and replication.

Patients with HBeAg-negative viraemia can have pre-S2 deletions as well as precore mutations. Which appears first and whether there is any special functional significance or interaction is not clear. In Koreans who seroconvert to anti-HBe, precore and pre-S variants appear almost simultaneously.[120] Deletions in the pre-S2 region often include the pre-S2 initiation codon, thus preventing M protein synthesis.[107,121] Internal deletions[107,110] occur within the spacer region of the polymerase ORF and do not affect virus viability. As the M protein is not obligatory for virus production, such variants can clearly exist without complementation with full-length genes. Both pre-S1 and pre-S2 internal deletion variants increase the intracellular retention of envelope proteins as well as reducing the secretion of the S envelope protein. However, unlike the pre-S1, the effects of pre-S2 internal deletions on reducing the secretion of the small envelope protein are modest, and also, no apparent cytotoxicity in cell cultures transfected with pre-S2 internal deletion variants, has been detected.[110]

## Conclusion

HBV has evolved in humans into genotypes, antigenic subtypes and other variants, some antigenically important, others not. Virus strains can clearly be shown to be restricted geographically, due to random mutations linked to immune pressure. Further pressures can be mounted by medical intervention such as antibody therapy, drugs or vaccines. The swarm of genetic variants that can be found in any patient infected with HBV tend to present a mixture of viruses with varying replication fitness and selection advantages under the changing conditions of host cell type, immune response or pressure from drug treatment. The fitness of the predominant population changes in response to changing selection pressure.[26] There is good evidence that these variants are important causes of vaccine failure in infants born to HBeAg-positive mothers and that lamivudine can occasionally lead to variants that are not detected in HBsAg assays. Most manufacturers have altered their assays to better detect common mutants of HBsAg.

# Chapter 15
# Molecular variations in the core promoter, precore and core regions of hepatitis B virus, and their clinical significance

Peter Karayiannis, William F Carman, Howard C Thomas

## Introduction

The advent of the polymerase chain reaction (PCR) in the late 1980s revolutionized our understanding of virus genetics. Amplification of viral nucleic acids and their sequencing either directly, or after cloning, has added significantly to established sequence databases, thus permitting detailed genomic and proteomic analyses to be carried out. In the case of hepatitis B virus (HBV), sequencing studies have led to the identification of a number of stable virus variants normally found during the natural course of infection, or arising as a result of preventative or therapeutic intervention. Examples are the hepatitis B e antigen (HBeAg)-negative phenotype and the basic core promoter (BCP) variants, others affecting the enhancer II (EnII) region, as well as various deletion variants found in immunocompromised individuals. These variants will be reviewed in detail in this chapter. Variants of the hepatitis B surface antigen (HBsAg) and polymerase genes, arising after vaccination or treatment with monoclonal or polyclonal antibodies (anti-HBs), and treatment with nucleoside analogues respectively, are reviewed in Chapters 14 and 21.

## Virus biology and evolution

Hepatitis B virus isolates exhibit significant variation that may involve up to 12% of the virus nucleotide sequence. Natural variants exist, which give rise to the well-recognized serological subtypes and genotypes of the virus.[1] Multiple additional variants can also be found in a single host as a mixture of genetically related viral strains. This genetic diversity within an isolate is nowadays referred to as quasi-species variation. Such quasi-species populations are particularly evident in RNA viruses[2] because they have a high rate of nucleotide mis-incorporation during RNA replication or reverse transcription, coupled with the inability of the enzymes involved to correct such mistakes, as they lack proofreading capacity. Although HBV is a DNA virus, it replicates through an RNA intermediate (pregenomic RNA, pgRNA) which is reverse transcribed, thus rendering it liable to a high mutation rate.[3,4] As a consequence, HBV exhibits a higher mutation rate than would otherwise be expected for a DNA virus, amounting to $2 \times 10^{-4}$ base substitutions per site per year.[5] However, the potential for variation is constrained by the compact genomic organization of the virus, featuring overlapping open reading frames (ORFs) and the existence of regulatory elements of transcription, replication and encapsidation within these ORFs. For example, the surface ORF (S) is entirely overlapped by that encoding the polymerase (P). Any nucleotide change that leads to loss of function of either protein will be lethal or deleterious to the virus and therefore lost (*negative selection*). However, individual point mutations frequently have no phenotypic effect, either because of the redundancy of the genetic code (the nucleotide change may not result in an amino acid change) or because the change does not affect higher level structures of the RNA or protein. Some of these phenotypically silent mutations may become incorporated into the quasi-species pool.[6] The major force for evolutionary change within a virus population is *positive selection* by the host immune response. This subject has been covered in more depth elsewhere.[6–8]

### Biology of the precore/core gene

The precore/core ORF has two in frame initiation (AUG) codons, which lead to the synthesis of two co-terminal proteins. Initiation of translation at the first AUG results in the synthesis of the precore/core protein, the precursor of HBeAg (Fig. 15.1), while the second initiation codon is utilized for the synthesis of the nucleocapsid or core protein (HBcAg). The two proteins are synthesized from different messages known as the precore

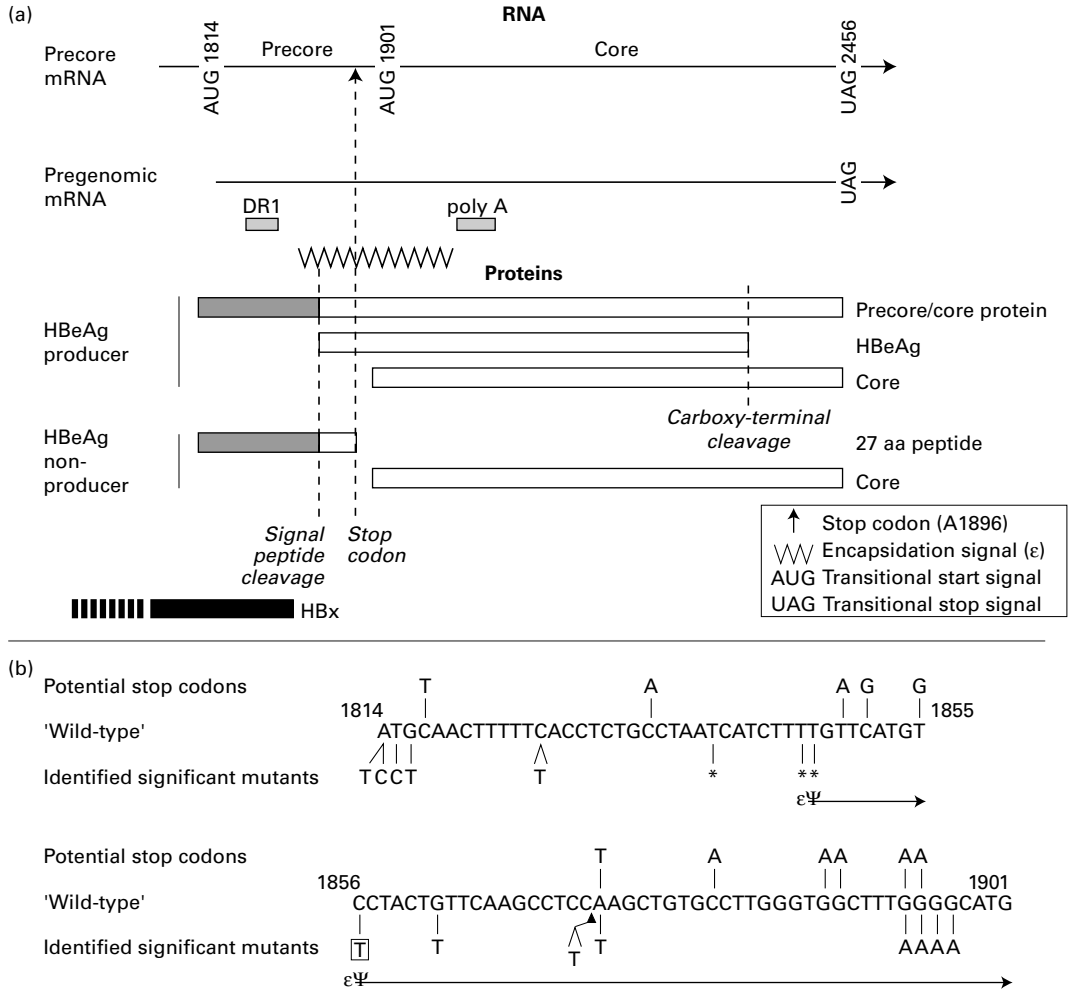

**Figure 15.1** Precore/core biology and nucleotide variation. (a) There are two in frame translation initiation codons (AUG) and one termination codon (UAG) in this gene. The precore/core protein translated from the first initiation codon is the precursor of HBeAg. This is generated by proteolytic cleavage of the first 19 amino-terminal amino acids (to remove the signal peptide) and the last 34 carboxy-terminal ones (codon 149 onwards). Translation from the second initiation codon produces HBcAg, the nucleocapsid protein of the virus. A G to A substitution at nucleotide 1896 (A1896) within the precore generates a stop codon that leads to abrogation of HBeAg production. HBcAg production is unaffected. Note that the X open reading frame (ORF) overlaps the 5′ end of the precore. (b) All the potential stop codons that could be generated by single mutations are indicated above the precore sequence. Nucleotide substitutions or insertions of variants that have been described are shown below the sequence. Note that there are some positions at which the potential stop codons have not been observed.

mRNA and pgRNA, respectively. Once synthesized, the precore/core protein is targeted to the endoplasmic reticulum (ER) by a 19 amino acid signal peptide at its amino-terminus.[9] Cleavage of this peptide releases the remainder of the protein into the ER lumen, where further processing of the carboxy-terminus results in the removal of about 34 amino acids from this end. What remains is HBeAg, which is released from the cell. HBeAg retains 10 amino acids from the precore region and shares the remaining 149 with HBcAg. The finding of antigenic epitopes that are different between the two proteins, even though they share most of their amino acid sequence, is explained by conformational changes in HBeAg related to the 10 amino acid precore peptide at its amino-terminus and the retained carboxy-terminal arginine-rich domain of HBcAg.

HBeAg is conserved within all members of the hepadnavirus family. It is secreted from the infected cell but is not part of the virion structure and does not have any known role in replication. In the neonate born to an HBV-infected mother, it has been suggested that HBeAg crosses the placenta and induces tolerance.[10,11] HBeAg may also have an immunomodulatory function during infection in adult life. Low molecular weight soluble proteins, such as HBeAg, induce a state of immune non-responsiveness, at the T-helper (Th) level. HBeAg-in-

duced tolerance results in T-cell non-response to HBcAg, as well as HBeAg-derived epitopes, so that elimination of HBV-infected cells does not occur. In transgenic mice, this non-response to nucleocapsid proteins can be broken by the injection of peptides bearing single amino acid substitutions. If such substitutions occur spontaneously during persistent infection, they may account for spontaneous HBeAg/anti-HBe seroconversion.[12] HBeAg probably also influences the host response by down-regulating cytokine (IFN-β) production.[13]

HBcAg forms the nucleocapsid of the virus, which has icosahedral symmetry, as demonstrated by cryoelectron microscopy.[14] The core protein dimerizes readily, and the dimers assemble spontaneously into particles that simultaneously encapsidate the pgRNA with a copy of the viral polymerase. The arginine-rich motifs at the carboxy-terminus of HBcAg are responsible for binding the pgRNA, and also the newly synthesized DNA strands of the virus. Encapsidation is triggered by the binding of the polymerase to a stem loop structure at the 5′ end of the pgRNA known as the encapsidation signal or ε (Fig. 15.2), with strict requirements of structure and sequence.[15] This structure, which is formed by the precore region sequences, is in turn recognized and bound by the polymerase. The latter uses the side-bulge of ε for the synthesis of a short primer for minus-strand DNA synthesis. Thus, any variation in this region may affect the stability of the signal and compromise virus viability.

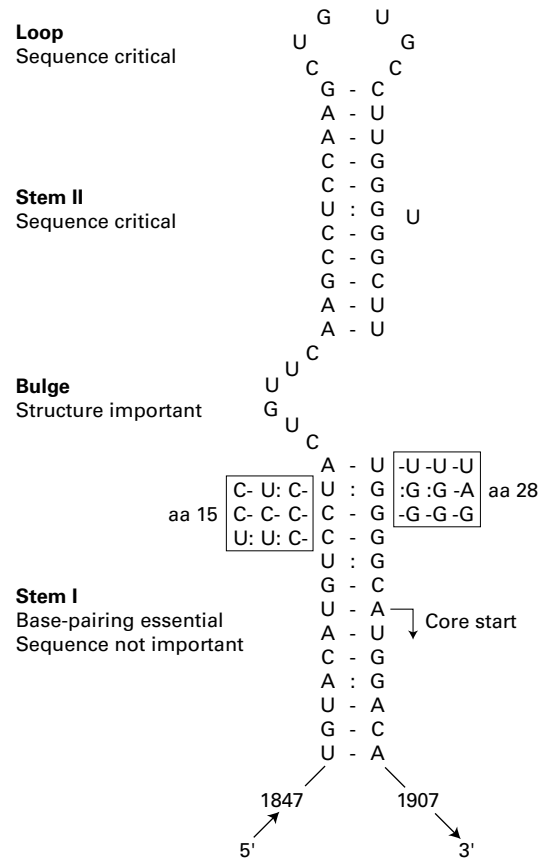

**Figure 15.2** Secondary structure and some variants of the pregenomic RNA encapsidation signal or ε. The 5' end of the pregenomic RNA, which starts just upstream of the precore AUG, folds into a stem loop structure as a result of base-pairing of complementary nucleotide sequences. This secondary structure is necessary for encapsidation of the RNA into nascent core particles. Unpaired regions form into a bulge and a loop. Note that nucleotides 1858 (third base of codon 15) and 1896 (second base of codon 28) are opposite each other on the lower stem. Sequences 1 and 2 (on the left side of the lower stem) code for serine, while sequence 3 and CCU code for proline. Sequence 6 is the stop codon variant, A1896. If there is imperfect base-pairing, as for sequences 1 and 4, a further mutation, for example sequence 2 or 6, will lead to instability of the stem and the virus will not survive.

## Biology of the core promoter region

The core promoter (CP) of the viral genome has a pivotal role in the replication and morphogenesis of the virus. It directs initiation of transcription for the synthesis of both the precore and pgRNAs. The CP consists of the BCP and upstream regulatory sequences, containing both positive and negative regulatory elements that modulate promoter activity.[16] The BCP overlaps with the 3′ end of the X ORF and the 5′ end of the precore region, and contains *cis*-acting elements that can independently direct transcription of the precore mRNA and pgRNA, both of which are about 3.5 kb in length (Fig. 15.3).[17] The pgRNA starts 3′ to the precore AUG and is translated into the core and polymerase proteins, but in addition serves as the template for the synthesis of the negative DNA strand of the virus by reverse transcription after encapsidation within the core particle.[3] The precore transcript, which is slightly longer than the pgRNA and is initiated upstream of the precore start codon, is the template for the translation of the precore/core protein that is proteolytically processed to produce HBeAg, as already described.

The enhancer II (EnII) element regulates the activity of the CP and partially overlaps with it and its upstream regulatory sequences. This whole region contains in addition nucleotide motifs that constitute transcription factor binding sites, imparting at the same time liver cell specificity for optimal function of these elements.[18–20] This interaction between the *cis*-acting elements with ubiquitous and liver-specific transcription factors is absolutely necessary for liver-specific expression from the CP. Moreover, the interaction between these *trans*-acting factors and the *cis*-acting elements allows the virus to co-ordinately or differentially regulate the transcription of the two mRNAs.[17]

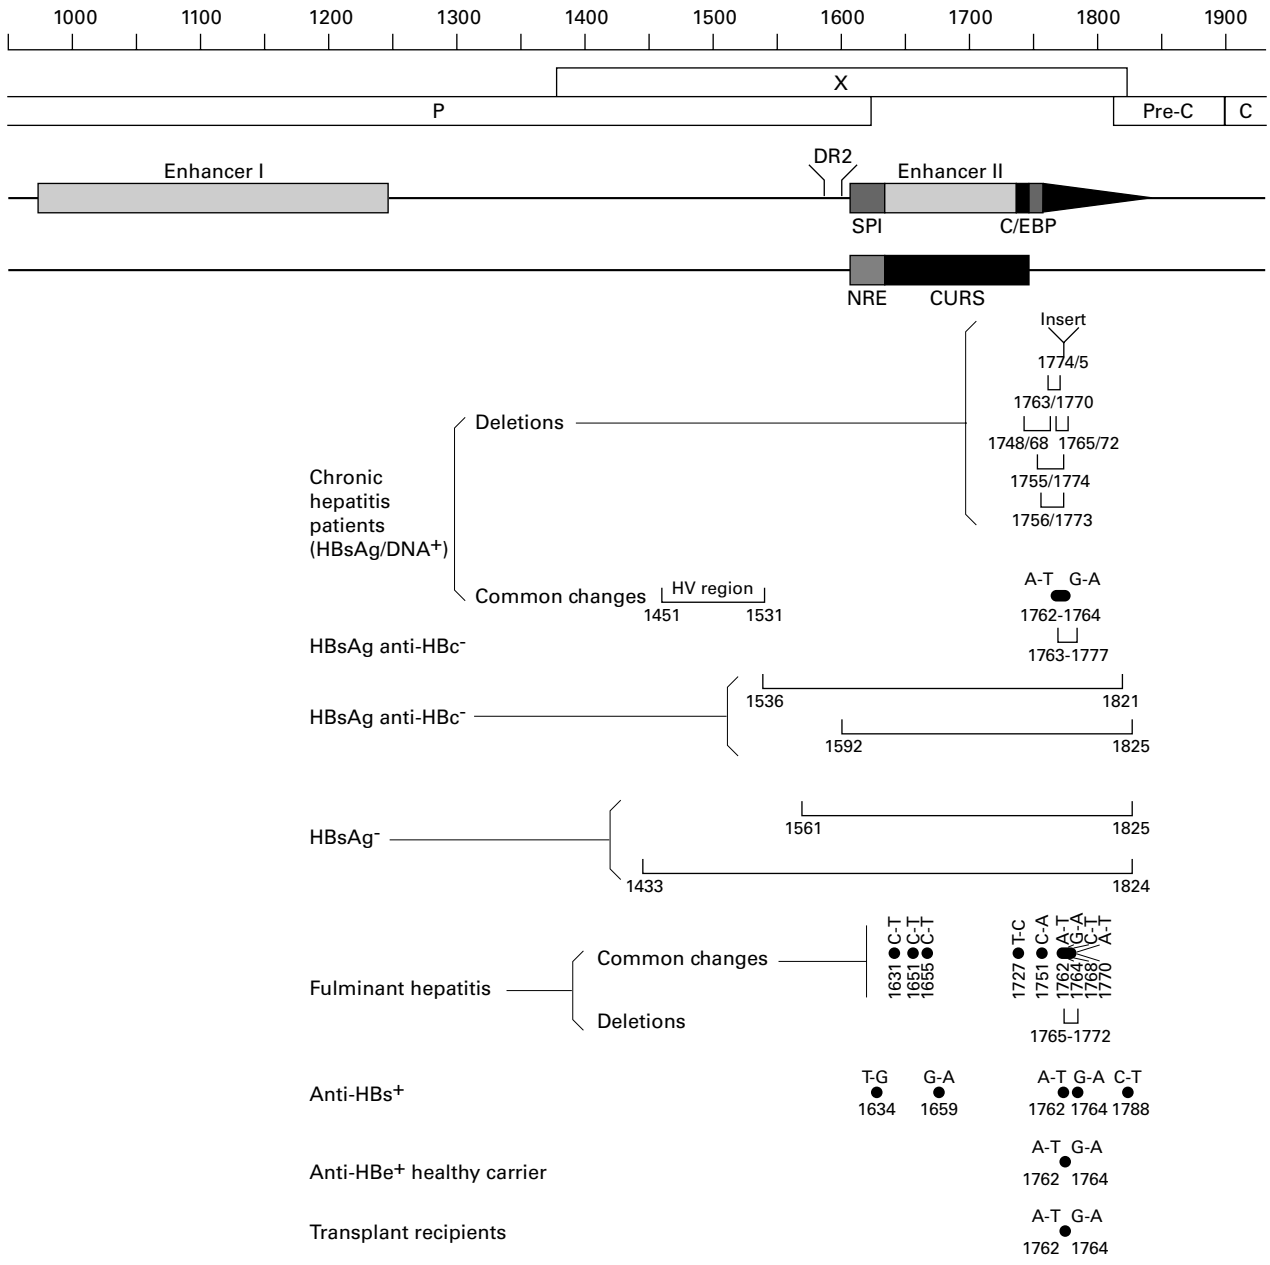

**Figure 15.3** Transcriptional regulatory elements – the X gene and variants. The promoters and enhancers involved in HBV replication are indicated. Note that they are upstream of the precore/core gene and, in the case of the BCP, overlap the 5′ end. The X gene is embedded within these elements. Thus, any nucleotide changes in one element may affect the amino acid sequence of HBx protein. Variability in a number of clinical scenarios is given. It is likely that deletions of X are not viable unless accompanied by a full-length gene. NRE, negative regulatory element; CURS, core upstream regulatory sequence; BCP, basal core promoter; DR, direct repeat. The ruler at the top is the nucleotide numbering.

## Precore variants

A molecular explanation for the HBeAg-negative phase of hepatitis B viraemia, first described in Mediterranean patients,[21,22] became apparent when a variant of HBV with mutations in the precore region was described by Carman *et al*. in 1989.[23] This variant had a G for A substitution at position 1986 (denoted as G1896A or A1896) (Fig. 15.1) which converted the TGG codon for tryptophan (codon 28) to TAG, a translational stop codon. This is by far the commonest substitution encountered in anti-HBe-positive patients.[23–27] A1897, seen less often, converts TGG to TGA, also a translational stop codon. Other mutations that have the same phenotypic effect are loss of the precore/core protein translation start codon (ATG to ACG or CUG),[25,28,29] mutation of the second codon to a stop codon, and frameshifts and deletions resulting in the synthesis of nonsense proteins.[27,29–34]

Although there are several additional positions within the precore sequence where stop codons could be generated by point mutations, these are rare, possibly because such mutations would destabilize the secondary structure of ε (Fig. 15.2). Precore amino acid substitutions have been detected in HBeAg-negative strains,[25,35] sometimes associated with A1896. The run of four Gs between nucleotide positions 1896–1899 is therefore a mutational hot spot and all four can be substituted by A. Two of these, A1898[35] and A1899,[23,36] are of unknown significance but are strongly linked with T1856 and A1896, respectively. These associations are likely to be related to encapsidation signal secondary structure requirements, but whether they have clinical relevance remains unclear even after years of inquiry. A1899 is primarily seen (with rare exceptions) together with A1896, implying that a second selection pressure is exerted on precore after emergence of A1896. In early studies, it was linked with severe disease, but subsequent work has failed to confirm this association.[37]

A significant proportion of chronic hepatitis patients in Mediterranean countries[21,38,39] and in the Far East[40] are infected with HBeAg-negative variants. It appears that this clinical picture has become the most common new presentation of chronic hepatitis B in Italy and Greece. In the Gambia and Brazil,[41,42] as well as northern Europe, there is a low prevalence of the precore stop codon mutation in anti-HBe-positive patients. These findings may relate to the prevalent HBV genotypes that circulate in these populations. Precore variation, not all of which affects translation of HBeAg, is distributed in particular genotypes. The stop codon mutation is not favoured in genotype A, C and F isolates, because they possess C at position 1858. This forms a canonical Watson-Crick pair with the G at position 1896 seen in wild-type strains. Inspection of the likely secondary structure of the encapsidation signal (Fig. 15.2) reveals a highly conserved lower stem that includes nucleotides 1856, 1858, 1896 and 1899. Mutagenesis experiments have shown that base-pairing is important in this region,[15] and various groups have confirmed these findings on clinically observed variants.[34,43–45] Viruses that have unstable stem loops do not encapsidate their pgRNA and do not compete successfully with other strains. Mutual exclusivity of A1896- and T1856-containing strains is explained by stem instability, as C1856T is always found with C1858, which is opposite A1896 on the stem. Of interest is that in anti-HBe-positive patients, C1858 strains appear more pathogenic than those with A1896.[46] A1896 is uncommon in genotype A patients as already mentioned.[34,47] Woodchucks may also exhibit precore variants of the woodchuck hepatitis virus, usually in the equivalent positions to HBV.[48]

## Chronic hepatitis

Following acute HBV infection, 5% of adults and almost 95% of children born to chronically infected mothers become chronic carriers of the virus, probably because of failure of induction or activity of cytotoxic T lymphocytes (CTLs). Viraemia continues for many years, and initially there is very little inflammatory necrosis of infected hepatocytes (Fig. 15.4).[40] As the years go by, this immune-tolerant phase gives way to increased hepatitic activity, presumably reflecting immune activation, perhaps as a result of viral antigenic variation caused by transcriptional errors as already mentioned. The role of CD4-positive lymphocytes in this process is supported by the observation of an increased response to the nucleocapsid proteins as HBeAg/anti-HBe seroconversion

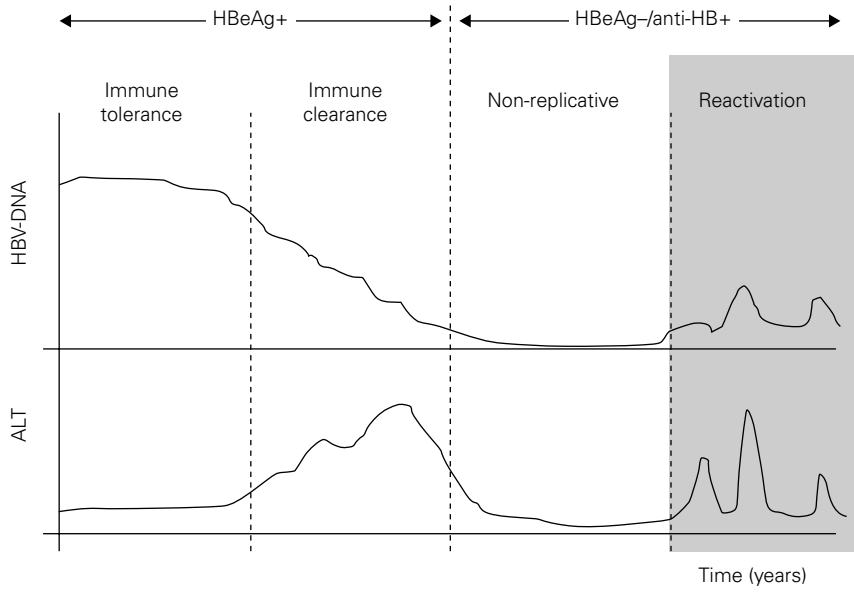

**Figure 15.4** Diagram of the natural history of HBV infection showing the immune-tolerant, immune clearance and non-replicative phases of disease. In some patients, the latter phase may be followed by a reactivation phase characterized by increased viral replication and liver damage (shaded area). Precore and BCP variants are the main isolates seen in such patients during this latter phase.

approaches.[49] These cells presumably provide help to CTLs and B lymphocytes. Either because of CTL lysis of infected cells,[50] or of cytokine production by CD4-positive lymphocytes, which inhibit virion production,[51] cells supporting productive HBV infection are cleared during the seroconversion hepatitis. About 5% of HBeAg-positive chronic infections may spontaneously seroconvert to anti-HBe per year. In the majority of these patients, HBs antigenaemia persists predominantly because of the presence of small numbers of cells containing integrated HBV sequences.[52] However, by PCR, it is possible to detect small amounts of HBV DNA in the serum of these HBsAg-positive, anti-HBe-positive subjects with normal liver function tests, indicating that viral replication is still occurring at low level.[23]

In some patients, particularly those infected at birth or in the early years of life from infected family members, there is emergence of an HBeAg-negative variant. This virus, along with the HBeAg-positive strain, can be detected in virtually all patients after HBeAg/anti-HBe seroconversion.[23] The A1896 variant is present in very small amounts during the latter period of the HBeAg-positive phase of the disease and is selected at, or after, seroconversion to anti-HBe, while the HBeAg-producing strain is gradually being cleared.[28] This process can take years, during which time a mixture of both strains is usually seen. HBeAg-positive cases with active hepatitis (in the immune clearance phase) have mixtures of HBeAg-producing and non-producing strains during this phase.[44,53] In contrast, anti-HBe-positive cases with a mixture usually have mild hepatitis.[23,54] Those in whom HBeAg and anti-HBe are intermittently detected tend to be infected with an HBeAg-producing strain during this period.[35] Similarly, in cases that reactivate after some years, the precore sequence tends to be similar to previous samples. For example, if cases had G1896 earlier, most likely that would be the dominant strain in later samples, even if the patient had become anti-HBe-positive.[55] Why in some patients the virus then emerges and replicates at high levels, and why patients then go on to develop further inflammatory liver disease,[56] is currently unknown. Clearly, some component of the immune response is responsible for control of the virus during the anti-HBe-positive phase. This is most probably a Th/CTL response to nucleocapsid proteins. Mutations within epitopes recognized by sensitized T cells involved in control of the infection, or immunosuppression, may tip the balance in favour of the virus re-emerging. It is noteworthy that during this phase of the infection, amino acid substitution in the core protein is frequent (see below). It seems likely that the important selection pressure is the presence of anti-HBe in the absence of an adequate CTL response, as most of the variants so far described emerging in the late phase of the infection have had a common phenotype, namely an inability to produce HBeAg.

## Fulminant hepatitis

There is strong epidemiological evidence linking A1896 with fulminant hepatitis B (FHB),[57–61] suggesting that such a severe outcome may be due to viral factors rather than being solely dependent on a strong immune response to the infecting viral strain.[61] A substantial body of evidence shows that those who are HBeAg-negative at the time of sampling are usually found to be infected with the A1896 variant.[57–60,62–64] As the source of the infection usually has minimal chronic hepatitis and is infected with a precore mutant of similar or identical sequence to that found in the FHB patient,[65–69] it is evident that the disease has been caused by the new host mounting a vigorous immune response to the particular strain of HBV. Although many FHB cases are associated with infection by precore variants, FHB may also be associated with HBeAg-positive HBV infection being infected with HBeAg-producing strains.[57,63] Furthermore, even in anti-HBe-positive cases, the link to A1896 is far from clear. This variant has not been found in many anti-HBe-positive FHB patients from Britain, Hong Kong,[70] France[71] or the United States.[72] It has therefore been hypothesized that precore variants may replicate rapidly, spread throughout the liver and precipitate a fulminant course only if the host mounts a strong lytic immune response. It is suggested that the absence of HBeAg-mediated immune modulation contributes to the rapid lysis of large numbers of HBV-infected cells. The development of FHB in neonates infected from HBeAg-negative mothers, and the observation that transmission of A1896 strains to children seldom gives rise to chronic carriage,[73] may also be partially explained by the absence of immunomodulation by HBeAg.

The picture has become clearer, although also more complex, with the discovery that variation within the *cis*-acting elements of the basic core promoter (BCP), that overlaps with the HBx protein encoding region (see later), is also associated with FHB. The commonest variants contain a double mutation (T1762/A1764) in the BCP. The working hypothesis is now that there are several routes to enhanced replication that, in a genetically predisposed host, may result in FHB. Although A1896 is often found, this does not necessarily mean that it is the variant *per se* that is causing the fulminant hepatitis. In fact, there appear to be multiple strains with A1896 associated with different outcomes. Transmission of an A1896 strain (with T1762 and A1764) to chimpanzees[74] resulted in more severe hepatitis than would be expected, although this was not accompanied by a higher than average level of viraemia. However, it has been dem-

onstrated that the precore region of HBV is involved in inhibition of HBV replication.[75–79] and it follows therefore that BCP mutations in the presence of A1896 may result in higher levels of viral replication. Furthermore *in vitro* experiments have shown that, although an A1896 genome did not have higher replication efficiency, a genome from an FHB patient with A1896, T1762 and A1764 produced very high levels of HBV DNA.[80] The major effect was on encapsidation. Variability at nucleotides 1766 and 1768 seems to be important in this process, implying that there is another region outside ε involved in encapsidation, perhaps indirectly.[81] Detailed phylogenetic analysis that included 20 epidemiologically unrelated FHB sequences,[82] revealed six clusters of fulminant strains each with distinct mutational patterns. Mutations were again clustered in the *cis*-acting regulatory regions and HBx protein, but no unique variant was specifically associated with this disease outcome. Rather, the combination of nucleotide variation in the enhancer/promoter regions plus amino acid substitution in HBx was almost uniquely associated with this disease. There was statistical evidence of a heightened replication rate of the FHB genomes.[82] Finally, oligonucleotides containing variant sequences failed to bind to some nuclear transcription factors, implying that an additional pathogenetic mechanism in FHB might be loss of inhibition of transcription. Clusters (viral lineages) and transcription efficiency were both strongly linked to mortality and rapidity of progression to fulminant hepatitis after infection

Viral selection during the course of FHB has also been demonstrated.[83] For example, in one infant–mother pair, the mother had a mixture of two subtypes and a mixture of quasi-species within each subtype, yet the infant was only infected by one subtype and a reduced number of quasi-species within that subtype. There is no evidence that this is of pathogenetic significance.

### Fibrosing cholestatic hepatitis

Fibrosing cholestatic hepatitis (FCH) occurs after liver transplantation,[84] occasionally after renal transplantation[85] and in human immunodeficiency virus (HIV) infection (personal observation). The common factor is clearly immunosuppression. These patients undergo a fulminant course and the hepatocytes are packed with HBs and HBc antigens. Although precore and HBc variants are often associated with FCH, it is difficult to link these causally with intracellular accumulation.[85,86] The issue has been raised whether cytopathic effect, rather than immune lysis, is primarily responsible for this form of hepatitis. In particular, it is possible that mutations that result in truncated proteins that have lost secretory signal sequences or exhibit altered cellular localization may cause cellular toxicity. The picture has been made more complex with a recent description of an S promoter variant in an FCH case.[87] The issue of direct cytotoxicity justifies further exploration.

### Acute non-fulminant hepatitis

The incidence of the precore mutation during acute, non-fulminant, hepatitis is presently unclear. Selection of A1896 strains does occur during acute infection[63,88] consistent with anti-HBe exerting an initial selection pressure followed by clearance of the HBeAg-negative virus by other immune mechanisms, possibly CTLs. However, other groups were unable to find evidence for this process during acute hepatitis,[28,58,89] finding instead that years were sometimes needed for emergence of precore variants. Using an amplification-created restriction site method, A1896 was shown to dominate in both acute and chronic hepatitis cases of various severity in Taiwan (58% in acute versus 70% in chronic),[90] but not so in a recent study from Japan.[89] Acute hepatitis in neonates born to anti-HBe-positive mothers is well described.[73] The description of a chronic carrier transmitting A1896 in a pure form and resulting in typical acute hepatitis with seroconversion to anti-HBe without there having been an HBeAg-positive phase, shows that anti-HBe is cross-reactive with HBcAg epitopes and that A1896 can lead to the same serological disease profile as G1896 viruses. [91]

## Basic core promoter variants

Mutations in the core promoter region may have repercussions on viral gene expression and/or replication, with a concurrent impact on viral pathogenesis. A double mutation in the BCP leading to substitution of A for T, and G for A, at positions 1762 and 1764, respectively, has been described in various disease states or settings of HBV infection.[26] The biological significance of the double A1762T/G1764A mutation is still under investigation, particularly in relation to the precore stop codon mutation. However, the puzzle is beginning to come together in spite of initial conflicting results. The double BCP mutation has been shown to be associated with HBeAg negativity in some studies, [26,92,93] but not in others.[94–101] These discrepant findings may be due to the fact that these are cross-sectional studies performed at different stages of chronic liver disease, coupled with incomplete data on mutations elsewhere in the genome, including that of the precore. However, the presence of the double mutation is clearly associated with downregulation of HBeAg production,[64,94,102,103] as demonstrated by transfection studies.[104–108] There is evidence to suggest that the double BCP mutation results in decreased levels of the precore mRNA and therefore diminished production of HBeAg. Laras and co-workers demonstrated that this is indeed the case using a transcript-specific PCR ap-

proach and liver biopsy material from HBV carriers with the double mutation. In all cases, there was absence or low levels of precore mRNA without a significant effect on total CP-directed transcription.[109] Conversely, it has been suggested that the double mutation may result in increased viral replication as a result of upregulation of pgRNA production, promoting encapsidation and core protein production.[104,154,107,108] Others, however, reported decreased precore mRNA levels, but wild-type levels of replication and gene expression.[106,110–112] This latter finding is supported by measurements of viral load in patient sera, which do not show any significant increases in the presence of the double BCP mutations.[99,102,107,113,114] A clear link between severity of liver disease and HBeAg negativity with the BCP mutations has been found in some studies,[93,103,115–117] but not in others.[114]

The differences seen in transcript levels in the presence of the BCP mutations are thought to be due to the conversion of a nuclear receptor binding site to one for hepatocyte nuclear factor 1 (HNF1).[111,118] This effect has been investigated further in HepG2 cells and in the woodchuck animal model.[119,120] Mutations in the HNF1 binding site decreased dramatically the synthesis of woodchuck hepatitis virus pgRNA, thus suggesting that the HNF1 site is essential for this activity. The double mutation in addition converts L to M at position 130 and V to I at 131 in the overlapping X-ORF gene product. In the work by Li *et al*.,[118] it was shown by transfection studies in Huh7 hepatoma cells that the removal of the nuclear receptor binding site had no effect on the transcription of HBV mRNAs, the two codon change in the X-protein suppressed both transcripts, and that the creation of the HFN1 site restored the pgRNA level. What is more, analysis of revertants with either one or the other of the BCP mutations showed that the T1762 change is critical for the mutant phenotype.[107]

Chan and co-workers found that the double A1762T/G1764A mutation was significantly more common in genotypes that have C at nucleotide position 1858, while in contrast the precore stop codon mutation was found in patients with a T at the same position.[95] Nevertheless, the double BCP and the precore stop codon mutations are far from being mutually exclusive.[95,116] The BCP mutations as mentioned before have been found in patients regardless of HBeAg status. However, in anti-HBe-positive patients the double mutation was often accompanied by a change at position 1753, from T to C or G.[101] In addition, other point mutations upstream and downstream of T1762/A1764 have been described, occurring either alone or in combination with the double mutation, and in different settings, including chronic hepatitis, FHB, hepatocellular carconoma (HCC) and liver transplantation. [64,65,74,80,92,94,100,103,115,121,122] It was recently shown that CP mutations other than those at positions 1762/1764 could have a major impact on viral replication and HBeAg expression.[123] Transfection studies with full-length infectious clones reveal that CP mutants with additional mutations at 1753 (T to C) and/or 1766 (C to T) replicated at high level. Site-directed mutagenesis shows that combined mutations at 1762/1764/1766 and 1753/1762/1764/1766 result in higher replication rates and lower HBeAg expression than 1762/1764 mutations alone, whereas the 1753/1762/1764 variant was not much different from the double BCP mutant. Deletions within the CP region varying in length from 1 to 21 bp have been reported once again in different settings. These include fulminant hepatitis,[124] chronic hepatitis,[78,125–128] asymptomatic infection,[92,129] serologically silent infection,[129–132] HCC,[133,134] renal dialysis,[125,126] liver and renal transplantation,[135,136] as well as in patients who have survived haematological malignancies or solid tumours.[137,138] Such deletion variants are often characterized by low viraemia levels,[139] and may need help from the wild-type virus for survival. Transfection studies with clones having an 8-bp deletion in the BCP (nt 1768–1775), demonstrated reduced levels of transcription and progeny virus production.[140] In contrast, three BCP deletion variants (either nt 1758–1777 or 1749–1768) from Singaporean chronic carriers had high viraemia levels.[140] It appears, therefore, that the strain genetic background in which the BCP and A1896 mutations arise, in relation to additional ones, determine replication rate, expression of HBeAg and pathogenicity.

Another variant with a G1862T substitution affecting codon 17 has been described in chronic carriers,[33,142] HCC[47] and in patients with fulminant hepatitis.[31] In the latter study, this substitution was found in association with G1862T and G1899A, in the absence of the double BCP and A1896 mutations. All patients, being Chinese, were infected with genotype B. The G1862T mutation leads to substitution of valine for phenylalanine, affecting the –3 position in the signal peptidase recognition motif. As demonstrated by functional studies, this results in impaired processing of the precore/core protein into HBeAg.[31] It was previously suggested that since the G1862T change affects the side-bulge of ε involved in DNA primer synthesis, this may in turn interfere with replication.[47] However, the detection of the variant on its own and in the absence of wild-type virus argues against this hypothesis.[31] What is more, it suggests that the primer for negative-strand DNA synthesis is likely to be only three nucleotides long.

Strains carrying the C1856T variation that leads to substitution of proline for serine at codon 15 of the precore may behave in a similar manner to the G1862T variant. This amino acid change affects the signal peptide also, and may therefore affect production of HBeAg from the precursor precore/core, but there are no experimental data supporting this proposition at the moment. This variant was initially found by chance while sequencing

the complete HBV genome of an HIV-positive patient with a strange serological profile,[143] and then in Hong Kong Chinese patients with chronic hepatitis.[35] T1856 or A1896 was found in about half of each of the studied Chinese population, but because of their positions on opposite sides of the stem of the encapsidation signal, these variants are mutually exclusive. T1856 was found both in the HBeAg- and the anti-HBe-positive phases of the illness, quite unlike the usual picture with A1896. On long follow-up during the anti-HBe-positive phase, no selection for A1896 was seen in those with T1856. Further analysis of the core gene showed that these strains are independent lineages[144] that can be transmitted within families.[145]

Recently, an additional class of variants has been described in black South Africans with substitutions in the –5, –3 and –2 positions upstream from the AUG codon of the precore ORF, which affected the Kozak sequence. Triple mutants exhibited severely impaired HBeAg expression, while –5 and –2 double mutants had reduced HBeAg expression to levels seen with the double BCP variants.[146]

### Chronic and fulminant hepatitis patients

The double mutation has been detected with increased frequency in patients with fulminant hepatitis including children,[62,64,68,69,74,81,82,92,96,98,100,122,124,147–149] HBeAg- and anti-HBe-positive chronic hepatitis,[68,92,98,101–103,127,150,151] and HCC,[94,121,152,153] but less so in asymptomatic chronic carriers.[26,94,97,102,103,121,151,152] In addition, they have been detected in immunosuppressed,[97] liver transplant[100] and seronegative patients.[130,131] There are also reports in which the BCP double mutation has not been seen in patients of the same disease groups as above. For example, the 1762/1764 mutations were rarely seen in patients with FHB in the United States, even though these are common in chronic carriers.[98] Similar results have been reported from Brazil.[41] This once again may relate to differences between prevalent genotypes in these areas.[154]

### Immunosuppressed patients

In patients with severe recurrent disease following liver transplantation, it was shown that although pre- and post-transplant sequences in the BCP and precore/core region were very similar in each patient, in those with severe recurrence there were more nucleotide and amino acid substitutions in the precore/core encoding region, but not in the core promoter, than in patients with mild recurrence. There was also a link between severe disease and genotype D isolates.[100] However, additional studies indicated that immunosuppressed patients with severe liver disease, or end-stage cirrhosis, had HBV isolates with deletions, insertions and/or base changes in the BCP region,[98,135,155] leading to the appearance of new transcription factor binding sites (HNF1, HNF3) or duplication of others (C/EBP, HNF4).[135] Moreover, such variants also had other deletions in the core gene and/or deletions in the pre-S1/2 regions, the former of which are discussed later.

## Emergence of variants during chronic infection

There is still controversy as to which one of the two groups of variants is the most important with respect to disease activity and which one of the two appears first. Studies from the Far East (Japan) suggest that the BCP mutation is the one that appears first.[156–159] However, both can be present during the HBeAg-positive phase in mixtures with the wild-type virus.[28,159] Contingent with the appearance of these mutations is a reduction in HBV DNA levels. The mutations, as well as the reduction in HBV DNA levels, are associated with HBeAg seroconversion.[160,161] It seems, therefore, that reduced HBeAg expression (BCP mutation, and other mutations described above that result in reduced expression) or complete abrogation (precore stop codon) are a prerequisite for successful seroconversion to anti-HBe. The reduction in the level of HBeAg may remove a tolerizing effect on the immune system, allowing seroconversion from HBeAg to anti-HBe, clearance of the wild-type virus and selection of the variants, which become the dominant species. The liver disease in many patients enters a quiescent phase with little, if any, virus replication and levels of viraemia $<10^3$ copies/mL, and minimal changes in the liver. It is the cellular immune response to HBV that appears to hold the virus under control.[162] In some patients, however, the virus continues to replicate at moderate levels, biopsies show increased histological activity and amino acid substitutions begin to accumulate in the core region. In some patients, there are frequent acute exacerbations accompanied by increased viral replication and alanine aminotransferase (ALT) levels rise, which on occasion may result in fulminating disease. In such patients, progression to cirrhosis or development of HCC at a faster rate than carriers with milder disease is not unusual. The immunological mechanisms that may be involved during these stages of disease are discussed later.

## Core gene variants

### Amino acid substitutions

The finding that precore mutants are found in those with both mild and severe disease after seroconversion led to the investigation of changes in other genes. Variation in the core gene is related to genotype, and thus there is ethnic/geographical variation in incidence. There are

well-defined epitopes in HBcAg that are recognized by antibodies, Th cells and CTLs (Table 15.1). A number of groups have now described mutations that are selected in the core gene of patients with progressive chronic hepatitis. In HBeAg-positive patients from the Far East with severe hepatitis, greater clustering of substitutions was noted between amino acids 84 and 101, compared with those with mild disease[163–167] (Fig. 15.5). In Korean patients who seroconverted to anti-HBe, clustering was again seen between amino acids 84 and 101 of HBcAg, indicating that this is a consistent region of immune pressure in Far Eastern patients. A further analysis by this group indicated clustering of mutations in B-cell and Th epitopes.[168] Chinese patients also select more variants during anti-HBe seroconversion than during the immune tolerant phase.[169] In anti-HBe-positive Mediterranean patients with minimal hepatitis, very few changes were noted. [170] In contrast, a mean of five or six substitutions was seen in an anti-HBe-positive group with progressive disease. In a cross-sectional analysis, these were statistically significantly clustered in B-cell and Th epitopes.[170] A sequential study confirmed this finding for B-cell epitopes but revealed a weaker association with Th epitopes.[171,172] Of interest is that, in those who seroconverted from HBeAg to anti-HBe and went into clinical remission, multiple substitutions occurred at amino acids 50–69, a Th epitope. The contrast with progressive disease was thus striking. HBcAg mutations also accumulate in Th epitopes in Chinese patients with HCC.[173] However, in Spanish patients, there were many substitutions in and around the HLA-A2 class I epitope from aa 11 to 27 and the B-cell epitope from aa 74 to 83.[174] It is clear that studies of variation in presumed T-cell epitopes must be related to major histocompatibility complex (MHC) phenotype. One example is instructive. In Mediterranean patients, an amino acid change from threonine to serine at codon 12 of the core protein (T12S) is significantly associated with progressive disease. Although this change is very close to an HLA-A2-restricted CTL epitope, it has no association with human leucocyte antigen (HLA) type. These patients selected T12S only after they had seroconverted to anti-HBe and selected A1896.[170,174] Yet, in nearly all HBeAg-positive Japanese patients, serine was found at this position. The implication of these conflicting results from different geographical areas is either that the host is an important factor in viral evolution or that functional constraints in some isolates from Japan do not allow this variant to be selected. This finding of a temporal association between mutation in the HBeAg encoding gene and HBcAg, the former preceding the latter, suggests that HBeAg production must stop before selection pressure falls on HBcAg epitopes. It is of interest that this variation in HBcAg occurs around the time of A1896 selection.[170–172,175–177] In some patients with acute exacerbations during the anti-HBe-positive phase, there is clearance of the pre-existing strain and emergence of new viral variants with amino acid substitutions in epitopes suggestive of immune selection.[171,177] In contrast, asymptomatic carriers without hepatitis have invariant amino acid sequences. It seems that, once A1896 has been selected, because HBeAg shares common T-cell epitopes with HBcAg and the immune modulating effect of HBeAg has been lost, immune activity puts selection pressure on HBcAg.

Finally, the sequence of HBcAg from FHB cases is quite variable compared with strains from patients with chronic hepatitis.[61,65,66,178] This variation tends to cluster within epitopes and, as for chronic hepatitis, this is significantly associated with pre-selection of A1896.

## Core deletion variants

As mentioned earlier, genomic deletions affecting regions other than the BCP have been described for the core and pre-S coding regions. Deletions within the core gene are variable in length and usually affect the central region, although carboxy-terminal deletion variants have also been described. [128,175,179–182] Such deletions can

**Table 15.1** Statistical analysis of correlation between mutation and B-cell and Th epitopes in core protein*

| | | HBeAg to anti-HBe and into remission | | | Continuously anti-HBe-positive with severe disease | | |
|---|---|---|---|---|---|---|---|
| Epitope | T/B | Odds ratio | 95% confidence interval | *p* value | Odds ratio | 95% confidence interval | *p* value |

*The odds ratio and 95% confidence intervals represent the likelihood of amino acid substitutions occurring in the epitope in comparison to the remaining core sequence. *p* values are calculated using the $\chi^2$ test or Fisher's exact test. T/B, T- or B-cell epitope

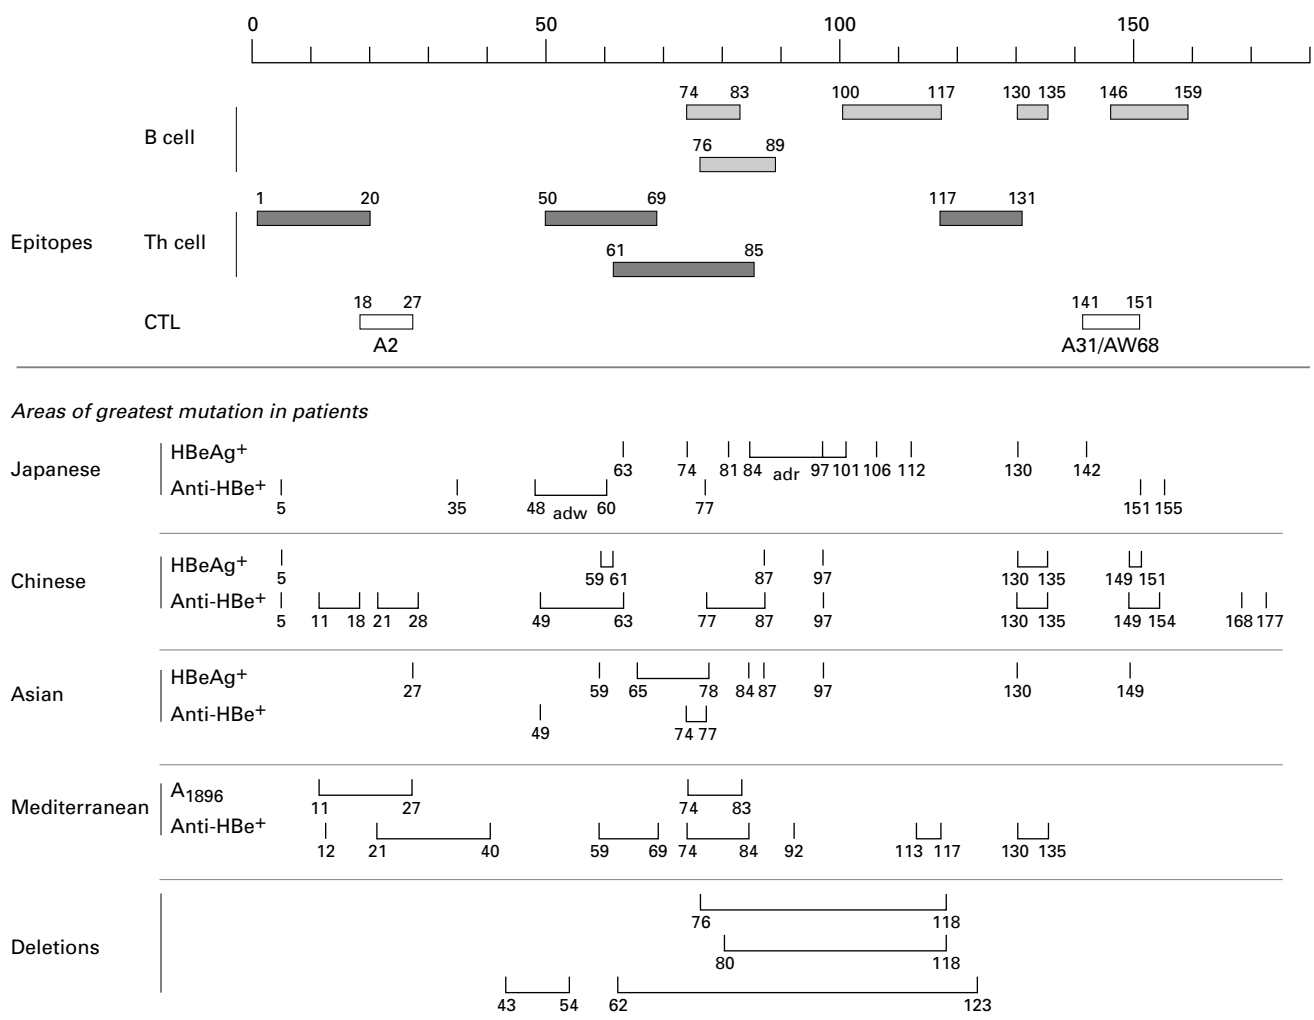

**Figure 15.5** HBcAg variability correlated with immunologic epitopes. The Th, B-cell and CTL epitopes are shown above. Below are shown areas of greatest variability highlighted by the authors or, if not provided, our subjective interpretation. Note that there is little consistency in these results. This may reflect methodological differences such as clinical parameters and a variable definition of consensus sequences against which results are compared, as well as ethnic and HLA profiles of the patients. Alternatively, it may simply be that there is no correlation. Deletions are also indicated; note that they cluster around the middle of the protein.

be in frame, resulting in the production of truncated core species, or out of frame, terminating core synthesis prematurely. There is experimental evidence to suggest that deletion variants are unable to produce capsids or that any capsids formed are unstable. Such variants therefore co-exist with the wild-type virus that provides the core protein for their encapsidation.[155,183,184] In view of this, the suggestion has been put forward that these deletion variants may act as defective interfering particles, involved in a cyclic interference-and-enrichment phenomenon between the variants and the wild-type.[183–186] Core deletion variants have been reported both in immunocompetent[181,187] and immunosuppressed individuals.[180,188] In the former individuals, the detection of core internal deletion variants was associated with lower levels of viraemia and early seroconversion to anti-HBe, with concurrent disappearance of the variants.[181,187] In contrast, in long-term immunosuppressed patients following kidney, or even liver transplantation, the presence of deletion variants was associated with increased risk of developing liver cirrhosis and end-stage liver disease.[180,187] Why this should be the case remains unanswered. It has been suggested that internally deleted core variants may represent immune escape variants, particularly if they are lacking the region containing the main B-cell epitope. It should be pointed out that core internal deletion variants have also been described in the woodchuck animal model.[189,190]

Two further types of genetic variant exist. The first is a 36-bp insertion found around and including the core ATG associated with A1896.[30,142] It was initially seen in an HIV-infected patient and a carrier treated with inter-

feron (IFN). These are likely to be isolates of the newly described genotype G of the virus. Isolates of this genotype have a stop codon at codon positions 2 and 28 of the precore, and a 36 nucleotide insertion at the N-terminal end of core.[191] It has also been observed that this genotype may co-exist with genotype A, which explains the HBeAg positivity in such patients, in spite of the presence of the precore stop codon mutation.[192] However, little is known about the pathogenicity of genotype G, as its detection worldwide remains quite low at present.

The second type of genetic variant is an abnormal spliced mRNA species that may play a role in disease progression.[193,194] This singly spliced 2.2-kb RNA leads to the secretion of defective particles, which are more common in those with chronic hepatitis. After transfection, HBcAg accumulated in cells and increased amounts of HBeAg were secreted.

## Mechanisms of emergence of variants

The major issue in explaining the origin of A1896, the BCP and all other variants that lead to diminished production or absence of HBeAg, is whether such strains have a survival advantage over HBeAg-producing ones. If they do, the implication is that they will eventually become dominant. In addition, if these variants do cause more severe liver disease, then these findings would give cause for concern. T1762/A1764 and/or A1896 strains appear to have become dominant in Mediterranean countries (measured as new presentations to liver clinics) and the Far East, but this could be because these patients present later than those with HBeAg-producing strains, and there has been a general reduction in new HBV cases across the world, as a result of effective vaccination programmes.

There is growing evidence that a vigorous and efficient polyclonal class I restricted CD8+ CTL and class II restricted CD4+ T-helper response to HBV proteins is necessary for recovery from acute symptomatic infection.[51,195,196] A strong and multi-specific response against epitopes from core, polymerase and envelope proteins is critical for a successful outcome during the acute phase of HBV infection and in recovery.[197–201] Such responses persist in recovered individuals, probably as a result of continued CTL activation in the presence of low levels of viraemia, which they continue to keep under control.[202] More recently, it has been shown that HBV replication within hepatocytes can be inhibited by antiviral cytokines without the requirement of hepatocyte lysis.[203,204] The absence of similar responses in patients with chronic hepatitis almost certainly contributes to viral persistence. CTL responses are of low frequency in such patients, they have a narrow repertoire and although insufficient to clear the virus, they contribute to the inflammatory picture seen in liver biopsies.[162,205–207] Failure of antigen presentation to CD4+ helper T cells,[208] failure of such cells to proliferate,[209] immune modulation by secreted proteins,[10,11] viral mutation and integration of viral DNA into the cellular genome[52] may all be contributory factors. The CTL response in chronic carriers seroconverting to anti-HBe naturally or after IFN therapy, has been shown to be similar in strength to that seen during acute hepatitis.[50,210,211] This indicates that immune responses against HBV can recover under the appropriate conditions. The above described findings have in recent years been confirmed and extended using more sensitive assays than chromium release, such as ELISPOT and tetramer technology.[212–216]

It is generally accepted that the natural history of chronic HBV infection goes through at least three phases. These are the immune tolerance and immune clearance phases when the patient is HBeAg-positive, and the low replicative phase following seroconversion to anti-HBe.[40] This latter phase, in view of what has been described above, can in a subgroup of patients be followed by a replicative/reactivation phase, characterized by the emergence of variant viruses.[56] The immunological events that lead to the predominance of the variants and suppression or clearance of the wild-type virus are not clear, but one can speculate on the possible mechanisms that may be involved. The immune clearance phase is characterized by reduced HBeAg and fluctuating but progressively diminishing HBV DNA levels, which are followed by increasing transaminase levels and seroconversion to anti-HBe. It is suggested that HBeAg is the most significant factor in tolerizing the immune system to the presence of high levels of replication during the tolerant phase.[11,217] Moreover, HBeAg has been shown to elicit a Th-2-like immune response[12] while downregulating Th-1 responses by inducing apoptosis of the effector cells.[217] Diminishing levels of HBeAg therefore lead to progressive breakage of tolerance. In addition, the intracellular distribution of HBcAg shifting from nuclear to cytoplasmic, followed by membrane display of core peptides, may result in CTL attack.[218] It has been shown that some variants of the nuclear localization region, found in natural isolates as well as those generated *in vitro*, lead to redistribution to the cytoplasm after expression *in vitro*.[219] Hepatocytes harbouring the wild-type virus come increasingly under attack and are destroyed, and the immune system contains any residual replication. At this time HBV DNA is detectable only by very sensitive techniques, such as real-time PCR. Hepatocytes containing pre-existing variants or variants arising during the non-replicative phase, escape immune recognition.[220–222] Thus, during this phase the number of patients carrying detectable variants increases significantly. Why they do so remains unknown, but one contributing factor may be low level expression of viral proteins, but also accumulation of mutations within critical epitopes that allow

the infected cell to escape lysis by CTLs. It appears that in some patients this may be the case,[162,171,177,223] while in others, mutations do not occur with each flare, at least in HBcAg.[172] Some may have transient variants that may attract immune attention and then be cleared.[171] Whether anti-HBe plays a role in antibody-dependent cell cytotoxicity during this period is not fully known, but is a possibility,[224] as HBeAg can be expressed on the cell surface.[225] These events would undoubtedly favour the elimination of HBeAg-expressing hepatocytes. During this period mixtures of variants and wild-type virus are detectable at very low levels.[23]

In many patients, the low replicative phase may last for years. HBV DNA is absent or barely detectable during this time, histological examination shows minimal changes in the liver and as a result transaminase levels are normal or barely raised. These patients are the asymptomatic or normal carriers.[226,227] However, in some patients the low replicative phase is followed by HBV reactivation, immune-mediated liver cell injury and increases in transaminase levels. Such patients appear to be seen in clinics more frequently in recent years.[228–230] These reactivation episodes may occur at frequent intervals and may be accompanied by increases in IgM anti-HBc levels.[171] During these cycles of reactivation the immune system exercises control of the wild-type virus. It has been shown that antigen-presenting cells infected with HBeAg-expressing constructs but not those infected with HBcAg were able to stimulate HBcAg/HBeAg-specific CD4(+) T-cell clones.[231,232] Therefore, HBcAg-expressing cells may be spared, allowing the dominance of HBeAg-negative variants. By this stage the precore stop codon appears even in strains carrying the BCP double mutation. Moreover, additional mutations may appear in the core region, some of which are in well recognized B- and T-cell epitopes,[171,187,233] or may affect areas that influence intracellular localization such as the carboxy-terminus.[100,50,168] Interestingly, patients who exhibit a more severe form of HBV infection such as FHB[122,150] or who have had liver transplants can have several mutations in the carboxy-terminus of HBcAg. In mice transgenic for HBV replication, CTLs can clear active infection by a post-transcriptional mechanism mediated by IFN-γ and tumour necrosis factor-α (TNF-α).[76] If cytokines prove to exert as strong an antiviral effect in natural HBV infection as is observed in the transgenic mouse model, investigation of this area may prove fruitful in explaining viral persistence and ongoing disease.

## HBeAg-negative variants and treatment

### *Interferon*

Therapeutic interferon (IFN), while inducing an antiviral state, is also believed to amplify immune activity against infected hepatocytes, perhaps by enhancing MHC expression, thus facilitating presentation of peptides to CTL. HBeAg-positive patients who respond to IFN already have evidence of immune activity, as shown by raised transaminases and relatively low levels of HBV DNA. Patients at this stage may have minor populations of HBeAg-negative variants present. One small study showed that those with precore mutants in the HBeAg-positive stage are more likely to respond to IFN,[234] although this was not confirmed in two other studies,[235,236] which showed no precore variant in HBeAg-positive patients before seroconversion, whether they responded to IFN or not. In other studies, however, where HBeAg-positive patients were investigated for both the precore and BCP mutations, such patients responded better to IFN in the presence of these mutations.[127,237,238] Others have found low frequency of mutations in the BCP region in HBeAg-positive patients and of little help in predicting IFN response,[239] while one other study indicated that HBeAg-positive patients responding to IFN had a high number of mutations in the BCP region in contrast to anti-HBe-positive patients who had a low number.[240] Anti-HBe$^-$, HBV DNA-positive Mediterranean patients with chronic hepatitis often respond poorly to IFN therapy[36,241] and if they do respond, they tend to relapse.[242–245] Interestingly, T1856-containing strains may respond poorly to IFN,[246] compared with A1896 or G1896/C1856 strains, but this remains to be confirmed. In keeping with this is the observation that anti-HBe-positive patients with C1858 (which is often associated with T1856) have more inflammation and fibrosis than those with A1896.[46] A wide variety of stop codons, non-functional start codons and amino acid substitutions arise in HBeAg-positive cases who respond to IFN therapy.[247] One study[235] also compared the frequency of selection of mutants after successful IFN therapy with natural seroconversion to anti-HBe. There was a trend towards less frequent and slower emergence of mutants in those who seroconverted during IFN therapy. Sequence variability of HBcAg is greatest in anti-HBe-positive non-responder patients.[235] These substitutions were greatest in the 'promiscuous' Th epitope between amino acids 50 and 69. This concept was supported by the finding that variability in the HLA-A2 CTL epitope was greatest in IFN non-responders.[249] However, no correlation was found by another group in Chinese patients.[169]

### *Lamivudine*

Lamivudine, a nucleoside analogue, has also been used for the treatment of anti-HBe-positive patients with HBV variants carrying the BCP and precore mutations. Such patients respond well whilst on treatment, with 65–96% showing normalization in ALT levels and loss of HBV DNA. However, on stopping therapy the major-

ity relapse and sustained response rates range between 10% and 15%.[245] Treatment for periods longer than 1 year achieves higher rates of sustained response (40%), but the patients run the risk of developing lamivudine-resistant variants. It has been established that lamivudine treatment results in the replacement of the BCP and precore variants by the wild-type virus albeit at low titres, and during prolonged treatment the variants reappear.[249–251] In HBeAg-positive patients carrying genotype C, the presence of BCP/precore mutations was independently associated with HBeAg loss. Moreover, this occurred earlier in the presence of variant isolates than the wild-type virus.[252]

### Precore variants: detection methods

As sequencing can be time-consuming, various approaches have been tried to screen PCR products for A1896. Hybridization with oligoprobes has met with success[253] and has been applied to clinical material to assess the relative importance of mutants to clinical severity.[254] Alternatives are to use a common primer at one end of the DNA of interest and a second that contains either a G or an A at the 3′ end,[70] which has been applied to paraffin-fixed sections, single-labelled nucleotide (G or A) addition to a primer that ends either at 1895 or 1897[255] and digestion of PCR products that have been generated with primers incorporating novel restriction sites.[53] However, none of these are as comprehensive as sequencing. Recently, a line probe assay has been released by Inno-Lipa for the detection of the precore and BCP mutations, as well as HBV genotypes. This has so far proved to be rapid, sensitive and reliable.[256]

## Conclusion

HBV is highly evolved. It has a small and compact genome that makes very efficient use of its nucleotide sequence. Many regions are highly conserved, even between different hepadnaviruses. Yet the potential for significant change is also present. The interaction between HBV and its host is complex. The precore/core gene and BCP variants have been described in detail but why such variants arise is still not clear. Their appearance, however, heralds the beginnings of the seroconversion phase from HBeAg to anti-HBe. Whatever the nature of the variant, the end result is the reduction or abrogation of HBeAg production. The removal of the tolerogenic effect of this soluble serum protein leads to the 'awakening' of the immune response. However, the mechanisms of selection of the variants and clearance, or downturn of wild-type virus production, remain to be defined. Equally undefined are the determinants of active liver disease once the variants are selected. There may be an interplay between host genetic make-up and further virus variation within the core protein, for example, and possibly other viral proteins. These variants are increasingly recognized as independent lineages of HBV, as markers of variation elsewhere in the genome and of clinical relevance. These variants are associated with fulminant hepatitis but host factors are also necessary. Resolution of these issues is still hampered by the absence of a reliable and robust cell culture system. Moreover, the use of cloned material in transfection studies, a lot of the time using described genomic mutations out of the genetic background in which they are found, has caused additional confusion. Undoubtedly, we still have some way to go in identifying those genomic mutations that are important and are clinically relevant.

# Chapter 16
# Natural history of chronic hepatitis B and hepatocellular carcinoma

Massimo Colombo, Pietro Lampertico

Approximately 350 million people have chronic hepatitis B virus (HBV) infection, which may present as typical hepatitis B e antigen (HBeAg)-positive chronic hepatitis B or as HBeAg-negative infection.

HBV is classified into four serotypes (adr, adw, ayr and ayw) based on antigenic determinants of the surface antigen: prevalence of these subtypes varies in different parts of the world. Based on an intergroup divergence of 8% in the nucleotide sequence, HBV can be classified into seven genotypes, A–G: prevalence of these genotypes again varies in different parts of the world. The most common precore mutation, a G to A substitution at nucleotide 1896, common among HBeAg-negative patients,[1] is found in association with genotypes B, C and D but not genotype A, thus explaining the prevalence of HBeAg-negative chronic hepatitis B in southern Europe and Asia.[2]

Studies of naturally infected humans established the existence of acute and chronic infections with varying degrees of liver damage and the existence of a linkage between HBV infection and hepatocellular carcinoma (HCC).

Further understanding of the natural history of hepatitis B would not have been possible without the contribution of animal models. Chimpanzee inoculation studies demonstrated the infectivity of cloned HBV DNA.[3] In similar experiments, inflammatory changes in the liver, resembling those of viral hepatitis B, were observed in adult rats injected with HBV DNA directly into the liver.[4]

Studies in transgenic mice have led to the hypothesis that HBV may be directly cytotoxic to the liver in the presence of overproduction of HBV envelope polypeptides.[5]

Many intriguing aspects of the natural history of HBV await discovery. One such aspect is the many cases with 'occult' HBV infection that can be detected by studies with the polymerase chain reaction (PCR) technique. There is a low level of HBV replication in a variety of clinical conditions, including in individuals who lack all serological markers of HBV infection. However, it is still unclear whether occult HBV infection causes progressive damage to the liver or is an innocent bystander.[6]

## Natural history of infection

The clinical spectrum of chronic HBV infection ranges from asymptomatic HBsAg carriage with normal hepatic function and histology, to chronic hepatitis with varying degrees of histological severity, to cirrhosis and its complications. HBV infection is a dynamic process characterized by high and low replicative phases controlled by the host immune response. The outcome of HBV infection is largely influenced by the age at which infection is acquired, the integrity of the host's immune response and exposure to environmental co-factors.

### HBeAg-positive patients

See Table 16.1.[7–19] Chronic infection with HBV is more frequent in men than in women, in neonates than in adults (90% versus 5%) and in immunocompromised patients than in immunocompetent ones.[8] The risk of chronicity declines from 60% during the second year of life to 10% by 6 years of age.[7]

HBV infection acquired in the neonatal/perinatal period is characterized by a prolonged immunotolerant phase, normal or near-normal alanine aminotransferase (ALT) levels and a low rate of spontaneous HBeAg clearance.[20] The initial immunotolerant phase with serum HBeAg and high levels of serum HBV DNA is followed by the immunoactive phase, characterized by a decrease in serum HBV DNA and increase of serum ALT levels.[9] Most patients will seroconvert to anti-HBe with remission of liver disease: a significant number of these anti-HBe-positive patients will show hepatitis reactivation; others will proceed to an inactive HBsAg carrier state; a few will have hepatitis resolved with loss of HBsAg and anti-HBs seroconversion. In contrast, patients who acquire HBV during adolescence or adulthood and

become chronic carriers usually present in the immunoactive phase with active liver disease.

HBeAg seropositive patients with replicating HBV display various degrees of liver damage, from benign forms of chronic lobular hepatitis to more severe forms of active cirrhosis and HCC. Chronic active hepatitis is the result of persistent HBV replication eliciting host immune attacks on infected liver cells, and in most cases it subsides when virus replication is terminated and seroconversion to anti-HBe takes place.[6] For 70 adult Italian patients, the annual rate of HBeAg/anti-HBe seroconversion and disease remission was 16%.[11] Clearance of serum HBeAg in Chinese children is much slower: none of 11 children developed anti-HBe in a 2-year period.[9] Instead, in a 5-year period, 70% of 76 Italian children seroconverted to anti-HBe, cleared HBV DNA, and remained with persistently normal ALT values.[10] In no case was there reactivation of HBV after spontaneous anti-HBe seroconversion, suggesting that these children had become healthy carriers. Termination of HBV replication and clearance of HBeAg and HBV DNA were observed in 45 (51%) of 88 adult Italian patients followed for a mean of 5 years.[14] Although this event was accompanied by clinical, biochemical and histological remission of disease, during a 5-year follow-up 10 (22%) patients had transient spontaneous reactivation of HBV infection and exacerbation of disease. Thus, at variance with infantile HBV infections, seroconversion from HBeAg to anti-HBe during adulthood is not always stable. In two adult patients, HBV reactivation led to deterioration of the underlying liver disease from chronic active hepatitis to active cirrhosis. Similar studies with similar results were carried out in Chinese patients by Tong *et al*.[21] and Lok *et al*.[9] Reactivation of a latent HBV infection was a frequent event in immunocompromised patients infected with human immunodeficiency virus (HIV),[22] homosexuals[23] and patients treated with immunosuppressive agents.[24] In immunocompetent patients, the probability of clearing HBeAg within 5–10 years of diagnosis is about 50%.[10–13]

Seroconversion to anti-HBe is paralleled by exacerbation of hepatitis as a result of immune-mediated liver cell necrosis and progressive clearance of infected hepatocytes and serum HBV DNA ('inactive HBsAg' carriers). After seroconversion to anti-HBe, inactive carriers show long-term non-replicating latent HBV infection as a result of integration of the HBsAg coding for viral DNA into the liver cell genome. The condition of healthy carriers is clinically a long-term benign situation. A prospective cohort study of 92 Italian healthy carriers showed that the prognosis for these subjects was excellent, with a low risk of developing cirrhosis or HCC over 10 years.[25] Similar results were obtained in a prospective study of 317 asymptomatic HBsAg carriers from the Montreal area who were examined after 16 years of follow-up.[26] Three carriers had died of HBV-related cirrhosis, one of alcoholic cirrhosis and nine of causes unrelated to liver disease. No carrier had died of HCC. Determinants of HBeAg seroconversion include female sex, advanced age, ALT levels higher than five times the upper normal limit and severity of histological damage and genotype B of HBV.

### *Severity of the disease*

Persistent HBV replication is instrumental in the progression of the disease to cirrhosis and HCC. The prognosis for infected patients depends on the histological stage of the liver disease. Of 105 Italian patients who were followed prospectively for a mean of 5 years, 34%

of the patients with detectable amounts of serum HBV DNA developed cirrhosis, but only 15% of those without serum HBV DNA detectable by dot-blot technique.[15] In these patients, bridging hepatic necrosis was the histological feature predictive of cirrhosis. In a prospective study of 509 Chinese patients with chronic hepatitis B, cirrhosis developed within 6–64 months after entry in 35 patients, with a calculated annual rate of 2.4%.[16] The incidence of cirrhosis was significantly increased with increasing age at entry, in patients with repeated episodes of hepatitis exacerbation without anti-HBe seroconversion. In an 8-year prospective study in Düsseldorf of 53 patients with chronic infection,[19] 13 developed severe clinical complications without eliminating serum HBeAg. Ascites developed in two patients; jaundice and encephalopathy in one; jaundice, encephalopathy and oesophageal varices in one. Four patients had only oesophageal varices, and bleeding from the varices occurred in three of them during follow-up. Four patients died and one required liver transplantation.

### *Survival*

In 379 patients in the United States who had chronic hepatitis B, the 5-year survival rate was 97% for patients with mild forms of hepatitis, 86% for those with chronic active hepatitis, and only 66% for patients with cirrhosis.[17] In a German study of 53 patients with chronic HBeAg infection, four patients died and one required liver transplantation during a mean follow-up of 38 months. Survival without clinical complications was longer for the patients who spontaneously cleared HBeAg than for those who did not ($p = 0.006$).[19] The overall probability of survival for 43 Dutch patients with compensated cirrhosis was 72% at 5 years.[18] The variables significantly associated with the length of survival were age, serum AST levels, presence of oesophageal varices and the Child-Pugh scores. Multivariate analysis revealed that only age, bilirubin and ascites were independently associated with survival. As expected, the 5-year survival rate of patients with decompensated cirrhosis, determined by the presence of ascites, jaundice, encephalopathy and oesophageal bleeding, was much shorter than that of patients with compensated cirrhosis (14% versus 84%). Both compensated and decompensated HBeAg-positive patients survived for less time than the HBeAg-negative patients with cirrhosis. In a multicentre study, the calculated 10-year survival of 126 European patients was 68%.[27] Clearance of serum HBeAg during follow-up occurred in 64 patients and was more common in the 92 survivors than in the 24 who died (65% versus 17%, $p < 0.001$). Thus, once more, termination of virus replication during follow-up was correlated with better survival.

Despite specific immunoprophylaxis, recurrence of hepatitis B is a well-documented complication of post-transplantation HBV liver disease.[28] HBV almost invariably recurred in patients with serum HBV DNA, with massive virus load and a tendency to hepatitis with progressive fibrosis. The time lag between transplantation and recurrence of hepatitis was 41–307 days, and the short-term mortality rate of the recipients because of liver failure was 27%.[29]

## HBeAg-negative patients

See Table 16.2.[16,18,27,30] Approximately 5% of patients undergoing HBeAg seroconversion may continue to show increase in serum ALT and high levels of HBV DNA. These patients and those undergoing hepatitis reactivation after HBeAg seroconversion constitute the group of patients with HBeAg-negative chronic hepatitis B.

Virus heterogeneity is another important factor in the natural history of HBV infection. Genotypic variants of HBV were originally identified in an interesting group of already anti-HBe-positive patients who had serum HBV DNA measurable by dot-blot hybridization.[31–33] The more common genetic defect was a point mutation in the precore region of the HBV genome, generating an in frame stop codon at nucleotide 1896, which prevented the secretion of the HBeAg product of the nucleocapsid gene.[1] However, there were many other possible sites for mutation of an in frame stop codon.[34] Precore variants were not present as major species in the HBeAg phase of hepatitis, but emerged during or some time after seroconversion to anti-HBe. Immediately after seroconversion, a mixture of strains was present, but with time the wild-type became lost.[35] This selection process occurred in patients with both acute and chronic liver disease.

Chronic hepatitis B with anti-HBe in serum differs from chronic hepatitis B with HBeAg in terms of natural history. Its specific feature is the high frequency of spontaneous remissions followed by hepatitis exacerbations.[36] Latent replicative intermediates of precore variants are present in the livers of the patients during remission phases of the chronic liver disease and may pose problems of differential diagnosis with inactive HBsAg carrier state.[37] However, these apparently inactive reservoirs of mutant HBV strains may predispose to bouts of virus reactivation and worsening of the disease. It is not clear whether precore variants are the cause of

**Table 16.2** The natural history of Anti-HBe infection

severe liver disease *per se* or whether genetic mutations arise because of a successful response against HBeAg.

### *Severity of the disease*

One intriguing aspect is the varying degree of severity of liver disease observed in these patients, which seems to follow a geographical pattern.[38] In northern Europe and the United States, mutant strains occur rarely in hepatitis B, but were constantly detected in patients with fulminant hepatitis.[39] In Asia, precore variants were never detected in patients with self-limited resolving hepatitis.[40] Interestingly, they have been found in 18 carriers, unrelated to the severity of the underlying disease, including healthy carriers.[34] In 39 Bulgarian patients with chronic hepatitis B, severe liver disease was more common in patients with predominantly precore variants infection and high levels of viraemia.[41] The same was true for 23 Italian patients who were monitored for 8 years. Of the 20 patients with initial diagnoses of chronic hepatitis, seven were found to have cirrhosis at the end of the follow-up period.

In a prospective study of 175 Chinese patients, the calculated annual incidence of cirrhosis was similar to that (2.4%) found in 509 patients with HBeAg infection.[16] Like HBeAg cirrhosis, the incidence of cirrhosis in patients with anti-HBe chronic hepatitis B was correlated closely with the patient's age and frequency of acute exacerbations with HBeAg reactivation.

In a multicentre European study, the 10-year probability of patients with anti-HBe cirrhosis remaining compensated was 63%, indicating that hepatic decompensation usually occurs at a late stage in the clinical course of the disease. [30] During a mean follow-up period of 6 years, HCC developed in 9% of the 349 patients with compensated cirrhosis. By multivariate analysis, age, serum levels of platelets and liver firmness on physical examination were independent predictors of HCC. In our centre, HCC developed in 6 of 57 patients with anti-HBe cirrhosis who were monitored prospectively for 10 years (mean follow-up, 81 months). The yearly incidence of tumour was approximately 1%. During the 10-year follow-up period, eight patients (13%) developed complications other than HCC: four developed jaundice, two developed ascites and two bled from oesophageal varices.

### *Survival*

For 44 patients with compensated cirrhosis, the 5-year survival rate was 97%, compared with 72% for the 54 HBeAg-positive patients.[18] In a multicentre study, the 10-year survival rate of 240 European patients with anti-HBe-positive cirrhosis was 68%.[27] In Milan, the 10-year survival rate of a cohort of 57 patients with anti-HBe-positive cirrhosis and no signs of HCC who were monitored prospectively was 82%. Discrepancies in the survival rates between these studies could be accounted for by different criteria of patient recruitment and follow-up.

## Natural history of HCC

HBV-related HCC is the predominant cause of cancer mortality in Africa and China. Epidemiological and molecular epidemiology studies have disclosed that dietary exposure to aflatoxin is a synergistic risk factor for HBV-related HCC in these geographical areas.[42] There is also evidence that co-infection with hepatitis C virus (HCV) and heavy alcohol consumption increase the risk of developing HCC in HBV hyperendemic areas. In a prospective study of 11 893 men in Taiwan (2359 HBsAg-positive) Yang *et al*.[43] demonstrated 1169 cases of HCC for 100 000 person-years among the HBeAg carriers compared with 324 cases for the HBeAg-negative carriers and 39 cases for the HBsAg-negative subjects. After adjustment for age, sex, hepatitis C, tobacco smoking and alcohol abuse, the relative risk of HCC was 60.2 for HBeAg-positive carriers and 9.6 for HBeAg-negative carriers compared to HBsAg-negative subjects. This study clearly established that in areas hyperendemic for HBV, HCC may develop prior to seroconversion to anti-HBe, probably as a result of continuous or recurrent cycles of liver cell necrosis and proliferation. It is, in fact, well established that the inflamed liver is a mitogenic and mutagenic environment.[44] The same holds true for patients with HBeAg-negative infection who develop HCC. Most information on growth patterns and doubling volume times of HCC and of patients' survival comes from studies of patients with tumours of miscellaneous aetiologies or with predominantly HCV-related disease. With few exceptions, HCC is a slowly developing disease. One such exception is HCC among African black people, which is mostly associated with chronic infection with HBV and exposure to aflatoxin. This tumour, in fact, is quite different clinically and histopathologically from the slow-growing tumours seen in Japan and the Mediterranean basin, which are more often associated with infection with HCV. The most impressive difference noted between HBV-related tumours and HCV-related tumours in both the Western and Eastern hemispheres was that the patients with the former tumours were 10 years younger than those with HCV-related disease.[45,46] Differences in the epidemiology and age of infection with these two viruses could account for the observed discrepancies between HBV- and HCV-related tumours. HCCs developing after HCV infection have been reported to occur in patients with more severe histological features of liver disease than tumours developing after HBV infection.[47,48] In a 10-year prospec-

tive study of 57 patients with compensated HBV cirrhosis at our centre, six developed HCC that was unifocal in three and multifocal in the other three. In 175 Japanese patients who had undergone hepatic resection, HCCs in HCV-positive patients showed a higher incidence of multicentricity than those in HBsAg-positive patients (14% versus 0, $p < 0.05$).[49] In a retrospective clinicopathological study of 113 non-alcoholic Japanese patients with HCC, the HBsAg-negative patients, who were likely to be infected with HCV, more often had expanding-type tumours than the HBsAg-positive patients, who more often had infiltrative-type HCCs.[45] In a study in Japan, the 3-year survival rate for patients with HCV-related tumours was higher than that for patients with HBV-related tumours (68% versus 47%), implying that HBV-related disease was a faster process than the HCV-related cases.[46]

## Summary

The natural history of chronic hepatitis B depends largely on the age at which patients become infected, the integrity of the host's immunity, the interaction with environmental co-factors and the emergence of genetic variants of HBV. Chronic hepatitis caused by HBeAg-secreting strains is more common in men than in women and in neonates than in adults. Seroconversion to anti-HBe occurs less frequently in men and neonates than in women and adults. Hepatitis reactivation after anti-HBe seroconversion never occurs in children. The yearly rate in adults is 4.4%. The yearly incidence of cirrhosis is 2.4–7%, and the 5-year survival rate of patients with cirrhosis is 66–78%. In anti-HBe infection, the yearly rate for cirrhosis is similar to that in HBeAg-positive patients, and the rate of clinical decompensation is 3.7%. Approximately 1.5% of patients with cirrhosis develop HCC every year. The 5-year survival rate of patients with anti-HBe cirrhosis is higher than that of patients with HBeAg cirrhosis (97% versus 66%). The natural history of chronic hepatitis B is accelerated in the immunocompromised patient.

# Chapter 17
# Hepatocellular carcinoma: molecular aspects in hepatitis B

Marie Annick Buendia, Patricia Paterlini-Bréchot, Pierre Tiollais, Christian Bréchot

Hepatocellular carcinoma (HCC) is among the most common cancers in the world and one of the rare human cancers showing seroepidemiological association with viral infection. The role of hepatitis B virus (HBV) as a major aetiological agent of HCC has been firmly established, and the increased risk of developing HCC has been estimated to be 20–100-fold for chronic HBV carriers as compared with non-infected populations, placing HBV in the first rank among known human carcinogens.[1,2] Apart from epidemiological evidence, another factor linking HBV and liver cancer comes from related animal viruses, which with HBV form the hepadnavirus group and induce acute and chronic infections of the liver and eventually HCC (reviewed by Schödel *et al*.,[3] Buendia[4]). Whether HBV acts through any recognized oncogenic mechanism, either directly or indirectly, is an important unsolved question.

It is generally considered that HBV has no direct oncogenic or cytopathological effect on the infected hepatocyte. Malignant transformation occurs after a long period of chronic liver disease, frequently associated with cirrhosis, suggesting a non-specific mechanism triggered by the host immune response. Chronic inflammation of the liver, continuous cell death and consequent cell proliferation might increase the risk for cancer.[5] In a more specific pathway, persistent production of viral proteins might interfere with endogenous metabolic processes and sensitize liver cells to endogenous or exogenous mutagens. This notion is supported by transgenic mouse models in which unregulated expression of the viral X-protein, a promiscuous transcriptional activator, or that of the large surface protein are associated with hepatocarcinogenesis.[6,7] Alternatively, the virus might play a direct role as an insertional mutagen. Integration of viral DNA into the host genome might cause direct activation of cancer-related genes or secondary chromosomal alterations. Such a role has been suggested by the repeated finding of integrated viral sequences in the cellular DNA of HBV-associated HCC. Indeed, viral integration in nearby potential oncogenes has been described in an increasing number of HCC cases,[8–12] and genetic instability resulting from viral integration events has been documented. Integrated HBV sequences might also alter the host cell growth control in *trans*, through unregulated expression of native or modified viral proteins. All these potential mechanisms might not be mutually exclusive. To date, although information on risk factors causally linked to HCC has accumulated, the role of viral agents and carcinogenic co-factors is only partially elucidated, and no unifying model accounting for the contribution of viral and cellular factors to liver oncogenesis has been established.

In contrast, studies of naturally occurring models for HBV and liver cancer have outlined a predominant role of the *myc* oncogenes in hepatocarcinogenesis induced by rodent hepadnaviruses. Woodchuck hepatitis virus (WHV), a virus closely related to HBV, acts mainly as an insertional mutagen, activating *myc* family genes (c-*myc* and N-*myc*) in >90% of the woodchuck tumours analyzed.[13,14,16,16a] This virus represents the first example of a DNA virus producing insertional events at such a frequency. Another related virus, the ground squirrel hepatitis virus (GSHV), shows weaker oncogenic properties. Integration of GSHV DNA has not been implicated in the tumorigenic process in the natural host, but frequent amplifications of the c-*myc* oncogene have been described in squirrel tumours.[17] More recently, another related hepadnavirus was isolated from arctic ground squirrels in Alaska,[18] but the mechanisms of liver carcinogenesis in infected animals have not been identified so far. In human HCCs, there is no published evidence for a key role of activated *myc* genes, albeit amplification of c-*myc* has been occasionally described, suggesting a different transformation pathway. Whether these striking differences are related to viral determinants or to species-specific factors remains to be determined.

This chapter reviews the different mechanisms that may be implicated in the development of HBV-related HCC, with reference to naturally occurring animal models.

## Epidemiological association between HBV and HCC

Epidemiological research has contributed largely to the understanding of the aetiology of HCC. By the end of the 1970s, it became evident that chronic HBV infection was by far the major risk factor for liver cancer.[2] These conclusions stimulated the search for the molecular mechanisms linking HBV and HCC and pointed out the importance of vaccination against HBV infection as the appropriate strategy to prevent HCC. Other carcinogenic factors, such as exposure to dietary aflatoxins and excessive alcohol intake, have also been implicated in human hepatocarcinogenesis, and epidemiological data support a strong correlation between chronic infection with the human hepatitis C virus (HCV), cirrhosis and HCC.[19,19a]

Primary liver cancer (mostly HCC) ranks among the commonest cancers in many countries. A recent estimate indicates that HCC represents the fifth most common cancer of males, and the eighth most common cancer in females, with a total of 560 000 new cases each year, 83% of which occur in developing countries, and more than one-half in China alone.[21] Moreover, because of its very poor prognosis, HCC represents a leading cause of cancer death worldwide.[22]

Several lines of evidence associate chronic HBV infection with the development of HCC:

**1** The incidence of HCC and the prevalence of HBV serological markers follow the same general geographical pattern of distribution. HCC is common in regions where HBV is endemic, but comes far behind other types of cancer in regions where HBV infection is uncommon.[2,23–25]

**2** Serological evidence of HBV infection is detected in about 70% of HCC patients in Africa and more than 90% in mainland China, as compared with 10–20% of the total population residing in the same areas.[24] In regions of low endemicity such as Western countries, chronic HBV carriers still represent 16–19% of HCC patients.[26,27]

**3** A marked increased risk of HCC has been shown among hepatitis B surface antigen (HBsAg) carriers compared with non-carriers (up to 100 risk factors have been reported in different ethnic or social groups using different methodologies of investigations). [30,31,31a]

A long period of chronic HBV infection generally precedes the onset of liver tumours, but less frequently, HCC may also affect HBsAg-positive children under 12 years of age. In contrast, a large number of HBsAg carriers remain unaware of their carrier status before they die at an old age.[28] In the Far East, early detection of HCC is now frequent in asymptomatic carriers.[32,33] Epidemiological data have shown not only that HBV is causally related to HCC, but also that there is a great variation in HCC incidence among different carrier populations. This variation may be attributed both to differences in the intrinsic properties of HBV infection patterns observed among chronic carriers and to additional genetic and environmental determinants.

Chronic infections resulting from maternal–neonatal transmission present a greater risk of HCC than those acquired as adults, probably reflecting differences in the incubation time (Fig. 17.1). Among HBsAg carriers infected at an early age, an additional HCC risk has been associated with HBeAg carriage,[34] with significant liver damage and high level of anti-HBsAg antibodies in chronic active hepatitis, and with the presence of cirrhosis. A gender discrepancy (males have a twofold to eightfold elevated risk of developing HCC compared with females) and familial tendency (familial clusters of HCC are common in Asia) have also been documented as factors involved in the frequency of tumour development.[33,35]

In addition, inconsistent geographical variations in HCC mortality and HBsAg prevalence have been observed in endemic regions, suggesting that other inde-

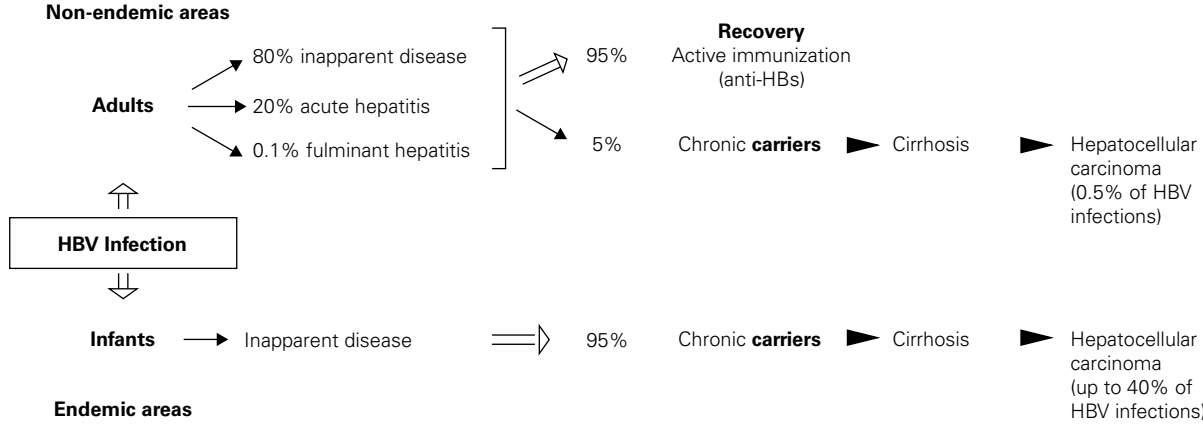

**Figure 17.1** Epidemiological association between HBV and HCC. Description of HBV transmission, progression to chronicity, and HCC incidence in endemic and non-endemic countries.

pendent or cooperative factors might be implicated. In highly endemic regions, particularly in South Africa and in southern provinces of mainland China, an association of dietary aflatoxins, notably aflatoxin B1 (AFB1) and HCC has been recognized in several reports, and synergistic effects of AFB1 and HBV infection have been pointed out.[25,36,37] The carcinogenic potential of aflatoxin $B_1$ in liver cells is well known in many species, and its effects in inducing p53 gene mutations are discussed later. Excessive alcohol intake also increases the risk of HCC in HBV carriers, as well as in cirrhotic men at advanced ages in regions of low prevalence for HBV.[38] However, the co-existence of HBV infection, often undetectable by conventional serological assays, and/or of HCV infection in >90% of alcoholic patients from various countries, has called into question the prevalence of chronic hepatitis induced by alcohol in the absence of viral infection.[39,40] The potential role of cigarette smoking and of long-term use of oral contraceptives is still debated.[38,41] Diabetes mellitus (DM) has been reported to increase the risk of HCC in the presence of other risk factors such as hepatitis C, hepatitis B or alcoholic cirrhosis.[42] In addition, infection with the human hepatitis D virus (HDV), which causes extremely severe hepatic injury and cirrhosis, might be associated with a more rapid onset of liver tumours.[43]

It is important to point out that HBV infection, alone or in association with co-factors, can be implicated only in <20% of HCC cases in low endemic regions such as North America, Europe and Japan. In these countries, the incidence of liver cancer has been continuously increasing during the last decade,[20] but the number of cases related to HBV was in slight decrease. It has been shown that infection with HCV, a human RNA virus related to Flaviviridae and Pestiviridae, plays an increasing part in the development of HCC in these regions, as well as in countries highly endemic for HBV (e.g. China). With the development of HCV markers, epidemiological evidence has been provided of an association between HCV infection, cirrhosis and HCC.[44–46] Liver cirrhosis is generally considered as a preneoplastic condition, but the relationship between cirrhosis and HCC appears to be complex, and the degree of correlation varies with aetiology of cirrhosis. Macronodular cirrhosis precedes or accompanies a majority of HBV- and HCV-associated HCCs (>80% in Asia and 40–60% in Africa) in adults as well as children. In contrast, the risk of HCC has been considered to be lower in HBsAg-negative micronodular cirrhosis observed in alcoholics.[28–30]

## The HBV genome

Since the earliest studies of the genetic organization of HBV and of the viral replication by reverse transcription of an RNA intermediate, there has been constant interest in the unique properties of HBVs. Virological and molecular studies have outlined the structural organization of the HBV genome, its coding potential, the mode of transcription of individual viral genes, and their functional capacities. The main aspects of viral DNA replication and virion assembly within infected hepatocytes have been unravelled (reviewed by Fourel and Tiollais[47]). Less is known about the viral–cellular interactions that control virus attachment, uncoating and entry into susceptible cells, and the cell-surface receptor for HBV has not been identified.

Nucleotide and deduced amino acid sequences of cloned HBV DNA from different virus subtypes (adw, adr, ayw, ayr) have revealed a genome size of 3.2 kb and the presence of four open reading frames (ORFs), localized on one viral strand in the same transcriptional orientation[48–50] (Fig. 17.2). The C and S regions specify structural proteins of the virion core and surface (or envelope). The longest one, P, encodes a polyprotein necessary for viral replication, which contains primase and replicase activities. The smallest, termed X, codes for a transcriptional transactivator. The entire viral genome is coding, and a large portion of the genome harbours two different reading frames. The overlapping of the P gene with the other viral genes is a feature common to

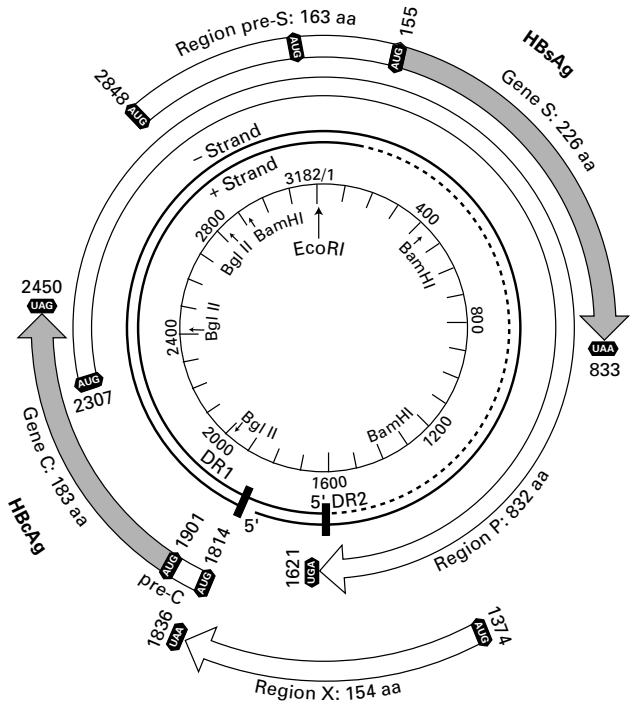

**Figure 17.2** Genetic organization of HBV. The inner cycle shows a restriction map of the *ayw* genome.[48] The partially double-stranded genome is represented as a thick line. Four open reading frames encoding seven peptides are indicated by large arrows. DR1 and DR2 are two directly repeated sequences located at the extremities of the viral DNA strands.

all structures presenting reverse transcriptase activity,[51] but the constant and unusual overlapping of coding and regulatory sequences (promoters, enhancers and termination signal) is more striking. The genomes of different HBV subtypes differ mainly by single nucleotide substitutions or by addition of multiples of three nucleotide blocks, preserving the reading frames and leading primarily to conservative amino acid changes. Genomic variability among viruses of the same subtype has been characterized in different patients and also in the same patient at different times during chronic infection.[52] These genetic variations can be attributed to errors during synthesis of the minus-strand DNA by reverse transcriptase, an enzyme that lacks polymerase-associated proofreading functions. A number of mutations in the pre-S/S region, in the pre-C/C region or in the core gene promoter lead to the outcome of HBV variants with modified immunological and pathological properties.[53–57] The most frequent mutations affecting the precore region inhibit the production of HBeAg and result generally in severe liver injury.[58–60] Defective viral particles carrying a deleted genome have been described,[61–64] showing that HBV shares with other viruses, notably with retroviruses, the property to develop defective variants in the natural host. However, there is no experimental evidence that free defective HBV genomes might present oncogenic properties, or that particular HBV subtypes might be more oncogenic than others.

Comparison of the HBV genome with those of animal hepadnaviruses reveals a basically identical genomic organization and extensive homologies at the nucleotide and amino acid levels. The best-conserved regions are located in the C and S genes and in the viral polymerase. The extent of homology is weaker in the pre-S1 region, which retains the same general conformation and hydrophobicity profile. The rather strict host range of the different hepadnaviruses suggests that the cellular receptor for these viruses, which has not been characterized, might be poorly conserved during evolution. Accordingly, viral sequences implicated in the interaction of the virion with the cellular membrane are located in the amino-terminal part of the pre-S1 domain,[65] a variable region among hepadnaviral genomes. Finally, the internal domain of the X-protein is the less conserved region among mammalian hepadnaviruses. This gene is missing in the avian hepadnaviruses. Two strong homology blocks in the amino- and carboxy-terminal parts of X might correspond to a conservative pressure for functional activity of the X transactivator, and of the viral RNase H encoded by carboxy-terminal P sequences that overlap with the 5′ end of X.[66–68]

The hepadnaviral genome, isolated from infectious extracellular virions, is made of two complementary DNA strands of different length, maintained in a circular configuration by base-pairing at their 5′ extremities.[69] The viral replication pathway, virtually identical for all hepadnaviruses, takes place in the nucleus and cytoplasm of infected cells, and although it can be instructively compared with the retroviral life-cycle, it is entirely extrachromosomal[69–71] (reviewed in Fourel and Tiollais[47]). Hepadnaviruses, like retroviruses and caulimoviruses, use a reverse transcription step during replication. Significant homologies between reverse transcriptases encoded by these viruses have suggested that they display a common evolutionary origin.

In productive hepadnavirus infections, a strict balance in the amount of individual viral gene products is necessary for active viral replication and release of infectious virions, as well as for survival of infected host cells. Despite the small size of the HBV genome and a very compact organization of coding sequences, the expression of the different viral genes is subjected to a complex regulation at various levels, both transcriptionally and post-transcriptionally. Each individual HBV gene is controlled by an independent set of regulatory signals, probably acting in cooperation with HBV elements that coordinate the relative level of viral gene expression. In chronically infected livers and in cell lines supporting active viral replication, two major HBV transcripts of molecular size 3.5 and 2.1 kb are produced from cccDNA template at roughly similar levels[72,73] and minor 3.9-, 2.4- and 0.8-kb transcripts have been described.[75–77] These polyadenylated RNAs direct the synthesis of seven viral proteins: the 3.5-kb species encode the core protein, the e antigen, and the polymerase; the 2.1-kb RNA encodes the middle and major surface glycoproteins, while the 2.4-kb RNA encodes the large surface protein; the viral X transactivator activity is specified by the 3.9- and 0.8-kb transcripts. The transcription patterns of WHV and GSHV in chronically infected livers are strikingly similar, whereas duck hepatitis B virus (DHBV) transcripts differ mainly by higher levels of 2.4kb RNA.[78–80] In the HBV genome, two enhancer elements stimulate transcription from the viral promoters: EN I, positioned about 450 by upstream of the core promoter, and EN II, located in the X gene-coding region.[81,82] Recent studies of the WHV, GSHV and DHBV enhancers have pointed to common liver specificity but significant evolutionary divergence among the hepadnavirus regulatory elements.[83–88]

## Oncogenic properties of viral proteins

It is generally considered that prolonged expression of viral genes may have no direct cytotoxic effects on the infected hepatocytes. Transfection of cultured cells with HBV DNA has not usually been associated with tumorigenic conversion, and most transgenic lines of mice bearing the full-length HBV genome or subgenomic constructs never show any sign of liver cell injury. However, studies, in particular experimental systems, have

indicated that abnormal overexpression of different viral proteins, including the X gene product and the surface proteins in native or modified forms, might play a part in malignant transformation of infected hepatocytes.

## The X transactivator

The smallest HBV ORF was initially designated X, because it was unclear at that time that it might encode a protein produced during HBV infection.[48] Examination of the nucleotide and amino acid sequences of HBx has led to the prediction of a regulatory function for the deduced X polypeptide and has revealed a codon usage similar to that used in eukaryotic cell genes, suggesting that X might have been transduced by the HBV genome.[89] The strong conservation of X sequences among HBV subtypes and the presence of homologous reading frames in the WHV and GSHV genomes suggest that their products may be of importance for viral replication.

Evidence for expression of the HBx gene was first obtained by Moriarty *et al*.[90] and by Kay *et al*.,[91] who reported that the sera of HBV-related HCC patients recognize synthetic peptides based on X sequences. Expression of the X reading frame in prokaryotic and eukaryotic cells, using various vectors, has allowed the identification of a 16.5-kDa polypeptide that reacted with serum samples from a number of HBV-infected individuals.[93–94] Anti-HBx antibodies have been detected in acutely infected patients about 3–4 weeks after the onset of clinical signs,[95] and more frequently in chronic HBsAg carriers showing markers of active viral replication and chronic liver disease.[96–98] The expression of HBx was found to be preferentially maintained in HCCs and the WHV X-protein was detected in HCCs that are permissive for WHV replication.[99,100] The X-protein was found to be localized mainly in the cytoplasm of *in vivo*-infected cells near the plasma membrane and at the nuclear periphery,[95] or at the mitochondrial membrane.[102,103] It has also been detected in the nuclear compartment in transfected cell lines.[104–107] In the absence of a nuclear localization signal in the HBx protein, it has been proposed that nuclear import of HBx might be mediated by its interaction with the NF-κB inhibitor IκBα.[108] Conversely, HBx carries a leucine-rich nuclear export signal (NES) motif, and interacts with Crm1, a nuclear export receptor that binds to Ran GTPase. Cytoplasmic sequestration of Crm1 by HBx has been reported to induce aberrant centriole replication and abnormal mitotic spindles.[109] This process leading to genetic instability of HBV-infected cells might contribute to viral-induced carcinogenesis.

Seemingly contradictory data have recently accumulated on HBx function in natural infections. At least two salient features deserve consideration. On one hand, the requirement for a functional X gene in the establishment of viral infection in woodchucks has been firmly established.[110,111] On the other hand, the finding that the X gene product can activate transcription from a number of HBV and heterologous promoters might be important in defining its role in viral replication and in pathogenesis (reviews[112–114]). The X-protein behaves as a broad-range transactivator. It activates transcription from the viral promoters coupled to HBV enhancers and stimulates the production of viral particles in transient transfection assays.[114a] It is also active on heterologous viral promoters such as the SV40 early promoter, the herpes simplex virus-thymidine kinase (HSV-TK) promoter, and the Rous sarcoma virus (RSV) and human immunodeficiency virus (HIV) long terminal repeats (LTRs), and on cellular promoters including the interferon, HLA-DR, c-*fos* and c-*myc* promoters.[116–119] HBx does not directly bind DNA and may stimulate gene expression by interacting with transcription factors such as CREB, ATF-2, C/EBP and Spl,[120–123] or with elements of the basal transcription machinery such as TBP, TFIIB, TFIIH and the RPB5 subunit of DNA polymerase II.[124–128] It has also been shown that it binds the PHD finger protein HBXAP to co-activate transcription.[129] Other studies support an indirect effect of HBx by activating signalling pathways mediated by the Ras-Raf-MAPK cascade or by protein kinase C, leading to the activation of AP-1 and AP-2.[130–133a] Moreover, HBx has been shown to activate the nuclear translocation of NF-κB and NF-AT through different mechanisms.[103,108,120,134–136] Such functions are important for HBx-mediated regulation of a variety of cellular genes, including oncogenes, growth factors and cytokines, which play important roles in HBV pathogenesis and in tumorigenesis.

More clues on the possible role of HBx in HBV pathogenesis have been provided by studies of HBx interactions with cellular proteins (Fig. 17.3). It has been reported that HBx binds the tumour suppressor protein p53 and inactivates its functions.[137–139] This finding might be correlated with high chromosomal instability of HBV-related tumours. Interaction of HBx with the cellular DNA repair protein UV-damaged DNA-binding protein 1 (DDB1, also called XAP-1), might affect cell ability to repair mutated DNA sequences and allow the accumulation of genetic changes.[15,140–144] The proteosome complex might also be a target of the X-protein.[145] More recently, it has been shown that HBx activation of Src is important for HBV DNA replication and that alteration of cytosolic calcium mediated by HBx activates Pyk2, an Src kinase activator.[146,147] Non-receptor tyrosine kinases of the Src family are known to activate Ras, and activation of calcium-dependent signalling pathway can have pleiotropic effects on cellular functions. Therefore, the ability of HBx to activate calcium-dependent signalling events might account for HBx activity in HBV replication as well as in apoptosis induction and carcinogen-

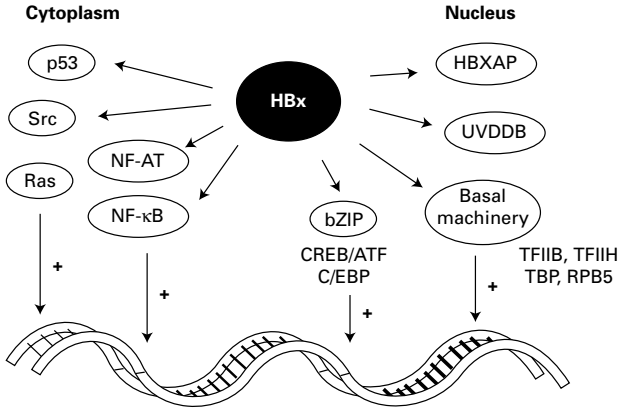

**Figure 17.3** Multiple interactions of HBx with cellular partners from cytoplasmic and nuclear locations. Left: HBx binds and sequesters the tumour-suppressor protein p53 in the cytoplasm, thereby inactivating p53 functions. Activation of Src is mediated by calcium-dependent activation of the Pyk-2 kinase. Activation of the Ras-Raf-MAPK cascade, including the extracellular signal-regulated kinases (ERKs) and jun N-terminal kinases (JNKs) leads to induction of the transcription factors AP-1. HBx induces nuclear translocation of the NF-κB and NF-AT transcription factors by various mechanisms. In the nucleus, HBs binds transcription factors of the bZIP family, including CREB, as well as several components of the basal transcription machinery and the PHD finger protein HBXAP to co-activate transcription. Interaction of HBx with the p127 subunit of the UVDDB complex (DDB1) might play a major role in diverse biological functions of HBx.

esis.[148] In chronic HBV infection, liver cell injury is thought to be mediated mostly by the cellular immune response, but there is increasing evidence that the HBx protein interacts with regulatory pathways controlling apoptosis. However, in this case also, apparently contradictory data have been reported. Arguments favouring pro-apoptotic properties of HBx have been provided in different experimental systems, showing that HBx can directly induce apoptosis through interaction with c-FLIP or by causing loss of mitochondrial membrane potential.[149–152] The hypothesis that HBx might play a role as a 'sensitizer' to other pro-apoptotic stimuli has been notably supported by its ability to increase cell sensitivity to apoptotic death induced by TNF-α, a pro-inflammatory cytokine implicated in chronic liver diseases.[153,154] Importantly, apoptotic functions cannot be dissociated from transactivation activity of HBx and these functions are conserved among mammalian hepadnaviruses.[155] In striking contrast, HBx has been found to inhibit apoptosis induced by p53 or by TGF-β and to promote cell survival through activation of phosphatidylinositol 3-kinase or NF-κB.[156–159] HBx is endowed with pleiotropic functions and is able to bind a variety of cellular partners. It seems therefore probable that HBx's effects on cell viability might be highly dependent on the cellular context. So far, however, the precise mechanisms by which HBx interferes with the control of liver cell proliferation and apoptosis in chronically infected patients and in liver tumours remain largely unknown.

So far, evidence for a direct oncogenic effect of HBx *in vivo* is scarce. It has been shown that high levels of X expression may induce malignant transformation of certain cultured cells, such as the NIH3T3 and REV-2 cell lines, and of immortalized hepatocytes expressing the SV40 large tumour antigen.[105,160,161] In co-transformation assays of rat embryo fibroblasts, HBx has been reported to either cooperate with Ras or to inhibit Ras transformation by inducing apoptosis.[162,163] Studies of transgenic mice carrying the X reading frame controlled by its natural HBV enhancer/promoter sequences or by heterologous liver-specific promoters have given rise to conflicting results. In a transgenic mouse line generated in the outbred CD-1 background, high level expression of HBx in the liver induced the progressive appearance of altered hepatocyte foci, proliferative adenomatous nodules, and malignant carcinoma that killed most male animals before 15 months of age.[7] In contrast, a second mouse lineage with lower HBx expression developed liver tumours at the same rate as normal CD-1 mice,[164] and other HBx transgenic lines generated in different mouse strains developed no obvious hepatic pathology, although the X gene was expressed in liver cells and the HBx protein could be detected in some cases.[165–167] These data suggest that HBx has no acutely transforming activity, but its overexpression in the susceptible CD-1 mouse strain might cooperate with activated cellular oncogene(s) in multi-step hepatic transformation. Arguments favouring this hypothesis were recently provided by the finding that the hepadnavirus X protein sensitizes liver cells to malignant transformation in transgenic mice treated with chemical carcinogens[99,168] and cooperates with c-*myc* in hepatocarcinogenesis.[169] Following AFB1 exposure of HBx transgenic mice, the expression of HBx correlated with an approximately twofold increase in the incidence of G/C to T/A transversion mutations.[170] Other studies have shown that expression of HIF-1alpha and vascular endothelial growth factor was increased in the liver of HBx-transgenic mice, suggesting that the cross-talk between HIF-1alpha and HBx may lead to transcriptional activation of HIF-1alpha target genes, which play a critical role in hepatocarcinogenesis.[171] While some data demonstrated that HBx is able to induce hepatocellular proliferation, other studies by contrast detected increased apoptotic death in HBx transgenic livers.[144,151,172] Moreover, *in vivo* expression of HBx could also exert a paracrine inhibitory effect on liver regeneration, providing an alternative mechanism of HBx-related pathogenesis.[173]

Analysis of integrated viral sequences in tumour DNA has shed new light on one of the mechanisms leading to

persistent expression of HBx in HCC. HBV sequences are frequently interrupted between the viral direct repeats DR1 and DR2 upon integration into host cell DNA, and overproduction of hybrid viral/host transcripts may result from HBV DNA integration in a hepatoma cell line.[174] Consistent with this model, viral/host junctions have been mapped near DR1 in the carboxy-terminal region of X in a majority of human HCCs.[175–178] The presence of viral/host transcripts containing a 3′ truncated version of the X coding region fused with flanking cellular sequences and retaining transactivating capacity was first described in a human HCC.[179] Moreover, enhanced transactivating capacity of the integrated X gene product has been related to the substitution of viral carboxy-terminal residues by cellular amino acids.[180] By contrast, more recent studies have detected truncated and mutated forms of HBx in HCC, which were less effective in transcriptional transactivation, apoptosis induction, and in supporting HBV replication.[177,181–183] However, integrated HBx mutants were also shown to bind to p53 *in vitro* and to retain the ability of wt HBx to block p53-mediated apoptosis *in vivo*, which may provide a selective clonal advantage for preneoplastic or neoplastic hepatocytes. [184] This suggests that the integrated X gene might be essential for maintaining the tumour phenotype that develops at the early stages of carcinogenesis. Collectively, the recent studies on HBx protein function have contributed to better delineate the importance of X gene product as a co-factor in malignant transformation induced by persistent HBV infection.

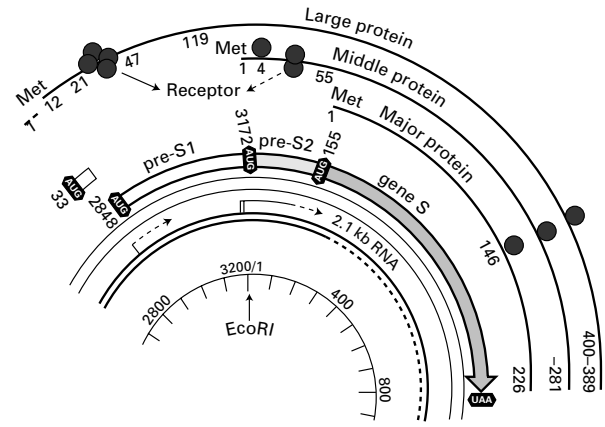

**Figure 17.4** Genetic map of the three HBs proteins (subtype *ayw*). The inner circles represent a part of the HBV genome shown in Fig. 17.2. The transcription start sites are indicated. The outer circles denote the large (LHBs), middle (MHBs), and major or small (SHBs) proteins of the envelope. Numbers refer to the amino acids of the primary translation products. Met, methionine initiator codon. The large black round spots mark the positions of the glycosylated residues, and the black hemispheres correspond to regions probably involved in the binding to the cell membrane.

## Surface glycoproteins

In natural HBV infections, the production of infectious virions and HBsAg particles depends on a tight regulation of the relative levels of the three envelope glycoproteins (Fig. 17.4). Neither liver lesions nor HCCs have been observed in any of the published transgenic lineages that produce the middle and major surface proteins from HBV-derived regulatory sequences.[185–188] When the endogenous pre-S1 promoter is replaced by an exogenous promoter (the metallothionein or albumin promoter), the production of roughly equimolar ratios of large S protein with respect to middle and major S leads to intracellular accumulation of non-secretable filamentous envelope particles within the endoplasmic reticulum of transgenic mouse hepatocytes.[189] This results in histological and ultrastructural features of 'ground-glass' hepatocytes, which have been described in some cases of chronic human liver diseases and are considered to be typical of chronic hepatitis B, ultimately killing the cells.

In pre-S/S transgenic mouse lineages, mild persistent hepatitis was followed by the development of regenerative nodules and eventually HCCs by 12 months of age.[6] At preneoplastic stages, strong hepatocellular proliferation and extensive oxidative DNA damage were noted,[190,191] and the preneoplastic nodules and tumours displayed a marked reduction in transgene expression, suggesting that hepatocytes that express low levels of the large S polypeptide would have a selective survival advantage. Exogenous, chemical co-factors are not required for tumorigenic induction in this model, but exposure of adult transgenic mice to hepatocarcinogens produced more rapid and extensive development of preneoplastic lesions and HCC under conditions that do not alter the liver morphology of non-transgenic controls.[192] These data show that inappropriate expression of the large S protein has the potential to be directly cytotoxic to the hepatocyte and may initiate a cascade of events that ultimately progress to malignant transformation, although the molecular mechanism connecting viral and host factors in this process has not been elucidated.

Studies of integrated HBV sequences in human liver tumours have also suggested a possible role for abnormal expression of rearranged viral S genes in HCC development. Deletion of the carboxy-terminal region of the S gene generates a novel transcriptional transactivation activity.[193] Integrated HBV sequences from a human tumour and a hepatoma-derived cell line, as well as different constructs bearing similarly truncated preS2/S sequences,[194] can stimulate the SV40 promoter in transient transfection assays. Although the mutated S polypeptide is retained in the endoplasmic reticulum and Golgi membranes, transactivation occurs at the transcriptional level. The c-*myc* P2 promoter is also ac-

tivated in *trans*,[180] and more recently, specific activation of c-Raf-1/Erk2 signalling by the truncated pre-S2S protein was observed, resulting in an increased hepatocyte proliferation rate.[195] These findings support the hypothesis that accidental 3′ truncation of integrated pre-S2/S genes could be a causative factor in HBV-associated oncogenesis.

## Viral integrations in HCC

The hepadnavirus replication pathway in infected cells takes place within nuclear and cytoplasmic compartments and does not require a step of viral DNA integration in the host cell genome. However, hepadnaviruses share with other retroelements of common evolutionary origin the ability to integrate their DNA into cellular chromosomes. The molecular events leading to the invasion of cell DNA by hepadnaviral DNA have not been fully elucidated.[101]

The main question is whether viral integrations might play a part in the virally induced transformation process, either by conferring a selective growth advantage on targeted cells, leading to the onset of preneoplastic nodules, or by providing an additional step in tumour progression. Whereas insertional activation of proto-oncogenes has emerged as a common event in WHV-induced woodchuck HCC, a related mechanism seems to be less frequent in human HCCs, in which different activities for integrated HBV sequences have been proposed.

### Integrated HBV sequences

Integrated HBV sequences have been observed in established hepatoma cell lines and in about 80% of human HCCs.[196–198] HBV DNA integrations occur at early stages in natural acute infections and in experimental infections of cultured cells.[115,199,200] As a result of multiple integrations in chronic hepatitis tissues,[201,202] integrated HBV sequences have been detected in most HBV-related HCCs that arise from clonal outgrowth of one or a few transformed liver cells (see Matsubara and Tokino[203]) Single HBV insertions are common in childhood HCCs but are rather uncommon later in life, suggesting that multiple integrations occurring during the course of long-standing HBV infections might accumulate within single cells.[204] Studies of the organization of cloned HBV inserts in liver tissues and HCCs have shown that HBV sequences are fragmented and rearranged and that integration and recombination sites are dispersed over the viral genome, indicating that HBV integration does not occur through a unique mechanism, as in the case of other retroelements and retroviruses. The absence of complete genomes in virtually all HBV inserts, which consist either of linear subgenomic fragments or of rearranged fragments in different orientations, shows that these sequences cannot serve as a template for viral replication. Integrated forms made of a subgenomic fragment, which are frequent in HCC and hepatitis tissues from children[115] are believed to represent primary products of integration. They are of particular interest in the study of the molecular mechanisms responsible for HBV DNA integration.

Highly preferred integration sites have been mapped in the HBV genome within the 'cohesive ends' region, which lies between two 11-bp direct repeats (DR1 and DR2) highly conserved among hepadnaviruses.[175,178,205,206] A narrow region encompassing DR1 has been shown to be particularly prone to recombination.[115,176,207] This region coincides with a short terminal redundancy of the minus-strand DNA, which confers a triple-stranded structure to the circular viral genome. Integration sites are tightly clustered at both the 5′ and 3′ ends of minus-strand DNA, suggesting that replication intermediates and specially relaxed circular DNA might be preferential preintegration substrates.[175,176] Invasion of cellular DNA by single-stranded HBV DNA, using mainly free 3′ ends, might take place through a mechanism of illegitimate recombination, also suggested by frequent patch homology between HBV and cellular sequences at the recombination breakpoints. Although different minor changes in flanking cellular DNA have been associated with viral integration (both microdeletions and short duplications), more precise mechanisms have been proposed. The recombination-proficient region spanning DR1 is located close to a U5-like sequence highly conserved between hepadnaviruses, suggesting that sequences necessary for precise recombination with cellular DNA have been retained from a common ancestor with retroviruses, despite the absence of a gene coding for an integrase in the HBV genome. Mapping of a set of preferred topoisomerase I (topo I) sites near DR1 and DR2 and *in vitro* studies of WHV DNA integration into cloned cellular DNA have sustained the hypothesis that topo I might promote illegitimate recombination of hepadnavirus DNA *in vivo*.[101]

As a consequence of the viral integration process, sequences of the S and X genes and of the enhancer I element are almost systematically present in HBV inserts, whereas those of the C gene are less frequently represented. It has been shown that the pre-S2/S promoter is transcriptionally active in its integrated form in HCCs and that HBsAg may be produced from viral inserts.[208,209] Highly rearranged HBV inserts show virus junctions scattered throughout the viral genome, and, in some of them recombination breakpoints have been mapped in the S coding region.[175] It has been recently shown that truncation of the S gene between residues 77 and 221 confers a transcriptional activation activity to the mutated pre-S2/S products.[194] The shorter pre-S2/S protein lacks carboxy-terminal signals for transloca-

tion through the endoplasmic reticulum membrane and should be retained in the bilayer. Activation of the c-*myc* oncogene promoter, demonstrated in *in vitro* assays, might result from an indirect transacting action of the truncated viral proteins.[193] Whether this or some related mechanism participates in liver cell transformation remains to be determined. Other studies have shown that a significant percentage of viral junctions are localized in the carboxy-terminal part of the viral X gene, predicting a fusion of the X ORF to flanking cellular sequences in a way that might preserve the functional capacity of the X transactivator. Evidence for transcriptional activity at integrated X sequences has been provided in tumours and chronically infected livers[68,179] and might be correlated with the detection of HBxAg in a number of human HCCs. However, there is increasing evidence that integrated, truncated forms of HBx also harbour a number of mis-sense mutations that abrogate the transactivation capacities of HBx.[177,181] Thus, while abnormal expression of integrated and truncated X gene might play a part in HBV-associated oncogenesis, the precise functions of these integrated sequences in *trans* remain to be determined.[210]

## Cellular target sites

Studies of different viral insertions in many human HCCs have revealed that integration can take place at multiple sites on various chromosomes (reviewed by Matsubara and Tokino[203]). These studies failed to demonstrate the presence of a known dominant oncogene or tumour-suppressor gene in the immediate vicinity of any integration site. It has been reasoned that integration of HBV DNA occurs at random in the human genome and that it has no direct mutagenic effect on growth control genes in most cases. It has been proposed that simple repetitive elements are hot spots for HBV insertion in the human genome. Indeed, Alu-type repeats, minisatellite-like, satellite III, or variable number of tandem repeat sequences have frequently been identified near HBV insertion sites, suggesting that chromosomal regions accessible to specific families of mobile repeated sequences are also preferential targets for HBV insertion. However, contrary to a widely held opinion, integration of retroelements and retroviruses might not be entirely random. Genome-wide surveys have shown that integration of retroviruses occur preferentially within transcription units.[211]

Evidence for a direct *cis*-acting promoter insertion mechanism was first provided in two independent HCCs.[8,10] These investigators analyzed early tumours that developed in non-cirrhotic livers and carried a single specific viral integration. In one case, the HBV insertion occurred in an exon of the retinoic acid receptor-β gene (RAR-β) and fused 29 amino-terminal residues of the viral pre-S1 gene to the DNA-binding and hormone-binding domains of RAR-β.[8] Retinoic acid and retinoids are vitamin A-derived substances that have striking effects on differentiation and proliferation in a large variety of systems. Interestingly, another retinoic acid receptor, RAR-α, is implicated in the chromosomal translocation[17,212] found in acute promyelocytic leukemias. In the human HCC, it seems most probable that inappropriate expression of a chimeric HBV/RAR-β protein participated in the tumorigenic process. In a second HCC, HBV DNA integration occurred in an intron of the human cyclin A gene, resulting in a strong expression of hybrid HBV/cyclin transcripts.[10,213] Cyclin A plays a major role in both G2/M and GUS checkpoints of the cell cycle.[214] Recent data from our laboratory, based on the inactivation of cyclin A gene by homologous recombination, have demonstrated that cyclin A is an essential gene for cell cycle progression. The hybrid RNAs code for a 430 amino acid chimeric protein, in which the amino-terminal 152 amino acids of cyclin A are replaced by 150 amino acids from the pre-S2 and S viral proteins, while the carboxy-terminal two-thirds of cyclin A, including the cyclin box, remain intact. Therefore, the cyclin A degradation sequences located in the amino-terminal part of the protein are deleted, and, using an *in vitro* degradation assay with frog oocytes, we have verified that HBV/cyclin A is not degradable.[213] Furthermore, we have obtained *in vitro* results that demonstrate the transforming property of the HBV-cyclin A protein.[215] Several hypotheses can be proposed to account for this effect. The absence of degradation of a molecule retaining the ability to complex to and activate cdk kinases might lead to unregulated and premature DNA synthesis and thus to cell proliferation. It is also quite plausible that the location of the HBV/cyclin A protein is changed, given the membrane location of pre-S2/S molecules in HBV-infected cells, and we have obtained recent evidence that supports an abnormal location of this protein in the endoplasmic reticulum membranes, driven by pre-S2/S sequences. Finally, it is noteworthy that the pre-S2/S viral sequences present in HBV/cyclin A are deleted in their carboxy-terminal part and thus have a structure similar to the deleted pre-S2/S proteins described in the previous section. On the other hand, our group has shown that the expression of cyclin A RNA or protein is an interesting marker of tumour cell proliferation *in vivo*.[216,217]

However, surveys of human liver cancers did not reveal any other case showing rearrangement of a cyclin A or RAR gene. In these two HCC cases, analysis of single HBV insertion sites has allowed the identification of new genes involved in the control of cell growth and differentiation. Both studies have opened the way to novel approaches of the cellular pathways regulating cell division and differentiation.

The notion that HBV might play a significant role as an insertional mutagen in primary liver cancer has been recently strengthened by large-scale analysis of viral insertion sites. We have demonstrated that HBV frequently targets cellular genes involved in cell signalling, and that some of them may represent preferential target sites of the viral integration. By using HBV-Alu PCR, we have isolated, from 22 HCCs, 15 HBV DNA integration sites in which cellular genes targeted by HBV were key regulators of cell proliferation and viability.[11,12,218] We found HBV DNA integrated into the following cellular genes: sarco/endoplasmic reticulum calcium ATPase1 gene (SercA1); thyroid hormone receptor associated protein 150 alpha gene; mini-chromosome maintenance protein (MCM)-related gene; FR7, a new gene expressed in human liver and cancer tissues; nuclear matrix protein p84 gene; neurotropic tyrosine receptor kinase 2 (NTRK2) gene, IL-1R-associated kinase 2 (IRAK2) gene, p42 mitogen-activated protein kinase 1 (p42MAPK1) gene, inositol 1,4,5-triphosphate receptor type 2 (IP3R2) gene, inositol 1,4,5-triphosphate receptor (IP3R) type 1 (IP3R1) gene, alpha 2,3 sialyltransferase (ST3GAL VI or SITA) gene, thyroid hormone uncoupling protein (TRUP) gene, EMX2-like gene and human telomerase reverse transcriptase (hTERT) gene. Overall, we found that both the inositol 1,4,5-triphosphate receptor gene and the telomerase gene were targeted by HBV in two different tumours. Interestingly, several independent groups have found recurrent HBV DNA integrations into the hTERT gene encoding the catalytic subunit of telomerase, which is responsible for elongation of telomeric repeat DNA and maintenance of telomere length and structure.[12,219,220] None of the integrations altered the hTERT coding sequence and all resulted in juxtaposition of viral enhancers near hTERT, with potential activation of hTERT expression. Taken together, these data support the hypothesis that integration of HBV might induce cell immortalization and predisposition to carcinogenesis through activation of hTERT. In conclusion, there is now considerable evidence that the sites of oncogenic viral integrations are non-random, and that genes at the sites of viral integration may provide a growth advantage to a clonal cell population, leading to the accumulatation of additional mutations and to cancer development.

HBV DNA integration may also enhance chromosomal instability. In many tumours, large inverted duplications, deletions, amplifications or chromosomal translocations have been associated with HBV insertions, suggesting that this process may function as a random mutagen, promoting chromosomal defects in hepatocytes.[221–223] In addition, HBV DNA may promote homologous recombination at a distance from the insertion site.[224] However, a role for most of these chromosomal abnormalities has not been assigned as yet, although in a few cases the p53 or Hst-1 loci have been altered as a sequel of HBV integration in the same chromosomal region.[225]

## Insertional activation of *myc* genes in woodchuck HCC

The availability of naturally occurring animal models for HBV-induced liver disease and cancer has been largely exploited for a better understanding of the viral/host interactions. In the WHV/woodchuck model in particular, the natural history of viral infections, the presence and state of viral DNA, and the patterns of viral gene expression have been extensively investigated. Experimental inoculation of newborn woodchucks with infectious virions has given conclusive information on the oncogenic activity of WHV. This virus now appears to be the most potent inducer of liver cancer among the hepadnavirus group.[226] The GSHV and the arctic squirrel hepatitis virus appear to be more weakly oncogenic.[18,227]

Search for transcriptional activation of known proto-oncogenes and for viral insertion sites in woodchuck HCCs has revealed that WHV acts as a potent insertional mutagen, activating *myc* family genes (c-*myc* or N-*myc*) in a large majority of tumour cases.[13,14,16,212] Analysis of the mutated c-*myc* alleles in two individual tumours has shown integration of WHV sequences in the vicinity of the c-*myc* coding domain, either 5′ of the first exon or in the 3′ untranslated region.[13] Deregulated expression of the oncogene driven by its normal promoters resulted from deletion or displacement of c-*myc* regulatory regions known to exert a negative effect on c-*myc* expression, and their replacement by viral sequences encompassing the enhancer elements. Such a mechanism is highly reminiscent of that previously reported for c-*myc* activation in murine T-cell lymphomas induced by murine leukaemia viruses (MuLV). A survey of 56 woodchuck HCCs for c-*myc* rearrangements has shown only a few cases in which WHV DNA was inserted into the c-*myc* locus.[16] Presently, it may be estimated that insertional activation of c-*myc* is involved in about 13% of woodchuck tumours.

The insertional activation of N-*myc* genes was observed more frequently in woodchuck HCCs. In contrast to human and mouse, the woodchuck genome contains two distinct N-*myc* genes: N-*myc* 1, the homologue of known mammalian N-*myc* genes similarly organized into three exons, and N-*myc* 2, a functional processed pseudogene or retroposon, which has retained extensive coding and transforming homology with parental N-*myc*.[212,228] It has been shown that N-*myc*2, like c-*myc*, is a potent inducer of apoptosis in liver cells, and that this effect is counteracted by *Bcl*2 and insulin-like growth factor II (IGF-II). In woodchuck HCCs, N-*myc*2 represents by far the most frequent target for WHV DNA integrations. As shown in Fig. 17.5, in about one-half of cases,

viral inserts were detected either upstream of the gene or in a short sequence of the 3′ untranslated region, also identified as a unique hot spot for retroviral insertions into the murine N-*myc* gene in T-cell lymphomas. Activated expression of the N-*myc*2 retroposed oncogene, frequently correlated with overexpression of C-*fos* and C-*jun*, was observed in a large majority of woodchuck HCCs. Thereafter, integration of WHV DNA in two hot spot regions (*b3n* and *win*) located about 10 and 200 kb away from N-*myc*2 in the same chromosomal region (Xq24) was shown to contribute in N-*myc*2 activation in around one-quarter of woodchuck HCCs.[14,229,230] These loci contain S/MAR motifs that bind specifically nuclear scaffolds, suggesting that WHV integration might deregulate the S/MAR elements and indirectly affect the expression of the upstream N-myc2 gene.[231] Evidence for a direct role of WHV DNA integration into *myc* genes in hepatocyte transformation has been provided by the development of liver tumours in transgenic lines of mice bearing WHV and *myc* sequences from mutated alleles of woodchuck HCCs.[232,233] In these models, expression of the transgenes in liver cells induced primary liver tumours with high incidence.

Collectively, these data indicate that insertional activation of *myc* genes by WHV DNA, from short as well as from long distances, occurs in >90% of woodchuck HCCs (Fig. 17.5). Our findings also suggest that the role of HBV integration should be reconsidered, because a similar mechanism has not been investigated to date in human HCC.

Further evidence that *myc* family genes are predominantly implicated in rodent liver tumours associated with hepadnavirus infection comes from other studies of woodchuck and ground squirrel HCCs. In two independent woodchuck tumours, a genetic rearrangement fusing the coding domain of c-*myc* with the promoter and 5′ translated sequences of a cellular locus termed her has been observed.[234,235] In a study of ground squirrel HCCs, frequent amplifications of c-*myc* were found in tumour cell DNA (11 of 24 cases examined) and associated with enhanced expression of the oncogene.[17] Similarly, c-*myc* amplifications frequently occur in woodchuck HCCs induced by experimental GSHV infection. Integration of GSHV DNA into host cell genome, which occurs only rarely in squirrel tumours, has not been correlated with the observed genetic alterations of c-*myc*. Similar alterations have also been described in rodent liver tumours. Although amplification of c-*myc* has been observed on rare occasions in HBV-positive human liver tumours, there has been no experimental demonstration, until now, that deregulated expression of *myc* genes might be generally associated with HBV-induced tumorigenesis in human livers by any known *cis*- or *trans*-acting mechanism.

The strategy used by WHV in liver cell transformation now appears strikingly similar to that of some non-acute retroviruses, such as Moloney murine leukaemia virus (MoMuLV), which induces disease (usually leukaemias) slowly, emphasizing the described similarities between hepadnaviruses and retroviruses[89] (Fig. 17.5). These conclusions raise two different albeit related questions. What factors drive the oncogenic potential of WHV exclusively toward hepatocytes, as we know that this virus can infect a wide variety of woodchuck tissues, albeit at

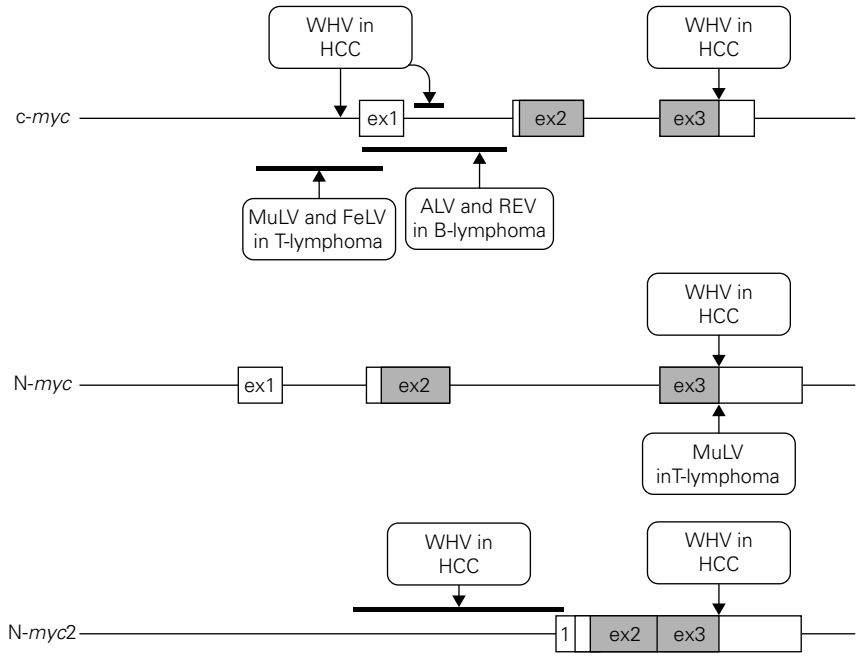

**Figure 17.5** Comparison of hepadnaviral and retroviral insertion sites in the c-*myc* and N-*myc* genes. Preferred target sites for WHV in *myc* family genes, in 56 woodchuck liver tumours are indicated above the corresponding genes, and those of murine and avian retroviruses in B- and T-cell lymphomas are shown under the genes. The intronless N-*myc*2 oncogene, generated by retrotransposition of the parental woodchuck N-*myc*l gene, is specific to the Sciuridae family of rodents. The win locus maps 180–200 kb downstream of N-*myc*2 on the woodchuck X chromosome. Insertional activation of *myc* family genes by WHV DNA was observed in about 90% of the woodchuck HCCs analyzed.

much lower levels? How can the apparent differences in the strategies of the closely related mammalian hepadnaviruses be explained at the molecular level? To address these issues and identify the genomic variations responsible for such discrepancies, the regulatory elements controlling viral gene expression have been compared among mammalian hepatitis B viruses.[83,84,87–88] These studies showed striking evolutionary divergence in the organization of nuclear factor-binding sites between the human and rodent hepadnavirus enhancers. Further *in vivo* studies are required to determine whether these differences play a role in the observed variations in hepadnavirus oncogenicity.

## HCC in HBsAg-negative patients

As stated previously, there are striking geographical variations in the association between chronic infection by HBV and HCC. In Western countries (e.g. northern Europe, United States) and Japan, only 15–20% of the tumours occur in HBsAg-positive patients, and other environmental factors, such as alcohol and infection by HCV, are clearly major risk factors. A number of epidemiological studies previously showed a high prevalence of anti-HBs and anti-HBc antibodies in the group of HBsAg-negative subjects (approximately 40–50% in France), indicating exposure to the virus (Table 17.1).[236–242] These antibodies generally reflect past and resolved HBV infection. However, in HBsAg-negative subjects with HCC, HBV DNA sequences can be detected in the tumours, demonstrating the persistence of the viral infection and suggesting its implication in liver carcinogenesis (Table 17.2).[39,209,237,243–260] With this view, it is indeed important to realize that the improvement in the sensitivity of assays for HBsAg detection, together with the introduction of sensitive tests for HBV DNA identification, has modified the criteria for the diagnosis of HBV infection. Thus, there is a spectrum of chronic HBV infections with a low replication rate, which might also be a risk factor for liver cancer.[39,59,121,261,262] In agreement with this, Shimada and colleagues studied 146 HBsAg negative primary liver tumours and provided evidence that the presence of HBV DNA fragment is a significant independent risk factor for development of HCC.[263]

HBV and HCV can interact with chronic alcohol consumption, and there is circumstantial evidence for a high prevalence of HBV and HCV infections in alcoholics. The increased prevalence of anti-HCV in alcoholics with cirrhosis (approximately 40–50%) as compared with those with minimal liver damage (approximately 20%) suggests that HCV infection might be implicated in the development of the cirrhosis in some of these patients. This observation may also account for the high prevalence of anti-HCV (50%) in alcoholics with HCC.[241,242,264,265] In contrast, there is no evidence for a role of HBV in the development of alcoholic cirrhosis, as the prevalence of anti-HBs and anti-HBc, although higher than in the general population, does not significantly differ whether or not a cirrhosis is diagnosed (approximately 20%). However, there is evidence for

the role of HBV in the liver cancers occurring in alcoholics, as the prevalence of HBV serological markers is significantly increased in these patients (approximately 50%), and the tumours frequently contain HBV DNA sequences.[236,266–268]

The actual prevalence of these HBV DNA-positive HCCs in HBsAg-negative subjects has been a matter of debate, owing to the presence in the tumours of a low copy number per cell of the viral DNA sequences (estimated at 0.1 to 0.001). Thus, studies performed in different geographical areas showed very different results (Table 17.2), probably as a result of different technical conditions (specificity and sensitivity) and distinct epidemiological situations. The sensitivity of the polymerase chain reaction (PCR) has now allowed confirmation of the previous observations, demonstration of the transmission of HBV particles present in the serum of these HBsAg-negative patients to chimpanzees, and determination of the nucleotide sequences of the HBV genomes. For example, in a study performed in patients from areas of high (South Africa) and low (France, Italy) HBV prevalence, HBV DNA was shown in eight of ten serologically recovered subjects and in six of thirteen patients without any detectable HBV serological marker.[269] Similar results were also recently obtained in Spain, Africa and the United States (Table 17.3).[217,269–275] There is no real correlation between the serological HBV profiles and the presence or absence of HBV DNA detection in serum or tumour. Taken together, they show a persistent HBV infection in a large number of subjects with HBsAg-negative HCCs. Whether these infections are clinically significant or purely 'occult' is an important debate.[276]

Related findings have been reported in the woodchuck and ground squirrel models of HCC. Liver cancer occurs in 17% of serologically recovered woodchucks, compared with a zero rate in uninfected animals.[277] WHV DNA was detected in the tumour tissues of seroconverted woodchucks, with a much lower number of copies per cell (about 0.1–0.3) than in HCCs from WHsAg-positive animals (100–1000 copies per cell). In the ground squirrel model, about 25% of serologically recovered animals develop HCC,[227,262] and integrated GSHV sequences have been characterized in two of five tumours analyzed.[17] In addition, HCC has also been observed in about 20% (six of thirty) of aged, seronegative squirrels. In these tumours, GSHV DNA is undetectable by conventional methods. However, low levels of GSHV DNA have been found in two different cases by using PCR,[17] reinforcing the established association between HCC development in ground squirrels and infection with GSHV.

With regard to the state of HBV DNA, its low copy number per cell has hampered the interpretation of the results of Southern blotting. However, using our PCR test and distinct primers distributed on the S, pre-S/S, C and X HBV genes, we were able to provide further information. For several patients, a positive result was obtained only with some of the HBV primers, a finding consistent with the presence of defective HBV DNA. In other cases, the tumour DNA scored positive with all the HBV primers, consistent with the presence of free or integrated HBV DNA showing no gross rearrangements. Interestingly, defective HBV genomes have been identified more frequently in tumours than in non-tumour tissues. In addition, they also have been shown more frequently in completely seronegative individuals than in anti-HBs- and anti-HBc-positive subjects. This observation probably reflects a technical point, as the presence of defective HBV DNA can be obscured by concomitant complete viral genomes. The PCR profiles obtained with DNA from tumour, non-tumour and serum samples from the same European patients showed marked differences. In the serum and non-tumour samples, amplification was achieved with all the primers tested. In contrast, tumour DNA repeatedly gave negative results with at least one primer. These findings demonstrate that the HBV DNA sequences in the tumour do not derive from contaminating non-tumour cells or serum-derived particles. They are also consistent with the clonal expansion of cells containing defective and integrated HBV DNA.[217] A high rate of mutations has been identified in the X gene in the tumour tissue from such HBsAg-negative HBV DNA-positive patients. This high rate of amino acid changes contrasted with a lower rate of X mutations in the non-tumour section from the same patient. It also contrasted with a lower rate of mutations in the pre-C/C sequence (Poussin *et al*., unpublished observations). These findings might have two important implications. X mutations might be implicated in

the low replication profile of the HBV genome in these tumours. In addition, such mutations might modify the biological properties of X in the tumour, and this possibility is now being tested.

Northern blot analysis has not proven sensitive enough for the detection of HBV RNAs in these tumours. In contrast, cDNA synthesis followed by PCR with primers on the S gene (RT-PCR) revealed HBV RNA sequences in most of HBV DNA-positive tumours from HBsAg-negative patients. Owing to the compact organization of the HBV genome, however, it was not possible to determine precisely which viral transcripts were synthesized.[269] We have investigated the HBV RNAs with primers located on the S, C and X encoding sequences. X, but not C and S, transcripts were identified in tumour tissues from seven of the nine HBsAg-negative HBV DNA-positive patients studied.[216] More recently, we confirmed these observations by detecting the X protein in these tumorous liver cells (Poussin *et al*., unpublished observations). This may provide a clue to the pathogenesis of these tumours in view of the potential transforming properties of the X protein envisaged in HBsAg-positive liver cancers. With this view the issue of the interactions between X and P53 is important. It is indeed tempting to speculate that two types of HCCs might emerge from studies focused on both P53 and X. Some tumours (altogether around 20%) show P53 mutations and thus would not 'need' X expression for P53 inactivation, whereas in the remaining cases, X might functionally inactivate wild-type P53. Preliminary evidence supports this hypothesis,[278] but further confirmation is required.

Taken together, results demonstrate a high rate of persistent HBV infection in patients with HCC negative for serum-HBsAg, many of whom also lack detectable antibodies to the virus. They also show clonal expansion of the tumour cells containing integrated viral DNA and preferential transcription in these cells of HBV RNA sequences encoding the viral X-protein. A direct role of HBV in these liver cancers is further suggested by the detection of HBV DNA in HCCs in HBsAg-negative patients, developing on non-cirrhotic, histologically close-to-normal livers. Thus, cirrhosis cannot solely account for the induction of the cancer in these cases.[279] Although these findings strongly argue for a role for HBV in the development of these tumours, one paradoxical result still remains to be explained: why is the copy number of HBV DNA per cell so low if clonal expansion of infected cells occurs? One may hypothesize that, after triggering the cascade of events that lead to liver cell transformation, the persistence of HBV DNA is no longer required. Furthermore, as discussed in previous sections, there is low or absent HBV replication in the tumour cells and thus no generation of new integrants from free viral genomes. Finally, chromosomal rearrangements might eliminate integrated viral DNA sequences from the tumour clones. This explanation may also account for human and bovine papillomavirus- and some retrovirus-related tumours.[280,281] Interestingly, there is recent evidence in the duck hepatitis model that supports these hypotheses.[282]

## HCV and HCC

HCV is clearly an important aetiological factor of HCC, although the impact of the viral infection varies among geographical areas. Chronic hepatitis plays a major role in the liver carcinogenesis related to this virus. It is presently not clear whether HCV might also exert direct effects in liver cell transformation, although some evidence supports this hypothesis.[284]

HCV RNA sequences can be detected in the tumorous tissues of patients with liver cancer. Sequencing of the hypervariable part of the E2 envelope region has confirmed that HCV RNA sequences persist in the tumour cells and do not merely reflect contamination by non-tumour cells or serum particles. Instead, mutations identified in the HCV RNA sequences from tumour as compared to non-tumour cells reflect infection by an identical HCV isolate, followed by replication at a different rate of the HCV genome when tumour develops.[216,283] In contrast with HBV, HCV genome does not integrate into cellular DNA, and replication is thus necessary to its persistence. Studies based on PCR for detection of negative HCV strand, as well as identification of different HCV proteins into tumour cells, have been consistent with replication of HCV genome. Such studies are complicated by technical pitfalls when searching for HCV RNA-negative strands by PCR[285] and for HCV proteins with the available antibodies. As previously discussed for HBV, a main issue for understanding HCV-related carcinogenesis is whether the virus is only acting by inducing chronic active hepatitis (CAH) and cirrhosis or might also directly modify the cellular phenotype.[286,287] Two factors favour the hypothesis of a direct effect of some HCV isolates. We have reported rare but well-characterized HCCs in livers with minimal histological lesions and that, despite detailed analysis, showed persistence of HCV RNA in the tumours as the only identified risk factor.[288] This study has demonstrated that, in some cases, HCC might be associated with HCV in the absence of CAH. *In vitro*, it has been shown that expression of a region of the NS3 viral protein induces a transformed phenotype in NIH 3T3 cells.[246] Furthermore, it has been demonstrated that the HCV capsid can cooperate with the c-Ha *ras* oncogene to transform rat embryo fibroblasts.[289] More recently, it has been shown that transgenic mice carrying the complete HCV genome, or expressing the HCV core alone, develop liver steatosis and have high rates of HCC.[290,291] The mechanism of core-induced HCC is not well understood, but may

involve interaction with one or more cellular proteins required for the control of cell growth. Moreover, the HCV core protein has been shown recently to induce oxidative stress in transgenic mice.[292]

Altogether, these studies suggest that HCV proteins might exert a direct effect in liver carcinogenesis. The mechanisms involved in this transforming property are not known. However, there are some interesting issues to consider. The viral core, especially carboxy-terminal deleted forms, might modulate expression of cellular genes, such as the *fos*, *myc* and *jun* oncogenes, the retinoblastoma suppressor gene, or the gene encoding for IFN-β.[293,294] The capsid might also interfere with the tumour necrosis factor pathway and thus modulate the sensitivity of the cell to this cytokine.[33] Finally, we have presented evidence for an accumulation of lipid-containing vesicles in the cells upon expression of the capsid, as well as its co-localization with apolipoprotein AII.[295] This is a potentially relevant observation in view of the high prevalence of liver cell steatosis in HCV carriers and the association of circulating HCV particles to lipoproteins. The localization in the cell of the capsid, therefore, is important for understanding the real impact of these findings, and in particular its nuclear localization is important to consider. HCV capsid shows predominant cytoplasmic localization. It has also been suggested that carboxy-terminally deleted forms of the capsid, generated from some isolates, might locate in the nucleus, but this is still a matter of debate.[296] In view of the potential role of HCV capsid in liver cell transformation, it is interesting that point mutations have been identified in HCV core sequences from HCCs developed in HCV carriers in the absence of cirrhosis or severe chronic hepatitis.[297] These mutants co-localize with PKR in Huh7 cells, and this association augments the autophosphorylation of PKR and the phosphorylation of the translation initiation factor eIF2alpha, which are two markers of PKR activity.[297] In addition, HCV genomes potentially encoding for truncated HCV capsids have been identified in other tumours.[298,299] Another protein of HVC, NS5A, also possesses many intriguing properties, including sequestration of p53 in the cytoplasm, downregulation of p21, activation of STAT3, inhibition of TNF-α-mediated apoptosis. It has been shown to alter intracellular calcium levels and induce oxidative stress.[300] Thus, persistent stimulation of cellular stress responses by accumulation of viral proteins within hepatocytes may predispose the cell to genetic alterations and play an important role in hepatitis virus-induced liver diseases and HCC. An important question regarding the role of hepatitis viruses in HCC is whether viral gene products are necessary for the establishment of HCC and whether the cancer, once established, becomes independent of the expression of viral genes.

The impact of HCV genotypes in the risk of developing HCC is an important issue to analyze. A number of studies point to the severity of HCV type 1-associated liver lesions, including HCC. Cross-sectional analyses indeed have shown higher relative prevalence of HCV 1 in patients with cirrhosis than in those with moderate CAH. However, these findings are difficult to interpret because the molecular epidemiology of HCV is presently changing as a result of the introduction, in France and Italy, of other types such as HCV 3 by intravenous drug users. In these conditions, duration of HCV infection differs from one type to another and markedly influences the risk of cirrhosis.[301,302] In prospective studies on the risk of developing HCC in patients with HCV-related cirrhosis, infection by genotype 1 has emerged as an independent risk factor.[303] Along the same line, HCV 1b was the most prevalent type among the patients we reported with HCV-associated HCC in the absence of cirrhosis.[288] Although these examples provide only indirect evidence, they are consistent with a particular profile of HCV 1 infection. *In vitro* studies are now mandatory to compare the different biological properties of various HCV isolates.

## Genetic alterations in HBV-related HCC

Different genetic alterations that cannot be clearly associated with a direct effect of viral infection have been described in human HCCs. These somatic changes include allele losses on several chromosomal regions, mutation and activation of cellular genes showing oncogenic potential, and deletion or mutation of tumour-suppressor genes. Search for activated oncogenes using the NIH3T3 cells in transformation assays has not been conclusive for most HCC DNAs analyzed. DNA analysis revealed a low rate (<10%) of point mutations in H-, K- and N-*ras*,[304] whereas other investigators failed to detect any *ras* mutation in the HCCs analyzed.[305]

Loss of heterozygosity on chromosomes 1p, 4q, 6q, 8p, 9p, 13q, 16p, 16q and 17q occurs frequently in human liver tumours, suggesting that these parts of the human genome contain some genes whose functional loss might be involved in hepatocellular carcinogenesis.[306,307] Essentially similar chromosomal regions were found to harbour changes in DNA copy number by comparative genomic hybridization[308] (reviewed by Buendia[309]). Because the large-scale chromosomal alterations that arise in cancer cells occur infrequently in normal cells, it is probable that control mechanisms that safeguard chromosomal integrity are abrogated in the development of malignancy.[310] Such changes might represent secondary events linked to tumour progression and reflect a general property of transformed cells. Interestingly, it has been found that HBV-related tumours harbour a higher rate of chromosomal abnor-

malities than tumours associated with other aetiological factors.[311,312] A role of HBV DNA integration and of the HBx regulatory protein in promoting genetic instability has been evoked.[109,224]

Allele loss of the short arm of chromosome 17, which includes the p53 gene, has been observed in 30–60% of human HCCs and in hepatoma-derived cell lines (reviewed[313,314]). The wild-type p53 gene negatively regulates cellular growth and, therefore, was designated a tumour-suppressor gene or *anti-oncogene*. Mutant forms of p53 frequently gain a growth stimulatory function. Genetic alterations of the gene generally consist in the deletion of one p53 allele and mutation of the second allele, and represent the most common feature in human neoplasms. Studies of the p53 gene at the DNA, RNA and protein levels have revealed abnormal structure and expression in most established HCC cell lines. A hot spot mutation affecting p53 at codon 249 was originally described in HCCs from regions with high prevalence of HBV infection and high levels of dietary aflatoxins.[315,316] This mutation, mainly a G to T transversion, appears to be specific for the mutagenic action of aflatoxin $B_1$.[317] This particular mutation was not observed in HBV-related HCCs from patients who have not had high exposure to the hepatocarcinogen. P53 codon 249 mutation was detected in apparently normal liver, and its frequency paralleled the level of aflatoxin $B_1$ exposure, suggesting that it occurs early during HCC development.[92,318] Functional characterization of the mutant p53 gene might provide a clue for understanding the oncogenic mechanism triggered by aflatoxin $B_1$. Structural aberrations of the p53 gene (mutations at different codons and loss of one allele) have been observed more frequently in advanced, less differentiated HCCs, often associated with abnormalities of another tumour-suppressor gene, RB.[319] The frequency of p53 mutations has been evaluated in tumours from diverse geographical and ethnic sources and found to be much lower than previously reported. Interestingly, it has been shown that the rate of p53 mutations is significantly higher in HBV-related tumours than in HCV-related and non-viral HCCs.[311] Although HBV DNA insertions in chromosome 17p have been described in some liver tumours, it seems most probable that the genetic alterations observed in a majority of human HCCs are not due to a direct action of the virus. Regional deletions spanning the RB locus on chromosome 13q have also been reported, but a low mutation rate was found in the remaining allele.[319] Candidate tumour suppressor genes in other frequently deleted chromosomal regions include the mannose 6-phosphate/IGF-II receptor (M6P/IGF2R) gene on chromosome 6q,[320] the p16INK4A and p14ARF genes on chromosome 9p[321] and the E-cadherin gene on chromosome 16q.[321a]

In conclusion, recurring deletions spanning many human chromosomes might inactivate a number of tumour suppressors and thus play a key role in hepatocarcinogenesis. Besides genetic alterations, epigenetic factors like methylation-associated gene silencing play an important role in the deregulation of cell cycle control and proliferation. Frequent hypermethylation of CpG islands in the promoters of p16INK4A, E-cadherin and adenomatous polyposis coli (APC) genes has been reported in HCC.[322,323] This epigenetic alteration occurs early during the tumoral process, accumulates step by step during tumour progression, and might be of prognosis value for HCC patients.

Activation of the Wnt/β-catenin pathway has been implicated as an important step in carcinogenesis, through activating mutations in the β-catenin gene, or defects in the adenomatous polyposis coli (APC) or Axin genes.[324] Activation of the Wnt signal induces translocation of β-catenin to the nucleus and its association with the transcription factors Tcf/LEF, leading to transcriptional activation of target genes such as c-myc and cyclin D1.[325] Recently, oncogenic mutations in the β-catenin gene have been evidenced in human and mouse liver tumours.[326,327] β-Catenin mutations were found in around 20% of HCC cases, predominantly in HCV-related tumours and in tumours associated with alcoholic cirrhosis.[311] Additionally, Axin mutations have been detected in 5–10% of liver tumours, but no mutation has been found so far in the APC gene in HCC, contrasting with the predominant role of APC in colorectal cancer. It is noteworthy that p53 mutation has been reported to induce nuclear accumulation of wild-type β-catenin in liver tumours, which might account for the observation that worldwide p53 and β-catenin mutation rates are inversely correlated in HCC.[328] Consistent with this notion, HBV-related tumours exhibit a high rate of p53 mutations, but rare β-catenin mutations, while the inverse situation is found for HCV-related HCCs.[309] Further studies are required to better characterize the molecular mechanisms leading to the appearance of β-catenin mutations and to understand their oncogenic impact. Genome-wide studies of gene expression in HCC and in chronic hepatitis by microarray screening will undoubtedly contribute to a better understanding of the complex mechanisms involved in virally induced liver tumorigenesis.

## Conclusions

Several lines of evidence contribute in linking chronic HBV infection and primary liver cancer. First, a strong epidemiological association has been provided by extensive prospective and retrospective studies in many parts of the world. Second, a network of indirect but convincing arguments has further supported the connection between HBV and HCC, including the existence of related animal viruses that induce HCC in their hosts, the weak

oncogenicity of the viral X transcriptional transactivator, the long-term tumorigenic effect of surface glycoproteins, and the mutagenic action of viral integration into the cell genome, which may, directly or indirectly, contribute to deregulating the normal cell growth control.

The exponential relationship between HCC incidence and age indicates that, as in other human cancers, multiple steps, probably involving independent genetic lesions, are required. In particular, the long latency of HCC development after the initial HBV infection may be interpreted as a sign of an indirect action of the virus. A long-term toxic effect of viral gene products and/or the immune response against infected hepatocytes would trigger continuous necrosis and cell regeneration, which would in turn favour the accumulation of genetic alterations. In this model, productive HBV infections might potentiate the action of exogenous carcinogenic factors, such as aflatoxins and alcohol. It might also be speculated that the latency period depends on the occurrence of a decisive HBV integration event that would promote genetic instability or lead to *cis*- or trans-activation of relevant genes. Investigations of the functional and pathological properties of HBV gene products and of the consequences of HBV integration in the liver DNA suggest that various and probably cooperative mechanisms may operate in the development of liver cancer, and that HBV may share a number of basic strategies with other human oncogenic viruses. The HBV genome encodes at least seven different polypeptides. None of them seems to act as a strong, dominant oncogene, but several lines of evidence indicate that the surface glycoproteins and the viral X transactivator might participate in carcinogenesis in a native or modified state. In this respect, it is noteworthy that in human oncogenic viruses, such as HTLV-1, EBV, and HPV-16 and -18, transforming capacity is associated with the transcriptional transactivation activity of viral gene products. Comparative analyses of the different viral transactivators may help guide future work in this field. Studies of mammalian HBV-related viruses have revealed strikingly different mechanisms and pointed out the importance of the activation of *myc* family genes in rodent hepatocarcinogenesis. However, a role for HBV in activating the c-*myc* oncogene, suggested by *in vitro* assays, has not been established *in vivo*, and recent data support a predominant role of tumour-suppressor genes such as p53 in human HCCs. The identification of the cellular effectors connecting HBV infection and liver cell transformation is the major unsolved component in this question.

# Chapter 18
# Murine models and hepatitis B virus infection

David R Milich

## Introduction

Because of the limited host range of the hepatitis B virus (HBV) and the lack of *in vitro* culture systems to propagate HBV, investigators have utilized murine systems as surrogates. Wild-type mice have been used to: (1) assess the comparative immunogenicity of HBV proteins; (2) identify putative T- and B-cell epitopes; (3) examine immunogenetic factors; (4) produce models of infection; (5) examine immune tolerance; and (6) design candidate vaccines. Furthermore, a number of investigators have expressed single HBV proteins, combinations of HBV proteins, the complete HBV genome and T-cell receptors (TCRs) specific for HBV proteins in transgenic (Tg) mice in order to study gene expression, pathogenesis, replication, inhibitors of replication, viral persistence, modulation of immune response and hepatocellular carcinoma (HCC). It was anticipated that expression of viral proteins in inbred mice, which possess well-characterized immune systems, would allow detailed studies of the immune response to viral proteins *in vivo*. Use of liver-specific promoter systems has allowed viral protein expression to be targeted to the physiologically relevant site, the hepatocyte. These Tg systems have yielded a number of interesting insights into the biology, immunology and pathogenic potential of these liver-tropic viruses. This chapter attempts to catalogue and characterize a number of the observations made in murine models that have contributed to our understanding of HBV, an important human pathogen.

## Immunogenicity of HBV proteins studied in mice

Table 18.1 lists a number of important observations first described in mice.[1–47] For example, early studies in the

murine system indicated marked strain variation in antibody production after immunization with the hepatitis B surface antigen (HBsAg)/P25 (major envelope protein).[2,3] Further studies in mice that were genetically identical except within the major histocompatibility complex (MHC) indicated a strong influence of MHC-linked genes on the immune response to HBsAg and identified high (H-$2^{d/q}$), intermediate (H-$2^{a}$>H-$2^{b}$>H-$2^{k}$), and non-responder (H-$2^{f,s}$) MHC genotypes.[4] When recombinant HBsAg particles containing the larger molecular weight polypeptides became available, studies were extended to examine genetic influences on the immune responses to pre-S sequences. Production of antibodies against the pre-S2 region after immunization with HBsAg/GP33 (middle envelope protein) is also MHC-restricted. However, the hierarchy of response status among strains differs from that of the S region. Additionally, immunization with HBsAg/GP33 can bypass non-response to the S region in HBsAg/P25 non-responder H-$2^{s}$ mice.[5] The immune response to the pre-S1 region of HBsAg/P39 (large envelope protein) is also influenced by H-2 linked genes, but again the hierarchy of response status differs from the responses to the S and pre-S2 regions. HBsAg/P39 immunization elicited anti-pre-S1-specific antibody on all strains and, furthermore, elicited anti-S and anti-pre-S2-specific responses in 'non-responder' H-$2^{f}$ mice.[6] These data indicated that distinct MHC-linked genes influence S-, pre-S2- and pre-S1-specific antibody production *in vivo*.

The ability of HBsAg/GP33 immunization to bypass S region non-responder status in H-$2^{s}$ mice and of HBsAg/P39 immunization to bypass S and pre-S2 region non-responder status in H-$2^{f}$ mice suggested that although these strains lack an S-specific T-cell response, they must possess pre-S-specific T cells that can 'help' B-cell clones specific for S as well as pre-S region epitopes to produce antibody. Studies of HBsAg and pre-S-specific T-cell responses have confirmed that the mechanism responsible for circumvention of non-responsiveness is mediated at the T-cell level. For example, H-$2^{s}$ mice do not possess T cells that can recognize the S region of HBsAg, but T cells of H-$2^{s}$ mice can recognize the pre-S2 region.[7] These studies indicated that the envelope polypeptides of HBV present an array of T-cell determinants to the host's immune system, the specificity of the T-cell recognition process is influenced by MHC-linked genes, and that T-helper cell recognition of one region can bypass non-response to another region. Because most current recombinant HBV vaccines contain HBsAg/P25 but lack pre-S sequences, a number of the results from murine studies have suggested that inclusion of pre-S sequences in future generation vaccines may be beneficial.

Using inbred murine strains investigators have identified a number of T-cell and B-cell recognition sites on HBV proteins.[22–28,31,32,42,44–48] The epitopes identified largely overlap with sites recognized by the human immune response. Use of synthetic epitopes for *in vitro* neutralization experiments,[10] and *in vivo* immunization with pre-S synthetic peptides[8,9,11–13] have shown that pre-S1 and pre-S2-specific antibodies in the absence of S region antibody can protect chimpanzees against experimental HBV challenge. Furthermore, a number of fully synthetic HBV candidate vaccines have been constructed using epitopes defined originally in mice.[14–19] Additionally, the use of synthetic hepatitis B core antigen (HBcAg) derived T-cell epitopes in mice demonstrated that HBcAg-specific CD4+ T cells can help HBsAg-specific B cells produce anti-HBs antibodies through a mechanism termed intermolecular-intrastructural T-cell help.[20] Athymic mice were used to demonstrate that the HBcAg can elicit anti-HBc antibodies in a T-cell-independent manner, whereas hepatits B 'e' antigen (HBeAg) is a T-cell-dependent antigen.[29] Earlier murine studies had demonstrated that HBsAg, although particulate like HBcAg, functioned as a T-cell-dependent antigen.[1]

Murine studies first revealed that HBcAg and HBeAg both can be cross-reactive targets of CD8+ cytotoxic T lymphocytes (CTLs).[30,31,34] HBeAg and the HBcAg also are cross-reactive at the level of CD4+ T-cell recognition.[32,33] However, in a non-infectious system HBcAg tends to elicit a CD4+ T-cell response of the Th1-like type, whereas HBeAg preferentially elicits a Th2-like response but also may activate a Th1-type response depending on the cytokine milieu.[35] For example, *in vivo* treatment with interleukin (IL)-12 can shift an HBeAg-specific Th2-like response to a Th1-like response in an HBeAg-transgenic (Tg) model.[49] Differential activation of Th cell subsets likely is due to the fact that HBcAg-specific B cells can function as the primary antigen-presenting cell (APC) for HBcAg, whereas the primary APCs for HBeAg are macrophages and dendritic cells.[36] It has recently been shown that HBeAg can enter both the MHC class I endogenous pathway for recognition by CD8+ CTLs and the MHC class II endogenous pathway for recognition by CD4+ T cells. HBcAg cannot enter the class II endogenous pathway.[37] Therefore, hepatocytes producing cytosolic HBeAg may be targeted for destruction by CD8+ and/or CD4+ T cells. This observation may help to explain how an HBeAg-negative mutant virus is selected by the immune response. Importantly, murine studies have suggested that secreted HBeAg may have a number of immunoregulatory properties that the HBcAg does not possess, as discussed later (see Table 18.4 below). A number of unique characteristics of the HBcAg including: ability to self-assemble; particulate structure; T-cell independence; ability to elicit intermolecular-intrastructural Th-cell function; ability to activate prima-

ry B-cell APCs, and the ability to accept the insertion of foreign-cell epitopes into the exposed loop region suggested that HBcAg could function as an efficient HBV and non-HBV vaccine carrier platform. A number of murine studies have validated that prediction.[38–43] Lastly, a non-Tg murine model of HBV replication, immunogenicity and viral control has been reported.[21] After hydrodynamic transfection of hepatocytes *in vivo* with a replication-competent, over-length, linear HBV genome, viral antigens and replicative intermediates were synthesized and virus was secreted. Persistence of virus was dependent on the host immune response. This promises to be a useful model system.

## HBV gene expression and viral replication in Tg mouse models

The first studies using Tg mice focused on the expression of the HBV envelope proteins (Table 18.2).[50–70] These early studies demonstrated that the envelope proteins could be expressed in the liver by using liver-specific promoters or the HBV endogenous promoters.[50–57] Using the endogenous HBV promoters resulted in expression in other tissues in addition to the liver. It was also demonstrated that envelope gene expression is developmentally regulated,[56] and is positively regulated by androgens and glucocorticoids.[57] Transgenic expression of the middle and major envelope proteins led to the assembly and secretion of 22-nm spherical particles as occurs during a natural HBV infection.[54,55] Inclusion of the domain encoding the large envelope protein (pre-S1-containing) in the transgene construct resulted in the assembly of long branching filamentous hepatitis B surface antigen (HBsAg) particles.[54] If the large envelope protein was overexpressed in relation to the middle and major proteins by the use of an exogenous promoter (i.e. albumin promoter), the filamentous HBsAg particles became trapped in the endoplasmic reticulum (ER) and were not secreted by the cell. This secretion defect eventually leads to a dramatic expansion of the ER in the hepatocyte and severe liver injury.[55] It has been suggested that such hepatocytes are analogous to 'ground glass' hepatocytes observed in the liver of chronically infected patients.[55] However, the nature of a putative secretion defect in infected hepatocytes is not clear.

**Table 18.2** HBV gene expression and replication in Tg mice

| Gene expression and replication | References |

| Hepatitis B 'e' antigen | 60,62,63 |
| X protein | 64–66 |
| HBV replication | 67–69 |
| Infectivity of Tg-derived HBV | 70 |

Both HBV nucleocapsid proteins, the particulate HBcAg and the non-particulate HBeAg, have been expressed in Tg mice (Table 18.2). HBeAg is efficiently secreted into the blood, and HBcAg accumulates in the nucleus of hepatocytes.[58–63] Expression of high levels of HBcAg revealed that intact HBcAg particles could not traverse the nuclear membrane in either direction.[58] The non-structural HBV X-protein has also been expressed in Tg mice.[64–66] The X-protein displays transcriptional transactivation properties, and it has been suggested that expression of this protein in the liver may play a role in the induction of hepatocellular carcinoma (HCC), which is associated with chronic HBV infection. In support of this hypothesis, high level liver-specific expression of the HBV X-protein has led to HCC in Tg mice.[64,65] However, other investigators have not observed the induction of HCC in independently derived X gene Tg mice.[66]

Several laboratories have used constructs containing the entire HBV genome and HBV-derived regulatory sequences to produce Tg mice capable of viral replication (Table 18.2). Interestingly, HBV replication occurred in the kidney as well as the liver, and the supercoiled form of HBV DNA (cccDNA) has not been observed in any lineage of Tg mouse.[67–69] In several Tg lineages, high level replication is sustained in 20–30% of primarily centrilobular hepatocytes, although virtually all hepatocytes express nuclear HBcAg.[69] This suggests that hepatocytes infected in a natural infection may not all be equally permissive for HBV replication. High level replication and HBV gene expression are not associated with liver pathology.[67–69] One group has successfully infected chimpanzees with viral particles derived from Tg mice.[70] This model of HBV replication has provided the opportunity to examine the influence of viral and host factors on HBV replication, pathogenesis and clearance, including the effects of the immune response. For example, a number of factors have been shown to be capable of inhibiting HBV replication in the Tg model (see Table 18.3).[71–90] These and other approaches are discussed in the following sections.

In summary, a number of investigators have expressed the structural proteins of the HBV in Tg mice, and these Tg systems have yielded a number of interesting results, which are detailed below. However, one

**Table 18.3** Inhibition of HBV gene expression and/or replication in Tg mice

| Inhibition | References |
|---|---|

IFN, interferon.

important conclusion from these studies is that the viral proteins themselves are not directly cytopathic within the liver. The only exception is the overexpression of the HBV large pre-S1-containing protein leading to a secretion defect.[55]

## Tg models of HBV pathogenesis and liver injury

Studies employing the adoptive transfer of CD8+, HBsAg-specific CTLs into HBV envelope-expressing Tg mice have demonstrated that CTLs can induce an acute necroinflammatory liver disease similar to that of natural acute HBV infection (see Table 18.3). The investigators described a three-step process through which the liver disease progresses. The first step involves the attachment of the donor CTLs to HBsAg-positive hepatocytes, which are triggered to undergo apoptosis. Thereafter, between 4 and 12 hours after injection, the CTLs recruit host-derived antigen-non-specific inflammatory cells (i.e. polymorphonuclear cells) that amplify the effects of the CTL (step 2).[71,72] This process results in necroinflammatory foci in which hepatocellular necrosis extends well beyond the location of CTLs, suggesting that most hepatocytes are killed by cells other than the donor CTLs. In these studies, the liver injury in most Tg lineages is transient and is confined to no more than 5% of hepatocytes. However, in recipient Tg mice that overexpress and accumulate HBsAg filaments (see above), the disease process proceeds to step 3, in which approximately half of the mice die of liver failure within 24–72 hours of CTL transfer.[73] The investigators suggest that this process resembles the histopathological features of HBV-induced fulminant hepatitis in humans, characterized by widespread necrosis of HBsAg-laden hepatocytes and diffuse lymphomononuclear inflammatory cell infiltrate and Kupffer cell hyperplasia.[73]

This same group of investigators has developed a model of prolonged chronic immune-mediated (CTL) hepatitis in HBV envelope Tg mice.[74] This was accomplished by transferring HBsAg-specific CTLs into thymectomized, irradiated, bone marrow-reconstituted envelope-Tg recipients. In addition to chronic hepatitis, the Tg recipients eventually (17 months) developed HCC, suggesting that a prolonged inflammatory immune response to an HBV protein can cause liver cancer,[74] consistent with a number of observations in chronically infected humans.[91]

In addition to the direct hepatocyte injury triggered by HBsAg-specific CTLs, a second non-cytolytic mechanism has been described in which the cytokines secreted by the HBsAg-specific CTLs profoundly suppress hepatocellular HBV gene expression and HBV replication in Tg mice.[76,77] The cytokines responsible for these non-cytolytic antiviral effects were CTL-derived interferon (IFN)-γ and CTL-induced tumour necrosis factor (TNF)-α.[76] The antiviral regulatory potential of inflammatory cytokines was confirmed by the fact that administration of recombinant TNF-α,[75] IL-18,[79] IL-2 and to a lesser extent IFN-α and IFN-β,[78] also inhibited HBV gene expression in HBV envelope Tg mice. In addition, direct cytokine-mediated antiviral effects on HBV replication and gene expression have been confirmed *in vitro* in immortalized HBV-Tg mouse hepatocytes.[92,93]

Inhibition of HBV DNA replication and HBV gene expression occur through independent mechanisms that exhibit distinct kinetics and cytokine dependence. The antiviral effects of cytokines in the murine model occur in two phases: (1) HBV DNA replicative intermediates disappear from the liver with no change in viral mRNA; and (2) HBV mRNA is down-regulated at a later time point.[76,81,84] It was demonstrated that HBV replication is inhibited by IFN-α/β at the level of assembly or stability of pregenomic RNA-containing HBV capsids[94] and, further, that this process is proteosome-dependent.[88] In terms of HBV gene expression, the effects of cytokines can be mediated at the post-transcriptional[76,85,86] or the transcriptional level[87] depending on the antiviral stimu-

lus. For example, HBV gene expression was controlled transcriptionally after repeated injections of polyinosinic-polycytidylic acid (poly I/C), an IFN-α/β inducer. Recently, the source of the inflammatory cytokines responsible for inhibition of HBV gene expression has been extended to include CD4+ T-helper (Th)1 cells,[80,83] NKT cells[81] and activated intrahepatic APCs.[82] Furthermore, it was demonstrated that HBsAg-specific CD4+ Th cells could be elicited by DNA immunization in HBsAg-Tg mice.[83]

## Tg models of persistence and/or tolerance

The function of the HBeAg is largely unknown because it is not required for viral assembly, infection or replication.[95–97] However, the HBeAg does appear to play a role in viral persistence. It has been suggested that the HBeAg may promote HBV chronicity by functioning as an immunoregulatory protein.[63,98] Infants born to HBeAg-positive HBV carrier mothers invariably become persistently infected. In contrast, infants born to HBeAg-negative HBV carrier mothers rarely become chronically infected and can often experience fulminant hepatitis.[99] To investigate the role of immunological tolerance mechanisms in chronic infection of the newborn, HBeAg-expressing Tg mice have been generated. HBeAg-Tg mice represent a model system to examine the consequences of *in utero* exposure to HBeAg on HBc/HBeAg-specific immune responses (see Table 18.4).[63,83,98,100-107] Characterization of tolerance in HBeAg-Tg mice and mice rendered neonatally tolerant indicated that T cells but not B cells were tolerized by HBeAg present in the serum at a concentration of 10–100 ng/ml; that T-cell tolerance elicited by HBeAg also extends to HBcAg-specific T cells; that Tg mice produced anti-HBc but not anti-HBe antibodies upon immunization; that the IgG but not the IgM anti-HBc response was diminished in HBeAg-Tg mice; and that the T-cell tolerance induced by a single neonatal exposure to HBeAg was reversible and persisted for 12–16 weeks.[63] Many characteristics of immune tolerance found in HBeAg-Tg mice parallel the long-term immunological status of neonates born to HBeAg-positive HBV carrier mothers, suggesting that the aberrant immunological responses of neonates born to carrier mothers may result from *in utero* exposure to HBeAg, as occurs in the Tg model. In support of the possibility that maternal HBeAg may traverse the placenta, non-Tg littermates born to HBeAg-Tg mothers were tolerant to HBc/HBeAg.[63] Although the ability of HBeAg to cross the murine placenta has been questioned,[108] HBeAg has been detected in the neonatal cord serum of infants born to HBeAg-positive HBV carrier mothers by an increasing number of investigators.[109–112] Furthermore, recent studies in HBeAg-Tg mice, which do not express the HBeAg until several days after birth, indicate that perinatal exposure to HBeAg is sufficient to elicit HBe/HBcAg-specific Th cell tolerance, which may diminish the requirement for HBeAg to cross the placenta in order to have a tolerogenic effect during perinatal infection.[100]

The precore region encoding the HBeAg is also conserved in the avian hepadnaviruses, in which *in utero* tolerance mechanisms are not relevant, suggesting an alternative role for HBeAg. Because adult infection with an HBeAg-negative variant is often associated with a fulminant course, HBeAg may play an immunoregulatory role in adult infection in addition to its effects on neonatal tolerance. As a model of chronic HBeAg exposure and to examine the tolerogenic potential of the HBeAg, HBc/HBeAg-transgenic (Tg) mice crossed with T-cell receptor (TCR)-Tg mice expressing receptors for the HBc/HBeAgs (i.e. TCR/Ag double-Tg pairs) have been produced. In a recent study, serum HBeAg was shown to be tolerogenic for HBc/HBeAg-specific TCR-Tg T cells and three distinct phenotypes of tolerance were observed in double-Tg mice.[100] One phenotype, illustrated by a high avidity (8/12–2) TCR-Tg lineage, was profound tolerance induction by the HBeAg even at very low serum concentrations (10 ng/mL) most likely mediated by clonal deletion and FAS-mediated apoptosis in the periphery. A second phenotype, represented by a low avidity (11/4-12) TCR-Tg

**Table 18.4.** Mouse models of HBV persistence or tolerance

| Model | References |
|---|---|
| Secreted HBeAg may induce T-cell tolerance *in utero* | 63 |
| Exposure to HBeAg perinatally induces T-cell tolerance | 100 |
| T-cell tolerance to the HBeAg is variable and MHC-dependent | 100,101 |

| Use of T-cell receptor (TCR)-Tg mice to study tolerance | 100,102,103 |
| Tolerance to the HBsAg can be broken *in vivo* | 83,104–107 |

lineage, is one of clonal ignorance in which low avidity HBc/HBeAg-specific T cells are neither tolerized nor activated by co-existence with even high concentrations of HBc/HBeAg and remain quiescent *in vivo*. However, 11/4-12 TCR-Tg T cells can be activated by antigen *in vitro* and can mediate liver injury upon adoptive transfer into HBc/HBeAg-Tg recipients.[103] The third tolerance phenotype, illustrated by an intermediate avidity (7/16-5) TCR-Tg lineage, is non-deletional and HBeAg concentration-dependent and is best described as adaptive tolerance or *in vivo* anergy. Exposure of 7/16-5 T cells to high concentrations of serum HBeAg *in vivo* does not result in clonal deletion in the thymus or the periphery, but instead the ability of the T cells to produce cytokines or proliferate to recall antigens *in vitro* and to provide T-cell help for *in vivo* anti-HBe antibody production is severely compromised. Importantly, this form of HBeAg-specific T-cell anergy is reversible in the absence of HBeAg, the tolerogen.

In the context of a chronic HBV infection, a multiplicity of HBeAg-specific T-cell clones are likely to co-exist, as demonstrated in the TCR/Ag double-Tg systems, and the balance between activation or tolerance status among the heterogeneous HBeAg-specific T-cell repertoire may influence degrees of liver injury and viral clearance. High avidity HBeAg-specific T-cell clones are likely to be physically or functionally deleted and not available to participate in antiviral clearance mechanisms after a chronic infection has been established. Intermediate or low avidity HBeAg-specific T-cell clones that are not physically deleted at least have the potential to be activated either through the reversal of adaptive tolerance (anergy) or the primary activation of 'ignorant' HBeAg-specific T cells (Fig. 18.1). Therefore, treatment modalities for chronic HBV infection should be directed at activating these relatively low avidity HBeAg-specific T cells. Given the efficacy of the current antiviral drugs in terms of reducing HBV and antigen load, reversing HBeAg-specific adaptive tolerance by reducing or eliminating circulating levels of the HBeAg may be an achievable goal and may in fact explain viral clearance in a percentage of chronic patients on long-term antiviral therapy.

Recent studies also demonstrated a 'split T-cell tolerance' between HBeAg and HBcAg. Secreted HBeAg appears significantly more efficient at eliciting T-cell tolerance than HBcAg.[100,102] In fact, one TCR × HBc double-Tg pair spontaneously seroconverts to anti-HBc positivity at an early age. However, the presence of serum HBeAg in TCR × HBc × HBe triple-Tg mice prevents anti-HBc seroconversion. Therefore, HBeAg can function as an immunoregulatory protein. HBeAg mediates its immunoregulatory effect by eliciting tolerance in HBc/HBeAg-specific T cells. These results suggest that hepadnaviruses have retained a secretory form of the nucleoprotein because it functions as a T-cell tolerogen and regulates the immune response to the intracellular nucleocapsid. Efficient T-cell tolerance induction by HBeAg is probably related to its monomeric structure and the fact that it is continuously secreted into the serum. Because HBeAg is secreted, it can transit to the thymus and induce central tolerance by deleting HBe/HBcAg-specific Th cells. Secreted HBeAg also may cause deletion of HBeAg/HBcAg-specific Th cells in the periphery by inducing apoptosis primarily in Th1-type cells.[98] Non-deletional mechanisms of tolerance (i.e. clonal anergy, clonal ignorance and Th1/Th2 cross-regulation) also have been described for HBeAg.[100,113] To demonstrate that the immunoregulatory function of the HBeAg is not unique to TCR-Tg murine systems, we recently compared the effects of activating HBc/HBeAg-specific polyclonal T cells in HBeAg-expressing, HBcAg-expressing and dual HBeAg × HBcAg-expressing Tg mice (Fig. 18.2). Injecting the dominant T-cell peptide (p129–140) into HBc-Tg mice elicited efficient anti-HBc seroconversion, whereas HBe-Tg mice were tolerant. Interestingly, anti-HBc seroconversion was significantly inhibited in p129–140-injected, HBc × HBe double-Tg mice (Fig. 18.2a). The HBcAg-specific T-cell responses, measured by IFN-γ production, in the three Tg lineages paralleled *in vivo* antibody production (Fig. 18.2b).

Assuming an immunoregulatory role for HBeAg in natural HBV infection, as suggested by these recent murine studies, one would predict that infection with an HBeAg-negative mutant virus would result in enhanced antiviral immune responses and decreased rates of chronicity. The clinical evidence is largely consistent with this prediction. A number of common mutations in the precore region[114] or in the core promoter region[115] either abrogate or reduce HBeAg synthesis, respectively. Neonates infected with HBeAg-positive wild-type HBV predominantly (90%) become chronically infected, whereas neonates infected with HBeAg-negative mutant viruses experience an acute infection often accompanied by fulminant hepatitis indicative of an enhanced immune response.[99] Similarly, there is a correlation between adult infection with HBeAg-negative mutant viruses and acute fulminant hepatitis.[116,117] Further, emergence of an HBeAg-negative mutant virus during chronic HBV (CHB) infection can lead to exacerbation of liver injury and a poor prognosis, especially if the HBeAg-negative mutant becomes predominant during periods of high viral load.[118,119] However, other reports suggest that emergence of an HBeAg-negative variant during CHB correlates with less liver injury and viral clearance.[120] A recent study by Chu *et al*.[118] may

help resolve this issue. At baseline, most CHB patients possessed mixed viral populations (HBeAg-positive/HBeAg-negative). However, predominance (>50%) of the HBeAg-negative variant before seroconversion hastened the interval to seroconversion, correlated with persistent viraemia and alanine aminotransferase (ALT) level elevations for at least 6 months after seroconversion, and correlated with an increased rate of cirrhosis. This study indicated that the timing of the emergence of an HBeAg-negative variant along the course of the chronic infection is one critical factor in determining the effects of the HBeAg-negative mutation during CHB infection and illustrates the difficulty of interpreting the data from a heterogeneous patient population.

We suggest that the ability of serum HBeAg to function as a T-cell tolerogen and to downregulate the immune response to the HBcAg results in the moderation of HBcAg-specific liver injury during an acute infection and in the promotion and maintenance of viral persistence during a chronic infection. Taken together, the clinical

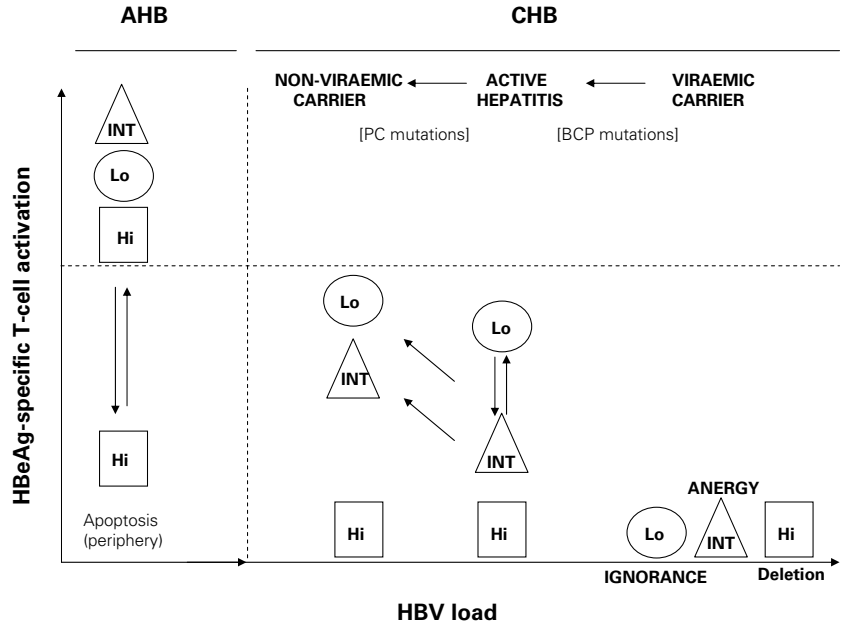

**Figure 18.1** Schematic illustrating the clonality and heterogeneity of HBeAg-specific T-cell tolerance and the possible consequences of the reversal of tolerance during different phases of chronic HBV (CHB) infection. During the so-called 'tolerance phase' or viraemic carrier state the vast majority of HBeAg-specific T-cell clones, including high (□), intermediate (Δ), and low (o) avidity clones, are tolerized by serum HBeAg. The mechanism of T-cell tolerance differs depending on avidity of each clone (see text). The maintenance of the HBeAg-specific T-cell clones in the various tolerance phenotypes (i.e. deleted, anergized or ignorant) depends on the presence of relatively high concentrations of HBeAg and a relatively non-inflammatory hepatic setting as exists in the tolerance phase of a chronic infection or in the neonate at the time of infection. The tolerance phenotypes of low and intermediate T-cell clones, which are NOT physically deleted, can be reversed should the level of the tolerogen (HBeAg) decrease, perhaps due to the emergence of common basal core promoter (BCP) region or precore (PC) mutations, or the hepatic environment becomes more inflammatory. In any event, the activation of previously 'ignorant' low avidity T cells or reversal of anergy in intermediate HBeAg-specific T cells may further reduce HBeAg concentration and/or increase inflammation and shift the balance away from T-cell tolerance and towards HBe/HBcAg-specific T-cell activation. Loss of tolerance in one HBeAg-specific T-cell clone is likely to influence the activation of other T cells via production of inflammatory cytokines, etc. Such a shift in the virus–host relationship may precipitate the so-called 'clearance phase' of chronic HBV infection. During the clearance phase the immune response becomes more active in reducing viral load, in provoking liver injury and in selecting escape mutants. Once a sufficient percentage of the HBeAg-specific repertoire has become activated, HBeAg ceases to be an effective tolerogen and may in fact become a target (i.e. cytosolic HBeAg) of the immune response together with the more immunogenic HBcAg. In this environment, selection of an HBeAg-negative mutant becomes more efficient. The reason the HBeAg-negative virus is not entirely successful in evading immune attack and may even lead to more severe liver injury in some circumstances (see Fig. 18.3) may be due to the loss of the immunoregulatory properties of serum HBeAg, which tend to downregulate the HBcAg-specific response. During an adult, acute HBV (AHB) infection the HBeAg-specific T-cell repertoire is more likely to be activated as opposed to tolerized due to an inflammatory environment in the liver. Even during an acute infection, serum HBeAg may have some regulatory function by eliciting early apoptosis of high avidity HBe/HBcAg-specific T cells in the periphery.

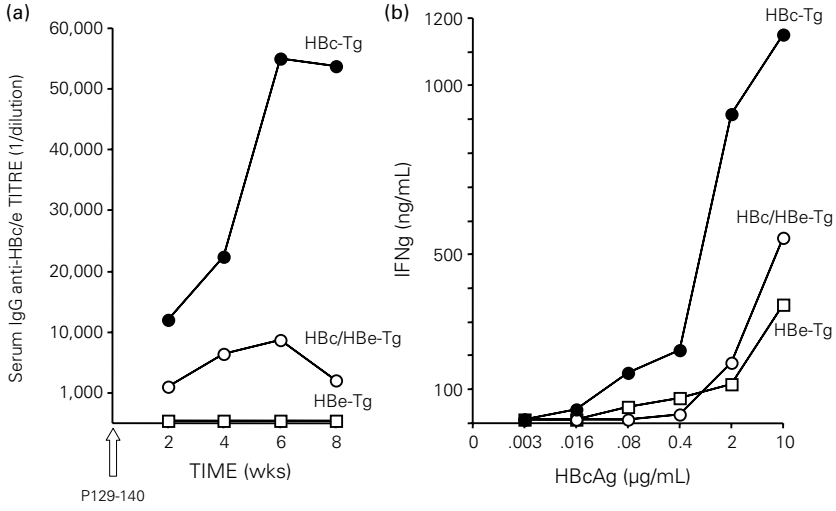

**Figure 18.2** Split T-cell tolerance between the HBeAg and the HBcAg and the immunoregulatory effect of serum HBeAg on the humoral and cellular response to the HBcAg. Groups of B10 HBcAg-Tg (HBc-Tg), HBeAg-Tg (HBe-Tg) and HBcAg × HBeAg double-Tg (HBc/HBe-Tg) mice were injected with the dominant T-cell activating peptide (p129–140), and anti-HBc or anti-HBe seroconversion was monitored by ELISA at the times shown (a). Ten weeks after p129–140 injection, spleen cells were harvested and cultured *in vitro* with varying concentrations of the HBcAg and T-cell activation was determined by IFN-γ production measured in the supernatant by ELISA (b).

observations and murine experimental studies suggest that the HBeAg is important in biasing the virus–host interaction towards chronicity and accomplishes this by downregulating the host T-cell response to the nucleocapsid antigens via a variety of tolerance-inducing mechanisms. The schematic in Fig. 18.3 illustrates the possible important relationship between HBeAg-specific T-cell tolerance, HBV viral load and liver injury. Perinatal or adult primary infection with wild-type (HBeA-positive) HBV results in no or relatively mild liver disease due to the presence of HBeAg-specific T-cell tolerance mechanisms, respectively. During the course of a wild-type chronic HBV (CHB) infection, HBeAg-negative mutants often accumulate with time, reflecting the loss of HBeAg-specific T-cell tolerance as the immune response selects the mutants. Simultaneously, the immune response is reducing viral load, and therefore, only moderate liver injury occurs. It is only when HBeAg-specific T-cell tolerance is lost and the HBeAg-negative mutant predominates in the presence of high viral load that liver injury can become more severe. The most extreme example of high viral load and the complete absence of HBeAg-specific T-cell tolerance is primary infection with an HBeAg-negative mutant virus. Either perinatal or adult infection with an HBeAg-negative virus correlates with a significantly increased risk of severe liver injury.

## Modulation of the immune response to HBV proteins in Tg mice

Tolerance to the HBeAg in Tg mice is MHC-dependent. Tolerance to HBeAg is complete in HBeAg-expressing Tg mice on an H-2$^s$ genetic background, and incomplete on HBeAg-Tg mice on an H-2b background at relatively low concentrations of serum HBeAg (10 ng/mL).[101] At high serum HBeAg concentrations (4–10 μg/mL) even H-2$^b$ mice are largely tolerant.[100] However, a population of functional, 129–140 peptide-specific Th cells co-exists with low levels of circulating HBeAg in

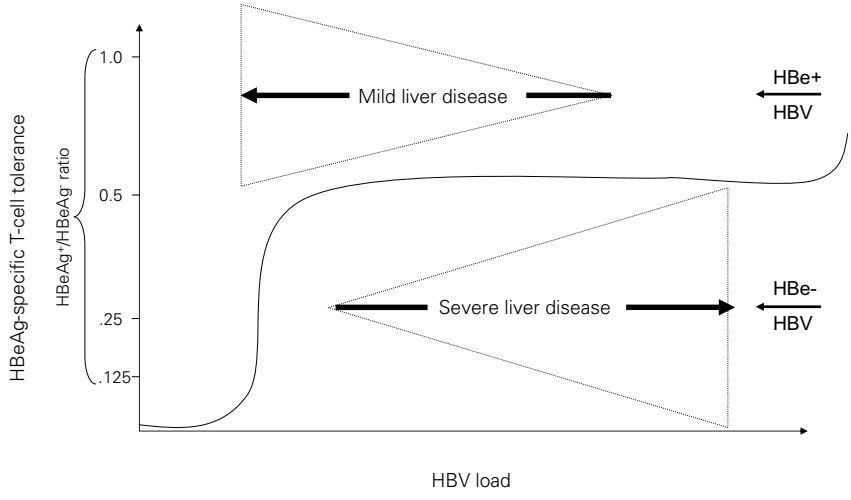

**Figure 18.3** Schematic of a putative relationship between HBeAg-specific T-cell tolerance, viral load and liver injury. The predominance of HBeAg-positive wild-type HBV (above the line) is associated with milder forms of liver injury and liver injury is inversely correlated with viral load. In contrast, predominance of HBeAg-negative mutant viruses (below the line) is associated with more severe forms of liver injury and liver injury is not necessarily inversely correlated with viral load. The triangles represent the degree of liver injury. See text for a discussion.

B10 HBeAg-Tg mice. The Th cells that evade deletion in HBeAg-Tg mice are quiescent unless activated by a dose of the 129–140 peptide as low as 0.6 μg, which induces anti-HBe seroconversion.[101] This model has been useful to test reagents that may modulate anti-HBe seroconversion. For example, soluble CD 152 (cytotoxic T-lymphocyte antigen-4) has been shown to suppress anti-HBe seroconversion in this model.[121] Similarly, IL-12 suppresses anti-HBe 'autoantibody' production and skews the Th cells toward the Th1 subset.[122] Finally, injection of an envelope (pre-S2) T-cell site peptide that binds the same MHC class II molecule as the 129–140 peptide inhibits anti-HBe seroconversion by competitively binding to $IA^b$ and preventing the activation of 129–140 peptide-specific Th cells.[101] This may have important implications during a natural HBV infection because envelope proteins circulate in tremendous excess of the HBeAg. Therefore, 'intraviral' protein competition for MHC binding sites may be a viral strategy to saturate MHC molecules and prevent less abundant, and possibly more relevant, T-cell recognition sites from gaining access to antigen presentation.

HBsAg-expressing Tg mice have also been shown to be tolerant at the T-cell level.[107] Nevertheless, several groups have induced seroconversion to the HBsAg in Tg mice. Immunization of HBsAg-Tg mice with HBsAg in adjuvant induced low level anti-HBs production, approximately 500-fold less than in non-Tg littermates.[105,107] Similarly, multiple immunizations with an HBsAg-vaccinia recombinant virus elicited low level anti-HBs seroconversion.[107] Induction of seroconversion to the HBeAg, the HBcAg or the HBsAg has not resulted in liver injury, indicating that antibodies specific for these viral antigens are not pathogenic. However, activated TCR-Tg HBc/HBeAg-specific T cells adoptively transferred into HBcAg-Tg recipients elicited low level liver injury with an interesting pattern of recurring and remitting ALT elevations.[103] Recently, one group immunized HBsAg-Tg mice with a DNA construct coding for the HBsAg and reported anti-HBs seroconversion, CD4+ Th cell priming and inhibition of HBsAg gene expression, probably due to IFN-γ production.[83] Finally, one group has suggested that the lack of anti-HBs production by HBV chronic carriers and in HBsAg-Tg mice is due to defective function of APCs rather than immune tolerance.[104] It was suggested that circulating HBsAg reduced MHC class II and B 7.2 (CD86) expression on dendritic cells in HBsAg-Tg mice. Treatment with IFN-γ or replacement of Tg dendritic cells with dendritic cells from non-Tg mice allowed Th cells from HBsAg-Tg mice to mediate anti-HBs production *in vitro*.

## Tg mice and hepatocellular carcinoma (HCC)

Several investigators have reported the occurrence of cancerous lesions in the livers of mice transgenic for various HBV proteins (Table 18.5).[54,64–66,74,123] As stated earlier, Tg mice expressing increased amounts of the HBV pre-S1-containing large envelope protein demonstrate an ER storage disorder, leading to massive hepatocyte death, causing a secondary inflammatory and regenerative response that eventually leads to HCC in mice strains that have a low incidence of spontaneous HCC.[123] Although excess pre-S1 protein is unlikely to accumulate in natural infection, a link between chronic liver injury and HCC has been demonstrated in a number of systems, including a recent Tg model of immune-mediated chronic hepatitis by these same investigators.[74] High-level expression of the HBV X-protein can also lead to HCC in Tg mice,[64,65] although other investigators have not observed the induction of HCC in independently derived X gene-Tg mice.[66] This discrepancy may relate to the level of expression or the genetic backgrounds of the mice. The Tg mice that developed HCC were produced on a CD1 background, which displays a high spontaneous rate of HCC.

**Table 18.5** Tg mice as a model for hepatocellular carcinoma

| Model | References |
|---|---|
| Overexpression of the HBV pre-S1 protein | 54,123 |
| High level expression of the HBV X-protein | 64–66 |
| Long-term chronic hepatitis | 74 |

# Chapter 19
# Pathogenesis of chronic hepatitis B

Mark R Thursz, Howard C Thomas

## Introduction

The epidemiological studies of hepatitis B virus (HBV) infection produce some remarkable statistics: worldwide 2 billion people have been infected, 350 million are persistently infected and 1 million people a year die as a result of the infection. These statistics generate important questions about the biology of HBV infection which we will address in this chapter. Specifically, those questions are:

**1** Why do some individuals clear the infection whilst others develop persistent infection?

**2** How does the virus cause liver cell damage and fibrosis?

In order to address these questions, it is vital to review the immunological responses to HBV which have been studied in patients with self-limiting or persistent infection and in animal models (see Chapters 12, 13 and 18).

The important question of how the virus causes liver cancer is addressed in Chapter 17.

## Immunological response to HBV

### Innate immunity

The initial line of defence is antigen non-specific and is mediated by the type 1 interferons (IFNs) and cells of the innate immune response, including natural killer (NK) and NK-T cells and macrophages. Type I IFNs are a family of monomeric cytokines with an amino acid similarity of 30–80%, very similar three-dimensional structure (5-α helix-bundle), that use the same receptor (IFNAR) to initiate a signalling response. The genes for type I IFNs do not contain introns and are located on chromosome 9 (9p21.3). They are strongly induced by virus infection, bacterial endotoxin (LPS), double-stranded RNA (dsRNA) and other immunostimulatory molecules, such as interleukin (IL)-1, IL-2 and tumour necrosis factor (TNF)-α. In viral infection IFN induction may be mediated by toll-like receptors (TLRs). TLR3 and TLR7 respond to double-stranded or single-stranded RNA, respectively, whilst TLR9 responds to hypomethylated CpG DNA, features which distinguish viral genomes and replication intermediates from host nucleic acid.[1–3]

Almost all cells have the ability to synthesize type I IFNs, although α-IFNs are mainly produced by lymphoblastoid cells and IFN-β by fibroblasts. Once secreted in response to an infection, after binding of the IFN to the cellular receptor, a signal transduction pathway results in the activation of a large number of cellular genes which inhibit viral replication and enhance the activity of the cells of the innate and adaptive immune responses[4] (Fig. 19.1).

Type 1 IFNs stimulate NK and NK-T cells, which recognize infected cells that are no longer displaying major histocompatibility complex (MHC) class 1 molecules.[5] NK-T cells are a resident population in the liver (see Chapter 2), representing 1% of the hepatic cells in humans, while NK cells are recruited actively from the spleen during the early phase of an infection.[6] NK cells induce apoptosis of virally infected cells and secrete IFN-γ, which suppresses viral replication and activates adaptive immune responses. NK-T cells are also important in regulating cellular immune responses. These components of the host response are therefore likely to be important in determining outcome of HBV infection.

### Adaptive immunity

Dendritic cells (DCs) act as a link between innate and adaptive immunity. Signals delivered by the innate immune system (type 1 IFNs) and contact with NK cells lead to maturation of DCs, which are critical in initiating the adaptive immune response. Virus-specific immunity is induced by DCs presenting viral antigens to T and B lymphocytes in the regional lymph nodes (Fig. 19.2). Thereafter, viral specific T-helper cells are activated and these cells initiate the antiviral immune responses of B lymphocytes and cytotoxic T lymphocytes (CTLs). Early, vigorous and multi-specific T-cell responses are associated with viral clearance, whereas low magnitude

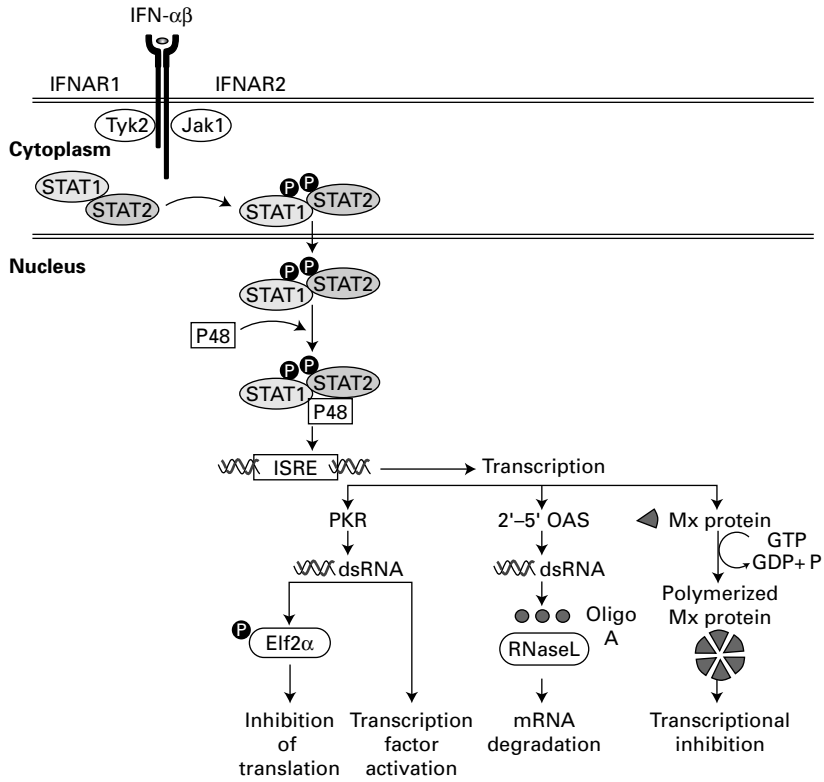

**Figure 19.1** Interferon-α and -β (IFNαβ) interact with the IFN-α receptor which is composed of two subunits (IFNAR1 and IFNAR2). Formation of the IFN–IFN receptor complex leads to autophosphorylation and to phosphorylation of the janus activating kinases (Jak1 and Tyk2). These in turn phosphorylate the signal transduction and activators of transcription molecules (STAT1 and STAT2) which form a complex with P48 (ISGF3), which binds to IFN-sensitive response elements (ISRE) in the regulatory regions of IFN-stimulated genes such as myxovirus resistance gene (MxA), the RNA-dependent protein kinase (PKR) and the 2′5′-oligoadenylate synthetase genes (2′5′-OAS).

oligospecific T-cell responses are associated with viral persistence[7] (Fig. 19.3).

After recognition of viral antigens, T-helper lymphocytes are differentiated to Th1 and Th2 cells according to the type of secreted cytokines. Th1 cells produce antiviral cytokines (IL-2, IFN-γ, TNF-α) and cytokines IL-2, IL-12 and IL-18, which are responsible for effective activation of CTLs. In contrast, Th2 cells secrete IL-4, IL-5 and IL-10, which are involved in activation of B lymphocytes and in production of neutralizing antibodies. It is likely that the failure to generate a strong Th1-lymphocyte response leads to inadequate activation of antigen-specific CTLs. These findings suggest that viral clearance is associated with the early devel-

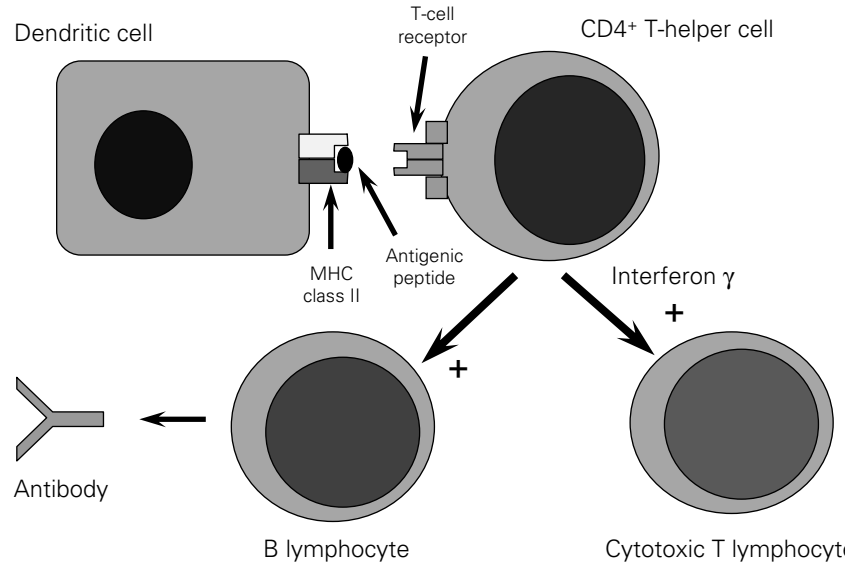

**Figure 19.2** MHC class II products and T-cell responses in acute hepatitis B. During acute hepatitis, the efficiency of antigen presentation is determined by the affinity of the HBV core peptides for the patient's MHC class II proteins. The resulting CD4 response is predominantly Th1 – cells produce IL-2 and IFN-γ – and induces a strong CTL response.

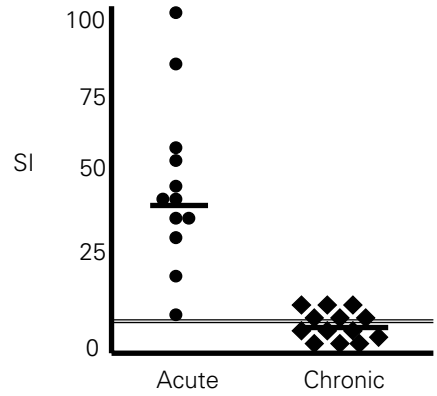

**Figure 19.3** T-cell proliferative responses to the nucleocapsid antigen (HBcAg) of HBV differ in both magnitude and breadth in acute and chronic infection (Tsai *et al.*, 1992).

opment and adequate mounting of the antiviral multispecific immune responses of T-helper and cytotoxic T lymphocytes.

### Cytokine control of viral replication

Type I IFNs induce the expression of more than 100 different genes.[8] Among these IFN-modulated genes are many which control intracellular viral replication. MxA is a GTPase from the dynamin family which, when induced by IFN, forms tubular structures associated with the endoplasmic reticulum.[9] In some viral infections MxA has been shown to associate with nucleocapsids, suggesting that it inhibits virion assembly.[10] The oligoadenylate sythetase gene product OAS is induced by IFN and activated by double-stranded RNA, usually from viral replication intermediates. OAS produces 2′,5′-oligoadenylate which activates the endonuclease RNAseL, thereby inhibiting protein translation. IFN-α suppresses viral replication *in vitro* and also *in vivo* before adaptive immune responses are detectable.

In a transgenic mouse model of HBV, Guidotti and colleagues demonstrated that CTLs controlled viral 'replication' even when there were insufficient CTL numbers to explain the degree of control on the basis of hepatocyte lysis.[11,12] Further experiments demonstrated that control of viral replication was achieved by secretion of TNF-α and IFN-γ. It is therefore likely that control of HBV replication by both the innate and adaptive immune systems is mediated through cytokines in addition to the elimination of infected hepatocytes by NK cells and CTLs.

## Self-limiting infection

The majority of individuals infected with HBV in childhood and adult life develop a clinical or subclinical self-limiting acute hepatitis, with spontaneous clearance of hepatocytes supporting HBV replication or suppression of viral expression, within a few weeks of infection. Some individuals infected with HBV, however, develop chronic infection. The age at which an individual is infected determines the likelihood of the development of chronic infection. Of babies born to mothers with chronic replicative HBV infection (usually, but not invariably, hepatitis B e [HBe] antigen-positive), 98% become infected, and 95% of these will develop persistent infection.[13] However, only 10–15% of children and <5% of adults infected with HBV develop chronic infection.

### Acute HBV infection

The existence of a period of viraemia without liver damage in the prodromal phase of acute infection[14] and of carriers with high level HBV replication without liver damage[15] suggests that HBV itself is not directly cytopathic. Recovery from HBV infection depends on the integrated activities of the patient's innate and adaptive cellular and humoral immune systems and the cytokine network. In acute infection, the production of IFN-α, followed by the induction of the cellular arm of the immune system, results in recognition and destruction of HBV-infected hepatocytes. The humoral (antibody) response to epitopes on the lipid-protein coat that envelops the virus is believed to be responsible for protective immunity against reinfection. Several cell types contribute to the immune response during acute HBV infection (Fig. 19.1).

### Innate response

Cells infected by virus secrete IFN-α, which acts through cell surface receptors to induce a number of antiviral responses. IFN increases the expression of MHC class I molecules, which expose viral antigens to the immune system.[16,17] IFN-α also induces the expression of proteins such as 2–5 A oligoadenylate synthetase and a protein kinase, which inhibit viral replication. The presence of circulating IFN-α at the onset of viraemia may explain the fever and malaise that most patients report 2–3 weeks before they develop dark urine, pale stools and icterus.[16]

### CD4+ T-helper cells (Th)

Soluble and particulate antigens are taken up by antigen-presenting cells (APCs). The antigen is digested into peptide fragments of 10–20 amino acid length, and these bind with varying affinity to MHC class II glycoproteins within the phagosome or endosome. These peptide/MHC complexes are transferred to the cell surface where they may interact with T-cell receptors of Th cells. When this interaction is coupled with the interaction of

co-stimulatory molecules such as B7 and ICAM-1 with their respective ligands, then Th cells will be primed and undergo proliferation. In the absence of co-stimulatory signals Th cells may be rendered anergic.

During acute HBV infection, there is a vigorous MHC class II-restricted Th response to the nucleocapsid antigens of HBV.[18] In contrast, Th responses to the envelope antigen (HBsAg) are virtually undetectable.[19] T-helper responses to the X and polymerase proteins have not been adequately documented for comparison.

T-helper lymphocytes recognize a number of peptide epitopes from the nucleocapsid antigens. The amino acid sequences between positions 1 and 20 and 50 and 69 appear to be recognized by most HBV-infected subjects, irrespective of MHC class II type.[18]

The mechanism by which these T-helper responses induce viral clearance are not adequately documented. However, by analogy to other immunological systems, the likely mechanism can be inferred. CTL responses are dependent on a strong Th response mediated through secretion of cytokines.[20] CTLs are stimulated by the Th1-secreted cytokines, specifically IL-2, IL-12, IL-18 and IFN-γ. CTL responses in acute HBV infection are vigorous and polyclonal and occur in temporal association with the Th responses, whereas in chronic infection CTLs are virtually undetectable.[7,21]

Th responses are also required to support B-lymphocyte production of anti-HBs.[22] As the envelope-specific Th response is poor, even in acute self-limiting infection, it is widely accepted that the nucleocapsid-specific T-helper response supports anti-HBs production. In the mouse, intermolecular help for anti-HBs production has been demonstrated.[22] It is thought that uptake of complete virions by HBsAg-specific B cells leads to expression of nucleocapsid peptides on MHC class II molecules.[23] This leads to further stimulation of nucleocapsid-specific T cells, which support B-cell maturation.

Certain MHC class II alleles (DRB1*1302) are associated with acute infection followed by recovery.[24] The mechanism underlying this association is not clear, but it is likely that the Th response induced by DRB1*1302 is qualitatively or quantitatively superior to that induced by other MHC class II alleles. In support of this, it has been shown that in mice, the MHC class II haplotype determines the Th1/Th2 phenotype of Th cells responding to nucleocapsid antigen stimulation.[25] Furthermore, Diepolder and colleagues demonstrated that Th responses to HBcAg were stronger in patients with HLA-DRB1*1302 that in those who did not possess this allele.[26]

Although it would be expected that a Th1-dominant response would enhance viral clearance (Fig. 19.1), characterization of lymphocytes derived from liver specimens has found predominantly Th1 cells in both acute and chronic HBV infections.[18] This suggests that it is the magnitude and breadth of the Th response rather than the balance between Th1 and Th2 which determines the success of viral clearance. This is supported by the failure of the Th1 stimulant IL-12, to facilitate clearance.[27]

## CTLs and NK cells

Analysis of the inflammatory infiltrate in patients with acute hepatitis demonstrates the presence of natural killer (NK) and cytotoxic T cells.[28,29] Increased NK functional activity has been demonstrated in the blood of patients with early acute HBV infection,[30] and it is probable that this is induced by IFN-α, as has also been demonstrated in the serum of chimpanzees during the prodromal phase of acute HBV infection.[16]

Viral antigens are present on the surface of the hepatocyte,[31–3] and it is probable that these and viral peptides associated with the MHC class I glycoproteins make the cell a target certainly for cytotoxic T-cell lysis[34–37] and possibly for antibody/complement lysis.[38] Uninfected hepatocytes usually express very little MHC class I glycoprotein but in the early stage of acute HBV infection, after the production of IFN-α, MHC expression on hepatocytes increases and coincidentally transaminase levels rise, presumably as a result of hepatocyte lysis.[34]

Investigation of the CTL response to HBV in acute and chronic HBV infection has been inhibited by the inability of HBV to grow in culture. Early experiments using autologous hepatocytes as CTL targets suggested that CTLs were present in both acute and chronic infections, were MHC class I restricted, and were hepatitis B core antigen (HBcAg)-specific.[34,39] However, the specificity of these responses was determined by inhibition of the responses by anti-HBc and anti-HBe polyclonal and monoclonal antibodies. Our current knowledge of MHC-peptide/T-cell receptor (TCR) interactions suggests that it is highly unlikely that an antigen-specific antibody could inhibit CTL responses to the same antigen. Thus, although the observations of the presence of CTLs and the ability of antibodies to HBc and HBe to inhibit CTL activity are reproducible, the mechanism is not understood. The observations are, however, further supported by the observation that infusion of the same monoclonal antibodies into chimpanzees resulted in the animals developing chronic infection after intravenous challenge with a standard innoculum which in control animals, not receiving the monoclonal antibodies, invariably resulted in self-limiting acute infection.[34]

Recently, new techniques have been described with which to investigate the CTL response. Peptide pulsed lymphocyte targets can be used to determine the presence and specificity of CTLs, which are restimulated *in vitro* for about 3 weeks.[40] The major drawback of these experiments is that there is no clear proof that the pep-

tides that elicit a response *in vitro* are the ones expressed in class I clefts *in vivo*. This issue is partially addressed by using target cells that have been transfected with plasmids expressing the HBV antigens.[40] HBV-derived peptides, in these experiments, will be loaded into the MHC class I cleft through the natural mechanism.

Using peptide pulsed targets, Chisari and Ferrari have shown that, in acute HBV infection, the CTL response is polyclonal and multi-specific. In chronic HBV infection, the CTL response is weak and has a limited repertoire.[7,41] In contrast with the findings in the early experiments described previously, relatively more CTL epitopes are found in the HBsAg and polymerase antigens than in HBcAg. The explanation for this phenomenon is unclear, but two possibilities have been discussed. First, exogenous HBsAg, found in great excess during HBV infection, induces MHC class I-restricted CTL responses through an unknown pathway. Second, HBsAg and the HBV polymerase have a large proportion of hydrophobic areas, which may be relatively rich in MHC class I-binding motifs.

HBV is widely recognized as a non-cytopathic infection in which hepatocyte damage occurs as a result of the immune response. Support for this hypothesis is derived from the presence of minimal liver disease in patients with high levels of viral replication and severe liver disease in patients with undetectable viral replication and strong T-cell responses to HBV antigens. Experiments with transgenic mice expressing HBV antigens indicate that neither expression of HBV antigens nor the process of replication itself is directly cytopathic.[42] An exception to this is a strain of mice that overexpress HBsAg. Hepatocytes in this strain are exquisitely sensitive to physiological concentrations of IFN-γ and eventually failure to secrete HBsAg leads to cell necrosis.[43] Adoptive transfer of MHC class I-restricted, HBsAg-specific CTLs into HBsAg transgenic mice induces apoptosis and necrosis with a histological pattern akin to that seen in human acute HBV infection. Increasing the dose of CTL increases the severity of hepatitis until the typical appearance of fulminant HBV infection occurs.[44]

## Humoral immunity

In acute hepatitis, liver damage coincides with the appearance of immunoglobulin M (IgM) anti-HBc, suggesting that the hepatitis associated with HBV infection is caused by immune lysis of infected hepatocytes, an essential part of the recovery process.[14,45] Current dogma suggests that it is the cellular rather than the humoral response that is involved in the mediation of infected hepatocyte lysis. However, the contribution of antibody-mediated lysis has not been ruled out. Compatible with a role for humoral immunity acting through complement activation is the demonstration that C1q and C3 metabolism are increased in acute HBV.[38,46,47]

Virus-neutralizing antibodies are directed to epitopes on the envelope of the virus. This is composed of three polypeptides, each with the same carboxy-terminus. These are designated the large, middle and small envelope proteins and arise from the pre-S and S of HBV. The amino-terminal 120 amino acid region of the large protein, which is not present in the middle and small proteins, is designated pre-S1. This hydrophilic area is myristilated, and recent data indicate that the region amino acids (aa) 21–47 is capable of binding to the membrane of the hepatocyte and is therefore probably involved in virus uptake.[48]

The antibodies found in convalescent serum bind predominantly to the epitopes of the HBs gene-encoded region, the carboxy-terminal region that is present in all the envelope proteins.[49] A hydrophilic region of this polypeptide, aa 124–147, forms two loops via intramolecular disulfide bridges, and these are the binding region for the majority (>80%) of the antigen-binding capacity of convalescent sera.[50] Using monoclonal antibodies binding to these regions, it has been possible to show that antibody to the region aa 124–137, when administered to chimpanzees, will prevent infection.[51] Antibodies to this region, as well as to other epitopes on the S gene-encoded polypeptide, are present in the serum of patients convalescent from HBV infection and in normal subjects immunized with plasma-derived and recombinant DNA-produced HBs vaccine.[21,52]

Although patients recovered from HBV or vaccinated with HBsAg are protected from further infection, there has been considerable debate on the importance of antibodies to the middle and large pre-S2 and pre-S1-bearing polypeptides. During natural infection, antibodies to pre-S1 and pre-S2 appear before antibodies to the HBs region.[50,51] If, as has been postulated, the pre-S1 region is important for binding of HBV to the hepatocyte during infection, antibodies to this region would be virus neutralizing and, therefore, their presence may be important in preventing entry of HBV particles into uninfected hepatocytes.[48] Interference with the production of anti-envelope antibodies thus may be expected to lead to protracted HBV infection, and this is seen in agammaglobulinaemic patients who, when exposed, frequently develop chronic HBV infection.

## Cytokines

In the transgenic mouse models IFN-γ and TNF-α inhibit HBV gene expression. Using a mouse that secreted HBsAg from the liver and that sustained little damage after infusion of HBsAg-specific CTLs, it was shown that secretion of IFN-γ and induction of TNF-α controlled

HBsAg expression in the absence of hepatocyte necrosis.[53] The magnitude of this effect in acute hepatitis B in human subjects remains to be determined.

## Factors leading to HBV persistence

The reasons why certain individuals develop chronic infection, rather than a transient acute infection, may relate to specific viral or host factors.

### Viral factors

The viral and immunological events that occur in the first weeks of HBV infection are probably crucial in determining the outcome of infection. Recent data suggest that the rate of rise of viral replication and of expression of viral antigens is important in determining the induction of innate and adaptive immune responses.[54] It is therefore of interest that the rate of rise of HBV viraemia is very slow. It is not until 6–8 weeks after infection that viraemia is detectable by sensitive polymerase chain reaction (PCR) assays and HBV-specific CD4 helper and CD8 cytotoxic T cells appear.[14,55] This long delay between infection and appearance of the cellular immune response contrasts with the reported kinetics of immune response in other infections (e.g. human immunodeficiency virus, HIV, and cytomegalovirus, CMV).[56,57]

#### *Induction of tolerance*

HBV establishes persistent infection with high-level viraemia which facilitates transmission of the virus to new hosts. Persistence is optimally achieved by inhibiting the initial immunological responses to viral antigens. To this end, the virus inhibits the expression of MyD88, a signal transduction molecule required for viral triggered innate recognition through TLRs.[58] In the absence of the 'danger' signals provided by these receptors, the IFN system is not activated and antigen presentation induces anergy or tolerance to viral antigens rather than effective CTL and T-helper responses.[59] Alternatively, tolerance may be induced by fetal exposure to viral antigens during thymic ontogeny.[29]

HBeAg may play an important role in the high rate of development of chronic hepatitis B infection in children born to mothers who are HBeAg-positive.[29] Almost every child born to an HBeAg-positive mother becomes infected with HBV, and 90% develop a chronic carrier state.[13,15,60] It has been shown that HBeAg crosses the human placenta, and a study (using a transgenic mouse model) has demonstrated that *in utero* exposure to HBeAg leads to a significant period of neonatal T-cell tolerance to HBeAg and HBcAg in non-transgenic offspring of HBeAg-expressing transgenic female mice[61,62] (Chapter 18). This immunological tolerance may play an important role in the development of a chronic carrier state in the neonate.[29]

Thus, it may be postulated that HBeAg in some way may reduce the cytotoxic T-cell response to infected hepatocytes (possibly by inducing immune tolerance to nucleocapsid-derived peptides) and thus reduces the degree of hepatic inflammation, lessening the risk of death of the host and elimination of the virus (both of which are disadvantageous to the virus). A healthy host with persistent infection is more likely to spread the virus to other individuals than a sick host with severe liver disease. When tolerance to the nucleocapsid is lost, as at the time of HBeAg to anti-HBe seroconversion, hepatic inflammation and damage increase until the virus is eliminated.

In addition to secreting soluble nucleocapsid proteins into the serum, the virus also secretes surplus surface (envelope) protein (HBs) into the blood. This excess HBs can be seen in the serum by electron microscopy as 22-nm particles. These particles may confer a biological advantage on the virus, as they will 'divert' antibody to HBs (anti-HBs) away from intact whole virus particles and thus reduce the chances of virus neutralization by these anti-envelope antibodies. Studies have shown that large quantities of murine monoclonal anti-HBs can overcome the antibody-diverting effect of non-infectious HBsAg particles and can shut off HBV replication in agammaglobulinaemic chronic HBV carriers, presumably by stopping infection of regenerating hepatocytes by virus neutralization in the interstitial space or by recruiting additional T-cell help, provided by T cells sensitized to murine globulin epitopes, to viral antigens complexed with heterologous (murine) anti-HBs.[63]

At some stage during the host's life, often during late teenage and early twenties, tolerance to the virus is broken down. The reasons for this are unclear. One explanation may be the random mutation of viral epitopes away from the sequences to which the host has become tolerant, as a result of errors generated by the viral reverse transcriptase. Alternatively co-infection with acute, possibly lytic viruses, may activate danger signals in the vicinity of HBV antigens which may initiate T-cell responses. However, in the face of established peripheral tolerance, T-cell responses are subdued relative to those seen in acute infection. This may explain the relative inefficiency of adaptive immunity in eliminating HBV-infected hepatocytes in chronic HBV infection.

#### *Inhibition of CTL lysis of infected hepatocytes*

The mechanism of replication of HBV – involvement of a reverse transcriptase – leads to the generation of genetic heterogeneity, which creates quasi-species, some of which theoretically may no longer be recognized by Th, CTLs or antibody.[64] Two HLA-A2 patients have been

described in which an HLA-A2 epitope in the HBcAg (aa 18–27) contains amino acid substitutions that do not elicit the usual CTL response.[40,66] Although this confirms the theoretical possibility of CTL escape mutation, it is difficult to weigh up the importance of this finding when the CTL response is documented as multi-specific. Perhaps, only in the context of a weak and limited CTL response, as seen in chronic HBV infection, is this mechanism of any biological consequence. Some of the CTL epitopes that have been documented for HBV arise from highly conserved regions of the virus, which have important roles in viral replication. For instance, the HLA–Aw68/A31-restricted epitope at amino acid positions 141–151 of HBcAg is at a nuclear localization and genomic encapsidation site.[65] Escape mutation in these sites is not a viable mechanism for viral persistence, although there is a theoretical possibility that other amino acid sequences could compete with viral peptides for HLA binding without activation of the T-cell receptor.[66]

### *Collapse of the adaptive immune response*

When resolution of HBV infection is achieved, virus-specific cellular and humoral responses remain detectable for years.[67] In contrast, during chronic infection there is a progressive decline of adaptive immunity with lowering of circulating and intra-hepatic CD4 and CD8 T cells.[68] In addition, the subclass distribution of anti-HBc changes to a predominantly Th2 pattern.[69] Persistently high production of viral antigens can delete or tolerize antigen-specific T cells and B cells.[23,70] The production of the secreted form of nucleocapsid antigen (HBe) induces, in transgenic mice, the preferential production of Th2 cells by deletion of Th1 cells.[71,72] Alteration of the CD8 cells repertoire towards subdominant epitopes has also been observed during the course of the infection. T cells escaping deletion caused by exposure to large quantities of antigen are characterized by an inability to bind antigen-specific tetramers, in spite of being positive for high affinity antigen receptors,[70] indicating that they are functionally deficient in some way.[73]

Furthermore, chronic exposure to HBs has been shown to facilitate T-cell lysis of antigen-specific B cells[23], giving rise to the diminished capacity of patients with persistent HBV infection to produce antibody to HBs antigen after successful therapy of the infection.[23,74]

These changes indicate progressive collapse of the immune response because of continuing exposure to large quantities of soluble HBe and particulate HBs antigen.

### *Emergence of the HBe-negative variant of HBV*

A mutation in the precore region of the nucleocapsid reading frame creates a termination codon that prevents translation of the HBeAg (Chapter 15, Figure 15.1). Virus bearing this mutation appears after HBeAg to anti-HBe seroconversion in many patients around the Mediterranean and in the Far East.[75]

Although seroconversion is usually associated with control of viral replication, in cases where the precore mutant emerges, viral replication continues often with a more aggressive hepatitis. At first sight, therefore, this appears to be a successful escape mutation that emerges under the selection pressure of anti-HBe antibody. However, it has now been established that virus bearing the precore mutation may be found in patients in whom HBV replication has been controlled. DNA sequencing of viral isolates from patients after HBeAg to anti-HBe seroconversion reveals that mutations in antigenic determinants of the core region are associated with persistent viraemia, indicating that the precore mutation alone is probably insufficient for successful evasion of the immune response.

An alternative explanation for the increasing prevalence of the precore mutant virus is that the mutation in the precore stabilizes the structure of a critical stem loop structure in the viral pregenome (Figure 15.2), which acts as a packaging signal and also as the origin of replication.[76] Thus, the base-pair substitution may also give the virus a replication advantage that eventually leads to dominance of this mutant. However, *in vitro* experiments have not convincingly shown any replication advantage of the precore mutant. Interestingly, patients transplanted for HBV, infected with the precore mutant, exhibit re-emergence of the wild-type virus when heavily immunosuppressed for long periods – presumably because of removal of immune selection pressure.[77]

### *HBV integration*

It is now clear that HBV DNA becomes covalently integrated into the hepatocyte genome at some time during the chronic infection.[78,79] The continuous secretion of the viral coat protein (HBsAg) in the absence of active viral replication probably represents a phase of infection in which the viral DNA has become integrated into the host DNA, so that some of the viral genes are transcribed and translated as though they were hepatocyte DNA. This integration event may be involved (late in the infection) in the malignant transformation of hepatocytes.[80] The cells containing integrated sequences must evade the immune elimination processes, and probably do so by not expressing HBc and HBe antigens (the putative targets for CTLs). Because the preferred site for integration on the viral genome is in the promoter region of the HBV core gene, this transcription unit is destroyed during the integration process, and thus no nucleocapsid antigens are produced.[81] HBsAg, however, continues to be expressed in these cells because this gene is intact in the integrated viral sequence. As long as the cell is

not recognized by CTLs as being infected, integration of the virus will result in viral persistence. Whether HBV integrates depends on the duration of infection and is usually found if infection has been present for 2 or more years. Studies of attempts to eliminate HBV infection using IFN therapy have indicated that patients who have had chronic infection for many years, and who have integrated HBV DNA, are much less likely to clear HBsAg than patients with a short period of chronicity and in whom integration is not found.[82] In individuals who have cleared replicating virus (HBV DNA, HBV DNA polymerase and HBsAg all negative) and have no evidence of liver disease, reactivation of infection (presumably from integrated HBV) has sometimes been seen when immunosuppressive therapy or acquired immune dysfunction occurs.[83,84]

## Host factors

### *Genetic susceptibility*

Twin studies from China indicate that the outcome of HBV infection is partly determined by the host genotype.[85]

A number of disease association studies have identified polymorphisms that influence susceptibility to persistent HBV infection. The MHC class II alleles DRB1*1302, DRB1*02, and DRB1*04 are associated with resistance to persistent HBV, whereas the allele DRB1*07 is associated with increased susceptibility to persistent infection.[24,86] In individuals who are heterozygous at the MHC class II loci the repertoire of viral epitopes, which may be presented to Th cells, is increased and as expected, heterozygosity at the MHC class II loci reduces susceptibility to persistent HBV infection.[87]

### *Deficient production of IFN*

IFN-α production during the early phase of acute HBV infection is believed to be important for successful resolution.[16] In acute HBV infection, IFN-α is responsible for the initial increase in MHC class I antigen display on hepatocyte membranes and the activation of the 2′,5′-oligoadenylate synthetase (2,5-OAS), endonuclease and protein kinase systems, which result in an effective antiviral state within the liver. However, in chronic HBV-infected subjects, there is evidence of abnormal activation of hepatocytes by IFN. Levels of 2,5-OAS are only minimally elevated, and MHC class I proteins are present only in very low density on the infected hepatocytes.[32,88] Furthermore, studies of peripheral blood mononuclear cells (PBMCs) taken from patients with acute and chronic HBV infection have revealed that the production of IFN-α is subnormal.[89–92] It is possible that this reduced production of IFN is directly attributable to HBV infection.[93] Suppression of type 1 IFN production in cells expressing the core region of HBV has been shown.[94] However, as reduced IFN production is also seen in lymphocytes taken from patients with resolving acute HBV,[89] it is unlikely that IFN deficiency is the cause of most cases of persistent HBV infection. This is further supported by studies showing that IFN-α therapy results in clearance of HBV infection in only about one-third of treated patients.[95] If persistence of infection was due to deficient IFN production by PBMCs in all cases, then we could expect to see much higher seroconversion rates with IFN-α therapy.

### *Deficient response to IFN*

In patients with moderate to severe chronic hepatitis B, treated with IFN-α, there is a reduced rate of rise of serum beta 2 microglobulin, a component of MHC class 1 glycoprotein, in patients failing to respond to therapy.[96] These abnormal responses to IFN may be acquired as a direct result of infection with HBV. *In vitro* transfection of HBV into cells in tissue culture makes them specifically unresponsive to IFN. They remain susceptible to lysis by Sindbis virus, and MHC class I induction does not occur.[97] MHC class I display is believed to be important for recognition and elimination of HBV-infected hepatocytes by cytotoxic T cells, and the decreased MHC expression, in addition to the reduced 2,5-OAS activation, may contribute to failure to clear the virus.

It is possible that this abnormal cellular response to IFN is directly attributable to the virus itself, but the exact mechanism by which the virus might achieve this is not clear. One hypothesis is that it may be due to the presence of a short nucleotide sequence at the beginning of the core gene of the virus.[98] The nucleotide sequence of this region shows a striking homology to a consensus sequence within the host genome that is upstream from genes induced by IFN in mammalian cells.[99] The IFN-induced secondary messenger binds to this site, and the presence of multiple homologous consensus sequences on episomal or integrated HBV DNA might compete for this messenger.

Another possible mechanism of interference is by the HBV replicative enzyme (HBV DNA polymerase). One study has shown that cells transfected with the HBV DNA polymerase gene produce polymerase protein and become unresponsive to the effects of IFN-α.[100] In this study, transfection with other HBV genes did not affect the cellular response to IFN.

Finally, genome-wide scanning studies in sibling pairs with persistent HBV infection have identified a polymorphic locus on chromosome 21q22.7, which is in linkage disequilibrium with HBV persistence.[101] This

region contains a cluster of cytokine receptor type II genes, including IFN-α receptor chains 1 and 2, and IL-10 receptor B chain.

Transmission disequilibrium studies undertaken on Gambian families identified the causal polymorphism(s) within this region to be in codon 47 of the IL-10 receptor B (IL10RB) gene ($p$ = 0.018) and in codon 8 of the IFN-α receptor 2 (IFNAR2) gene ($p$ = 0.01). When the allele encoding phenylalanine at position 8 of IFNAR2 and the allele encoding lysine at position 47 of IL-10RB are analyzed as a haplotype, the evidence for association is compelling ($p$ = 0.0009).

The IFNAR2-F8S and IL-10RB-K47E variations represent significant changes in the physico-chemical properties of the amino acids at these positions.

Position 8 in IFNAR2 lies within the signal sequence domain of the polypeptide, which is essential for targeting to the secretory pathway of the cell and localization to the cell membrane. Structural modelling of the sequence variants, suggests that the S allele, which is associated with persistent infection, would result in receptor expression at lower density than the F allele, thereby reducing the efficiency of signal transduction and induction of the intracellular antiviral state.

Position 47 in the IL-10RB protein lies in the extracellular domain adjacent to the ligand binding residues. IL-10RB is a promiscuous cytokine receptor. IL-10RB was initially identified as the second subunit of the IL-10 receptor. More recent studies implicate IL-10RB as one of the components of the receptor for novel cytokines IL-28A, IL-28B and IL-29 with antiviral properties which have been termed IFN-λs[102] (Fig. 19.4).[103,104] Consequently, the effects of polymorphism in this receptor will need to be explored in three different systems: IL-10, IL-22 and IL-28/29. It is easy to speculate that changes in the signalling of antiviral functions by IL-28/29 are responsible for the different outcomes in HBV infection but more data are required to support this hypothesis.

### *Antibody to nucleocapsid antigens*

The first host-induced immunological marker of HBV infection is IgM antibody to the core protein (anti-HBc), which appears shortly after the time HBsAg is first detected in the serum.[14,105] Anti-HBc is not a neutralizing antibody, and high titres of anti-HBc in the absence of HBsAg and anti-HBs may indicate the presence of continuing replication of HBV in the liver and infective HBV particles in the serum.[106] Cytotoxic T cells sensitized to nucleocapsid-derived peptides displayed on the hepatocyte membrane recognize and destroy HBV-infected hepatocytes.[34,107,108] However, it has been shown that anti-HBc and anti-HBe block cytotoxic T-cell killing of HBV-infected hepatocytes.[34,108] This blocking effect may be the result of simple steric hindrance if the B- and cytotoxic T-cell epitopes are displayed close to each other on the cell membrane.[34] Thus, circulating anti-HBc, depending on its specificity, may modulate T-cell-mediated lysis of infected cells[109] and, by analogy with chronic measles infection of the central nervous system,[110] may be one mechanism leading to viral persistence. Consistent with this hypothesis is the observation that some adult patients progressing from acute to chronic infection produce anti-HBc before those that clear the virus,[14] and injection of monoclonal anti-HBc and anti-HBe with the virus produces prolonged viraemia.[34]

Of babies born to HBsAg-positive mothers, 90% become infected, and >90% of these develop a chronic infection.[13] It has been speculated that the active transport of maternal IgG anti-HBc via placental Fc receptors contributes to the persistence of HBV-infected cells in the child's liver,[29,34,111,112] which, together with the immatu-

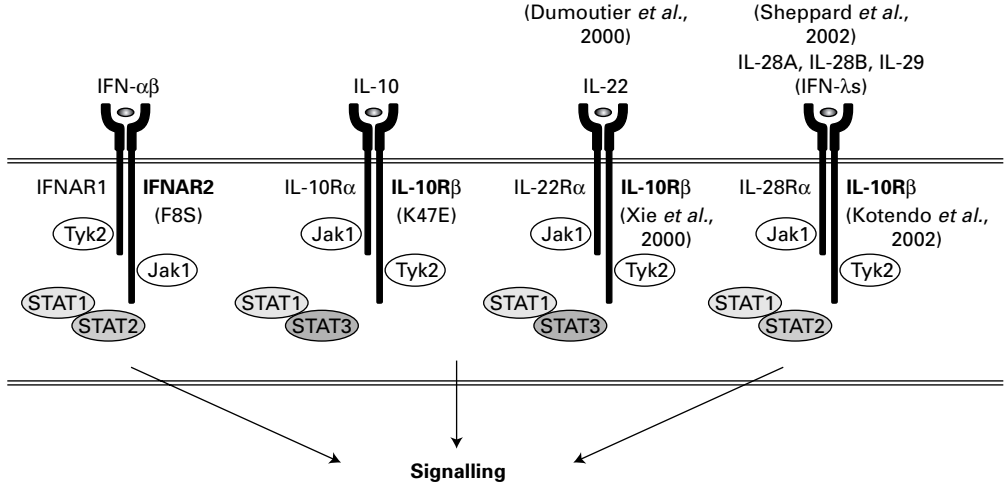

**Figure 19.4** The IL-10 receptor B (IL-10RB) participates in cytokine signalling for IL-10, IL-22 and IFN-λ (IL-28A, IL-28B and IL-29).

rity of the neonatal immune system,[113] results in chronic infection. IgG antibodies have been shown to modulate viral proteins from the membrane of infected cells,[114,115] a process that would prevent recognition by potentially lytic antibodies. Usually, the epitopes recognized by antibodies and cytotoxic T cells are different. In the case of HBV-infected hepatocytes, anti-HBc and anti-HBe will inhibit the lysis of infected hepatocytes by T cells, suggesting that the epitopes recognized by these antibodies and cytotoxic T cells are the same, or displayed near to each other on the cell membrane. Further confirmation of these findings comes from studies showing that murine monoclonal anti-HBc and anti-HBe, when injected into chimpanzees along with an infectious inoculum of HBV, result in a protracted infection lasting 12–18 months.[34]

### *Abnormalities of lymphocyte function*

It is thought that lymphocyte function is broadly deranged in chronic HBV infection,[111,112] and many studies measuring suppressor cell function in both acute and chronic HBV infection have been performed (reviewed by Dienstag[116]). Although the results are inconsistent, it does appear that there is a defect in suppressor cell function in both acute and chronic HBV infection as compared with control patients. Further studies of CD4/CD8 ratios also indicate a reduced ratio in acute and chronic HBV infection.[116] These findings suggest a virus-induced alteration in lymphocyte function in both acutely and chronically infected persons, but do not specifically incline an individual toward HBV persistence.

IL-1 production by monocytes from patients with chronic HBV infection with liver disease is also increased, and this correlates with the severity of fibrosis found within the liver.[117] However, once cirrhosis supervenes, IL-1 production is significantly reduced compared with normal persons,[118] probably because of a serum inhibitor found in these patients with advanced disease. However, this defect is not specific for HBV-induced liver disease. HBV carriers without liver disease have normal interleukin production.

The recent description of CD4+ and CD25+ regulatory T cells which modulate effector CD4 and CD8 cells, and the observation that they are present in chronic viral liver disease, suggests yet another mechanism of viral persistence that requires further investigation.

Defects in B-lymphocyte secretion of antibody in chronic HBV infection have also been described and are believed to be a physiological response of anti-HBs-secreting B lymphocytes to marked excess of circulating HBsAg.[74,119] The importance of these various lymphocyte abnormalities in terms of the likelihood of developing chronic HBV infection is not known.

### *Serum factors*

In addition to the described defect in interleukin production in most patients with severe liver disease,[117,118] studies have suggested that HBV carriers may secrete specific serum factors that predispose to viral persistence. Recent studies have shown that the T cells of the majority of chronic HBV carriers produce a secreted soluble factor (TSF) that selectively suppresses the production of anti-HBs by the B lymphocytes of the patient.[23] Other serum factors that are claimed to adversely alter lymphocyte function have also been described, but these are less specific and are not believed to play a primary role in HBV chronicity.[116]

### *Anti-idiotype response*

One important method of immunoregulatory control is achieved by synthesis of antibodies against the variable region of antibodies. These antibodies, known as anti-idiotypes, can either enhance or, more commonly, limit the immune response. One study looking at anti-idiotype antibodies in HBV infection showed that 70–80% of patients with persistent infection had these.[120] Individuals who subsequently cleared the HBV infection were less likely to have the anti-idiotype antibodies and, if they had the antibodies, they were of a lower titre than patients who did not clear the infection.[120] These data suggest that anti-idiotypic modulation of the immune response against the virus may be important in predicting viral persistence.

### *Gender and hormonal factors*

After exposure in adulthood, the likelihood of remaining chronically infected is greater in males than in females. The reasons for this difference are not known, although it may be speculated that they are hormonal in origin. There is a glucocorticoid responsive element in the genome of HBV,[121] and other studies have indicated that HBsAg gene expression is regulated by sex steroids and glucocorticoids.[122] In addition, HBsAg is cleared more slowly in male inbred mice than in female mice of the same genotype,[123] suggesting that phagocytic cells in males do not 'see' the viral protein as readily as those in females. Males are more likely than females to develop significant chronic liver disease.

## How does the virus cause liver cell damage and fibrosis?

### Lysis of HBV-infected hepatocytes

The existence of a period of viraemia without liver damage in the prodromal phase of acute infection and of

carriers with high-level HBV replication without liver damage suggests that HBV itself is not directly cytopathic.[14,15] Therefore, if it is not the virus itself which causes damage in the liver, then it must be the immune response to the infected hepatocytes. Support for this hypothesis is derived from the presence of minimal liver disease in patients with high levels of viral replication and severe liver disease in patients with undetectable viral replication and strong T-cell responses to HBV antigens. Experiments with transgenic mice expressing HBV antigens also confirm that neither expression of HBV antigens nor the process of replication itself is directly cytopathic.[42] An exception to this is a strain of mice that overexpress HBsAg. Hepatocytes in this strain are exquisitely sensitive to physiological concentrations of IFN-γ and eventually failure to secrete HBsAg leads to cell necrosis.[43]

A major pathway used by CTLs and NK cells to eliminate infected cells is via exocytosis of granule components in the direction of the target cell, delivering a lethal hit of cytolytic molecules. Amongst these, granzyme B and perforin have been shown to induce CTL-mediated target cell DNA fragmentation and apoptosis. Once released from the CTL, granzyme B binds its receptor, the mannose-6-phosphate/insulin-like growth factor II receptor, and is endocytosed but remains arrested in endocytic vesicles until released by perforin. Once in the cytosol, granzyme B targets caspase-3 directly or indirectly through the mitochondria, initiating the caspase cascade to DNA fragmentation and apoptosis. Caspase activity is required for apoptosis to occur. However, in the absence of caspase activity, granzyme B can still initiate mitochondrial events via the cleavage of Bid. Recent work shows that granzyme B-mediated release of apoptotic factors from the mitochondria is essential for the full activation of caspase-3. Thus, granzyme B acts at multiple points to initiate the death of the infected cell.[124] Intrahepatic mRNA of perforin and granzyme B are seen in most patients with hepatitis B and correlate with ALT levels and with HAI scores, indicating that these systems play an important role in liver cell injury in HBV infection.[125]

Recent data raise the likelihood that granzyme M represents a third major and specialized perforin-dependent cell death pathway that plays a significant role in cell death mediated by NK cells.[126] In the presence of perforin, the protease activity of granzyme M rapidly and effectively induces target cell death. In contrast to granzyme B, cell death induced by granzyme M does not feature obvious DNA fragmentation, occurs independently of caspases, caspase activation and perturbation of mitochondria, and is not inhibited by overexpression of Bcl-2.

Hepatocyte apoptosis also occurs in response to ligand activation of various death receptors, such as Fas, TNF-α receptor-1, TNF-related apoptosis-inducing ligand (TRAIL) receptor-1, which are displayed on infected hepatocytes and are activated by the respective ligands, released by HBV-sensitized lymphocytes.[127] The presence of these receptors, which are increased in the presence of HBV replication, suggests that these mechanisms are important in destruction of HBV-infected hepatocytes

Adoptive transfer of MHC class I-restricted, HBsAg-specific CTL into HBsAg transgenic mice induces apoptosis and necrosis with a histological pattern akin to that seen in human acute HBV infection. Increasing the dose of CTL increases the severity of hepatitis until the typical appearance of fulminant HBV infection occurs.[44]

### Hepatic fibrosis

Analysis of CTL populations in the livers of patients with chronic HBV infection reveals further insights into the mechanisms of hepatic damage. In patients with raised transaminases, high levels of viral replication and high levels of inflammatory activity on liver biopsy, the proportion of HBV-specific CTL detectable by tetramer staining is low.[68] In contrast, in patients who are HBeAg-negative with normal transaminases and low levels of viral replication, the proportion of HBV-specific CTLs in the liver infiltrates is high. These data suggest that where there is failure to control viral replication there is recruitment of non-specific inflammatory cells to the liver. These cells may be responsible for 'collateral damage' by secreting inflammatory cytokines and activation of stellate cells.

Liver fibrosis is the result of accumulation of matrix proteins (especially collagen types I and III) in response to liver injury. The process starts with the activation of hepatic stellate cells (HSCs) by a variety of cytokines (TGF-β, PDGF, etc.) produced by HBV-sensitized T lymphocytes and monocytes.[128] These stellate cells differentiate into myofibroblast-like cells which exhibit an increase in their synthesis of matrix proteins such as interstitial collagens. In addition, there is increasing evidence that liver fibrosis is a dynamic process in which altered matrix degradation may also play a major role. Extracellular degradation of matrix proteins is regulated by matrix metalloproteinases (MMPs) – again produced by HSCs – which in turn are regulated by several mechanisms which include apoptosis of the stellate cell, regulation at the level of gene transcription, cleavage of the proenzyme to an active form and specific inhibition of activated forms by tissue inhibitors of metalloproteinases (TIMPs).

## Summary

Acute self-limiting HBV infection usually has little impact on morbidity or mortality, whereas persistent HBV

infection is a major public health problem, particularly in the Far East and in sub-Saharan Africa. Persistent infection is usually accompanied by a state of partial tolerance to viral antigens, which may be the result of both viral and host factors. Total loss of tolerance may lead to viral elimination, but partial loss of tolerance (development of antibody in the absence of an adequate CTL response) may lead to an unstable equilibrium in which prolonged hepatocyte damage leads to fibrosis, emergence of HBV antigenic variants, and ultimately liver failure or hepatocellular carcinoma.

# Chapter 20
# Treatment of chronic hepatitis B

Patrick Marcellin, Tarik Asselah, Nathalie Boyer

## Introduction

Three agents are currently approved for the treatment of chronic hepatitis B: interferon-alpha (IFN-α), lamivudine and adefovir. Each agent has inherent limitations for use in the treatment of chronic hepatitis B.[1–3] IFN-α is effective in a minority of patients and has frequent side-effects that limit its tolerability.[4,5] The efficacy of lamivudine is limited by the emergence of drug-resistant hepatitis B virus (HBV) mutants, restricting its utility as a long-term therapy for chronic hepatitis B. Adefovir, which has been registered recently, is well tolerated and is associated with a low incidence of resistance, but its antiviral effect is not optimal.

Lamivudine and adefovir have the advantages of oral administration and excellent safety profiles. However, they induce a sustained response after withdrawal of therapy in only a minority of patients, and therefore the treatment needs to be indefinitely administered in the majority of patients. As a result, more effective therapy with more potent drugs used alone or in combination is needed and the treatment of chronic hepatitis B remains an open issue.

After a brief summary of the natural history of chronic hepatitis B to provide an understanding of the indications and the objectives of therapy, this review summarizes first the results obtained with current available treatments, IFN-α, lamivudine and adefovir. The second part of this review summarises the results obtained recently with pegylated IFN (PEG IFN), combination of PEG IFN with lamivudine, combination of lamivudine with adefovir and newer antiviral agents such as entecavir, emtricitabine, telbivudine and clevudine. Phase III studies of entecavir and emtricitabine have been achieved but final results have not yet been fully published. The other drugs are still in phase II trials and therefore the information available is limited (Table 20.1).

**Table 20.1** Nucleoside and nucleotide analogues for the treatment of chronic hepatitis B

| Antiviral agent | Status |
|---|---|
| Lamivudine | Approved |
| Adefovir dipivoxil | Approved |
| Entecavir | Phase III |
| Emtricitabine (FTC) | Phase III |
| Telbuvidine (L-dT) | Phase III |
| Clevudine (L-FMAU) | Phase II |
| L-dC, L-dA | Phase II |

## Natural history of chronic hepatitis B

Chronic hepatitis B is a dynamic process with an early replicative phase and active liver disease and a late low replicative phase with remission of liver disease.[1–3] The natural history of chronic hepatitis B can be schematically divided in three phases (Fig. 20.1).

The first 'immune tolerance' phase is characterized by hepatitis B e antigen (HBeAg) positivity, high HBV replication level (reflected by high levels of serum HBV

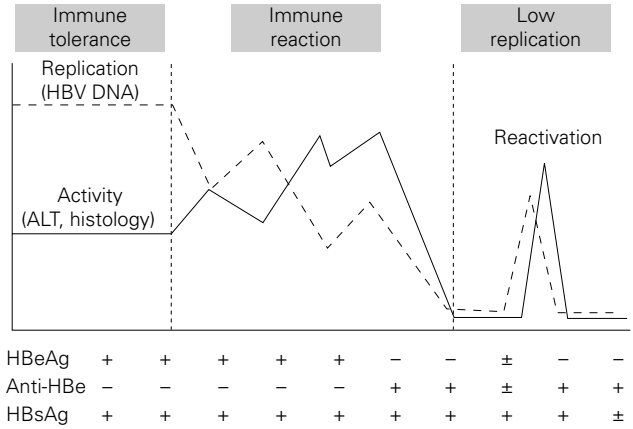

**Figure 20.1** Natural history of chronic hepatitis B. The natural history of chronic hepatitis B can be schematically divided in three phases: a first 'immune tolerance' phase with low activity of the liver disease and high level replication; a second 'immune reaction' phase with moderate to severe activity of the liver disease and low level replication; a third phase with very low level of replication and remission of the liver disease.

DNA), normal or low levels of aminotransferases, mild liver necroinflammation and no or slow progression of fibrosis. During this phase, the rate of spontaneous HBeAg loss is very low. This first phase is more frequent and more prolonged in subjects infected at birth or during childhood.

The second 'immune reaction' phase is characterized by a lower level of replication (as reflected by low levels of serum HBV DNA), increased levels of aminotransferases, moderate or severe liver necroinflammation and rapid progression of fibrosis. During this phase, the rate of HBeAg loss is high. This second phase is more frequent in subjects infected during adulthood.

Seroconversion from HBeAg to antibody to HBeAg (anti-HBe) marks the transition from chronic hepatitis B to the inactive hepatitis B surface antigen (HBsAg) carrier state with low or undectable serum HBV DNA and normal aminotransferases, and confers favourable long-term outcome with very low risk of cirrhosis or hepatocellular carcinoma (HCC) in the majority of patients. HBsAg loss and seroconversion to antibody to HbsAg (anti-HBs) may occur (resolved hepatitis B).

However, a proportion of patients (about 20–30% of cases) continue to have or redevelop high levels of HBV DNA and active hepatitis despite HBeAg seroconversion. These patients usually have HBV variants (with mutations in the precore or the basal core promoter regions) unable to express HBeAg (HBeAg-negative chronic hepatitis B).[6] HBeAg-negative chronic hepatitis B represents a late phase in the natural history of chronic hepatitis B and is associated with a very low rate of spontaneous disease remission. The proportion of patients with this form of chronic hepatitis B has been increasing in the last decades and the majority are in the Mediterranean countries.[7]

## Objectives of treatment

The first objective of the treatment is to decrease HBV replication in order to decrease necroinflammation in the liver and therefore prevent the progression of fibrosis. Thus, the interruption of the fibrogenesis process prevents progression to cirrhosis and its complications, including HCC, and therefore improves survival. The response to treatment can be classified into three phases. The first phase is characterized by the decrease of HBV replication (as reflected by the reduction of serum HBV DNA level). The liver necroinflammation diminishes, fibrosis is stabilized or may even regress but the risk of reactivation persists. If the antiviral effect is sufficient (<100 000 copies of HBV DNA per mL) and is maintained and accompanied by an effective immune response with clearance of infected hepatocytes, HBe seroconversion may occur; then the risk of reactivation is low. If HBV replication is completely interrupted (as reflected by the absence of detectable HBV DNA in the serum by sensitive assays), with stable HBe seroconversion, loss of detectable HBsAg (with or without HBsAg seroconversion) may occur, which is associated with complete disappearance of liver necroinflammation with no risk of reactivation.

With the drugs currently available, two different concepts can be proposed for the treatment of chronic hepatitis B. The first concept is that of sustained response obtained after a limited duration of therapy. The second concept is that of maintained response obtained during administration of therapy. The first strategy is the one usually used with IFN, whose duration of therapy is limited by the poor tolerability (Fig. 20.2). IFN therapy can induce a sustained response after withdrawal of treatment with a not inconsiderable chance of HBsAg loss or seroconversion. However, the limitation of this strategy is that the rate of sustained response is relatively low and sustained response is mainly obtained in patients with good predictors of response (i.e. patients in the immune reaction phase with active liver disease and low level replication). The second strategy is the one generally used with nucleoside or nucleotide analogues, whose withdrawal is generally accompanied by reactivation. Therefore, therapy needs to be administered indefinitely to obtain a maintained response (Fig. 20.3). Maintenance therapy is allowed by the good tolerability of these drugs. However, the limitation is the occurrence during therapy of HBV-resistant mutants associated with breakthroughs. Furthermore, HBsAg loss with or

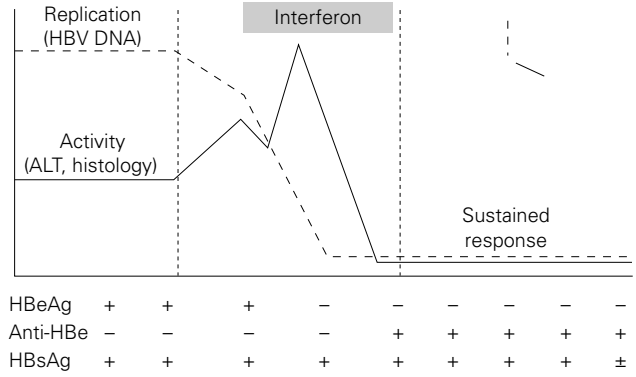

**Figure 20.2** Treatment of chronic hepatitis B with interferon alpha (IFN-α). During administration of IFN-α, there is an early antiviral effect with decrease of serum HBV DNA level, then there is an immune effect with increased cytolysis with elevation of serum alaine aminotransferase (ALT) level. In case of effective antiviral and immune effects, a sustained response is observed after withdrawal of therapy with very low serum HBV DNA level, normal serum ALT level and HBe seroconversion. If HBV replication is completely inhibited with undetectable serum HBV DNA (with a sensitive polymerase chain reaction [PCR] method), HBs seroconversion may occur within the years following treatment.

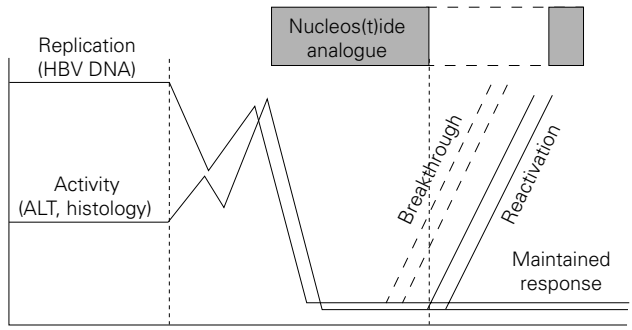

**Figure 20.3** Treatment of chronic hepatitis B with a nucleoside or a nucleotide analogue. During administration of the analogue, there is an early antiviral effect with decrease of serum HBV DNA level. However, there is no immune effect of the drug and therefore there is no increased cytolysis and no elevation of serum ALT level, which remains normal. The response is maintained as long as the drug is administered. However, in case of occurrence of a resistant HBV mutant, a breakthrough is observed with a reincrease of serum HBV DNA level, then a reincrease of serum ALT level. In the absence of an effective spontaneous immune response with HBe seroconversion, withdrawal of therapy is rapidly followed by a reactivation.

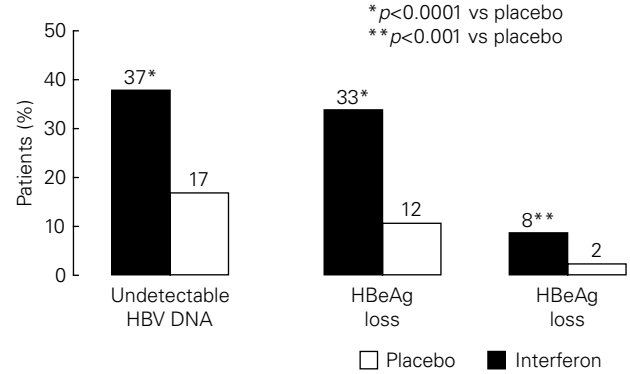

**Figure 20.4** Meta-analysis of interferon-alpha (IFN) trials in HBeAg-positive chronic hepatitis B (from Wong *et al.*, *Ann Intern Med* 1993[5]). In this meta-analysis including 15 randomized controlled trials (published between 1986 and 1992) comparing IFN versus placebo, including overall 837 patients with HBeAg-positive chronic hepatitis B, the superiority of IFN versus placebo was shown for the rates of undetectable serum HBV DNA (hybridization assays), HBeAg loss and HBsAg loss.

without HBs seroconversion is rarely observed with maintenance therapy with nucleoside or nucleotide analogues.

## Current treatments

### IFN-α

IFN-α has been used in the treatment of chronic hepatitis B for many years. IFN-α exerts an antiviral effect on infection with HBV through two mechanisms.[8] First, IFN-α has a direct antiviral effect by inhibiting synthesis of viral DNA and by activating antiviral enzymes. Second, IFN-α exaggerates the cellular immune response against hepatocytes infected with HBV by increasing the expression of class I histocompatibility antigens and by stimulating the activity of helper T lymphocytes and natural killer lymphocytes. Thus, IFN-α induces an early diminution of HBV replication (reflected by a diminution of HBV DNA in serum) and a late (about 2 months later) increase in serum alanine aminotransferase (ALT) levels. Many controlled studies of IFN-α in patients with chronic hepatitis B have been reported. In these studies, with various schedules, mean virological response rate was 37% versus 17%, mean HBeAg loss rate was 33% versus 12% and HBsAg loss rate was 8% versus 2% in the IFN-α-treated groups versus the placebo groups[5] (Fig. 20.4). A dosage of 5–10 MU three times a week for 4–6 months allows a good efficacy with a satisfactory tolerance.[2]

The discrepancies in the results of the different studies could be due, in part, to the different therapeutic schedules, but are mainly due to the populations of patients included in these trials. A certain number of factors are predictive of poor response to IFN-α[9] (Table 20.2). Low serum HBV DNA level and high serum ALT levels are predictors of non-response. Also, infection with HBV at birth or early in the patient's life (as is often the case in countries where HBV infection is hyperendemic, such as south-east Asia) is a factor in poor response to IFN-α.

### Lamivudine

Lamivudine, a nucleoside analogue which directly inhibits HBV DNA polymerase, was first developed as a reverse transcriptase inhibitor for use in HIV infection.[8] It also has activity against HBV at lower concentrations. Lamivudine (2′,3′dideoxythiacytidine) is a minus enantiomer and it is thought that this may help to explain

**Table 20.2** Predictors of non-response to IFN therapy in chronic hepatitis B

the very low rates of side-effects noted with this agent. Randomized controlled trials have shown the efficacy of lamivudine in the treatment of HBeAg-positive and HBeAg-negative chronic hepatitis B.

### *HBeAg-positive chronic hepatitis B*

One randomized placebo-controlled trial[10] showed that almost all patients treated with lamivudine (98%) had a reduction of serum HBV DNA levels. Serum HBV DNA levels became undetectable under lamivudine therapy (<0.7 meq/mL) in 44% versus 16% in the placebo group. At 1 year of treatment, the HBe seroconversion rates were 17% and 6% in the lamivudine and the placebo group, respectively (Fig. 20.5). Normalization of ALT levels was observed in 41% versus 7% in the placebo group. Histological improvement defined by a decrease of at least two points in the Knodell score was observed in 52% versus 23% in those on placebo.

The rates of virological, biochemical and histological response observed in three other randomized controlled trials showed similar results with HBeAg seroconversion rates ranging from 17% to 21%.[10–13]

The tolerability and safety of lamivudine are excellent. The incidence of adverse events was similar to that with placebo. Lamivudine therapy seems to be well tolerated for up to 5 years. However, data reported on long-term therapy with lamivudine are limited to small series of patients.

Pretreatment factors predictive of response are, as for IFN-α, high serum ALT levels and a high degree of histological necroinflammation.[14] Pretreatment ALT level seems to be the most important: response rates are low and similar to untreated patients in patients with levels below twice the upper limit of normal. The rate of HBeAg loss was highest among patients with pretreatment ALT levels greater than five times the upper limit of normal.

After withdrawal of lamivudine therapy, ALT flare-ups have been reported in 41 individuals treated with lamivudine for a minimum of 3 months and followed for at least 6 months after therapy.[15] Marked flares were observed in 17% and occurred 7–44 weeks after treatment. These flares were all associated with rising levels of HBV DNA, unlike the spontaneous flares associated with HBe seroconversion (with falling levels of HBV DNA). Two of these flares were associated with hepatic decompensation.

The major inconvenience of lamivudine is the high rate of occurrence of viral resistance related to mutations in the YMDD motif. Indeed, even if the HBeAg seroconversion rate may be increased by continuing treatment, the frequency of resistance increases with time from 24% at 1 year, to 38% at 2 years, 50% at 3 years and 67% at 4 years.[2,3,16,17]

The most important mutation is a substitution of valine or isoleucine for methionine in the YMDD motif of the HBV polymerase gene (rtM204V/I).[18] In many patients, this is accompanied by a second mutation substituting methionine for leucine in an upstream region (rtL180M). Lamivudine resistance is more likely to occur in patients with high baseline serum HBV DNA levels.

The emergence of lamivudine-resistant mutants is usually associated with a breakthrough with moderate increase of serum HBV DNA and ALT levels, which may remain lower than at baseline for several months. However, severe cases have been reported in patients with cirrhosis. In patients who develop lamivudine-resistant mutant, adefovir is effective and should be initiated rapidly if an increase in ALT is observed, especially in patients with cirrhosis who have a risk of hepatic decompensation. In order to diagnose the emergence of resistance earlier (before the appearance of detectable serum HBV DNA by standard assays and before the increase of ALT), monitoring of serum HBV DNA level by a sensitive assay is useful. Indeed, an increase of serum HBV DNA of more than one log generally reflects the appearance of a resistant mutant and this allows a switch to adefovir several months before the increase of ALT.[18,19]

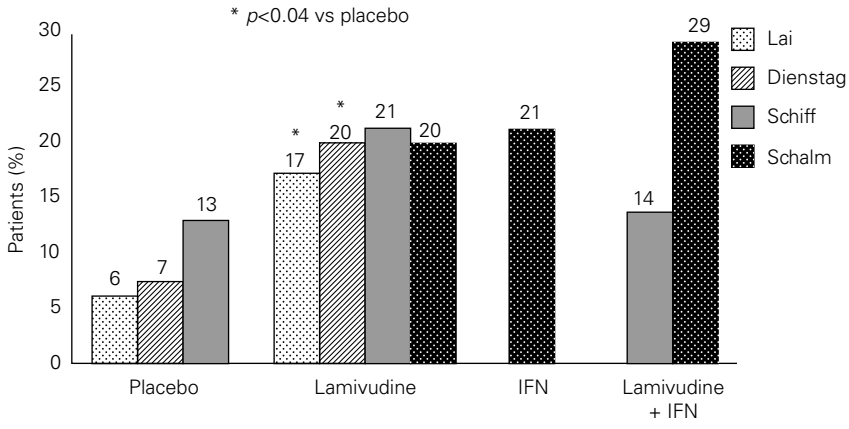

**Figure 20.5** Rates of HBe seroconversion in four randomized controlled trials of lamivudine. In four randomized controlled trials of lamivudine, HBe seroconversion rates ranged from 17% to 21% at 1 year of therapy versus 6% to 13% (spontaneous seroconversion) in the placebo groups. In one study, the rate of HBe seroconversion was comparable to that observed in the IFN group. In two studies, the rates of HBe seroconversion were lower or higher in the IFN plus lamivudine combination groups; however, the differences were not significant.

In case of HBe seroconversion during lamivudine therapy, it is usually recommended that treatment is prolonged for 3–6 additional months to decrease the risk of reactivation.[1,2] In the absence of HBe seroconversion, as withdrawal is almost invariably followed by reactivation, it is usually recommended that the treatment is continued as long as HBV replication is suppressed and serum ALT revels remain normal, until the appearance of viral resistance.

### *HBeAg-negative chronic hepatitis B*

In patients with HBeAg-negative chronic hepatitis B, one randomized controlled study[20] showed an efficacy similar to that observed in patients with HBeAg-positive chronic hepatitis B with the same rate of resistance. HBV DNA was undetectable (non-PCR-based assays) after 12 months of therapy in 90% of patients (70% with PCR-based assays). Serum ALT normalized in 75% of patients. A fall in HBV DNA and normalization of ALT occurred in only 5% of patients on placebo. Histological response was observed in 60% of lamivudine-treated patients. Predictors of response to lamivudine have not been established in this population. In patients with a virological response at the end of a 12-month course of lamivudine, the sustained response rate 6 months post-treatment was <5%.

In studies with prolonged therapy, response rates peak at 12 months and decrease thereafter.[21] At 30 months, rates of virological and biochemical responses were 30% and 60%, respectively.

The rate of resistance observed in patients with HBeAg-negative chronic hepatitis was similar to that observed in HBeAg-positive chronic hepatitis. Lamivudine-resistant mutants appeared in 10–40% of patients after 1 year of therapy, and in 50–60% of those treated continuously for 3 years.[21,22] As in HBeAg-positive patients, the emergence of resistant mutant HBV was accompanied by an increase of HBV DNA and, after a few months, by ALT elevation. Flares occurred in 30% of patients and were symptomatic or severe in some cases. As in HBeAg-positive patients, treatment by adefovir is generally effective in patients who develop lamivudine resistance.

### *Special groups*

In patients with decompensated cirrhosis, lamivudine therapy can induce marked improvement in liver disease, impacting favourably on survival.[23,24] However, the clinical effects are slow and impaired by the risk of emergence of resistance, which can be associated with flares responsible for liver failure and death. Antiviral therapy is required before liver transplantation in patients with detectable HBV DNA to decrease the risk of recurrence of HBV infection after transplantation. In addition, patients in whom lamivudine resistance develops before transplant have a higher risk of recurrent hepatitis B post-transplant. In this clinical situation, adefovir should be initiated rapidly if lamivudine resistance is suspected in order to prevent the flare. This explains why, in this setting, adefovir might be preferred because of the very low risk of resistance.

In case of recurrence of HBV infection after liver transplantation, lamivudine therapy achieves similar results to those in non-transplant patients with respect to inhibition of HBV replication and normalization of ALT. Breakthrough secondary to lamivudine resistance may lead to severe hepatitis flares, rapidly progressive liver failure and graft loss. For these reasons, after transplantation, the optimal prophylactic regimen seems to be the combination of lamivudine with anti-HBs immunoglobulins (HBIg).

In HIV-HBV co-infected patients, from the limited data available lamivudine appears to show similar effects in patients on HAART (highly active antiretroviral therapy) in terms of virological and biochemical response, to those in patients not co-infected with HIV.[25] In 40 HIV co-infected patients, 96% had undetectable serum HBV DNA (<5 pg/mL); serum ALT decreased compared with baseline; HBe seroconversion was observed in 11%. Drug-resistant HBV emerged rapidly during monotherapy with lamivudine: the incidence was 50% and 90% at 2 years and 4 years, respectively.[26] Because of the high rate of resistance to lamivudine and because a large proportion of HIV-HBV infected patients have already received lamivudine for the treatment of HIV and/or HBV, adefovir or tenofovir (which is registered for the treatment of HIV) are the drugs generally used in the treatment of chronic hepatitis B in this population.

## Adefovir dipivoxil

Adefovir dipivoxil has recently been registered for the treatment of chronic hepatitis B. Adefovir dipivoxil is the oral prodrug of adefovir. Adefovir is a nucleotide analogue of adenosine monophosphate. *In vivo*, adefovir dipivoxil is converted to the parent compound, adefovir, and through two phosphorylation reactions to adefovir diphosphate, the active intracellular metabolite that interacts with HBV polymerase. Adefovir diphosphate acts as a competitive inhibitor and chain terminator of viral replication.

Two large randomized controlled trials have demonstrated that adefovir dipivoxil is effective in patients with HBeAg-positive or HBeAg-negative chronic hepatitis B. Also, adefovir dipivoxil effectively suppresses lamivudine-resistant HBV in chronic hepatitis B patients

post-liver transplantation, patients with compensated or decompensated liver disease and patients co-infected with HIV.

### *HBeAg-positive chronic hepatitis B*

A large randomized, placebo-controlled study enrolled 515 patients randomized to receive adefovir dipivoxil 10 mg daily (n = 172), adefovir 30 mg daily (n = 173) or placebo (n = 170) for 48 weeks.[27] There was a rapid decrease in the median serum HBV DNA level in patients treated with adefovir dipivoxil, with statistically significant differences compared with placebo. At week 48, the median change from baseline in serum HBV DNA was –3.5 $\log_{10}$ for adefovir (10 mg) compared with –0.5 $\log_{10}$ copies/mL for placebo. Significantly more patients had undetectable serum HBV DNA levels (<400 copies/mL) (21% vs 0%, $p$ <0.001) (Fig. 20.6).[27] HBeAg seroconversion was observed in 12% of the patients receiving adefovir 10 mg compared with 6% in the placebo group ($p$ <0.05). ALT normalization was achieved in 48% compared with 16% ($p$ <0.001).

A significantly higher proportion of patients receiving adefovir 10 mg showed improvement in liver histology (improvement of at least two points in the Knodell score) at week 48 compared with those receiving placebo (53% versus 25%; $p$ <0.001) (Fig. 20.6). Results of the blinded ranked assessment of baseline and week 48 biopsies demonstrated that patients treated with adefovir 10 mg had better improvement of necroinflammatory activity ($p$ <0.001) and fibrosis ($p$ <0.001). Using the Ishak fibrosis score, fibrosis improved in 34% compared with 19% and fibrosis progressed in 11% compared with 21%.[28]

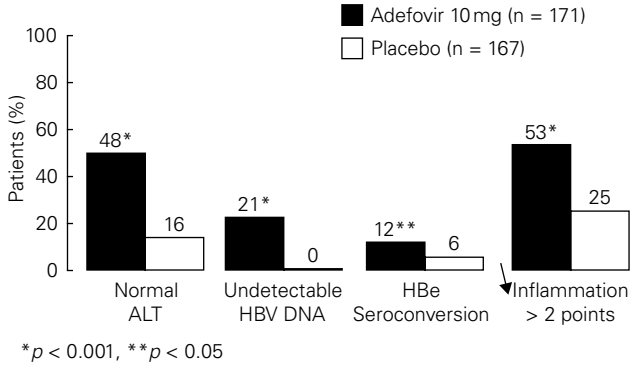

**Figure 20.6** Adefovir dipivoxil in the treatment of HBeAg-positive chronic hepatitis B (from Marcellin *et al.*, *N Engl J Med* 2003[27]). In this randomized controlled trial, at 48 weeks of therapy, the rates of normal ALT, undetectable HBV DNA, HBe seroconversion and histological improvement were higher in the group of patients receiving adefovir, at the dose of 10 mg daily, as compared with the group receiving a placebo.

The tolerability and safety profile of adefovir at the dose of 10 mg was similar to that of the placebo. Adefovir at the dose of 30 mg was associated with an increase in creatinine level in some patients. This increase was moderate, occurred after 24 weeks of treatment and resolved in all cases after withdrawal of the drug. However, this observation chose the 10-mg dose as the best dose with regard to the benefit/risk ratio and the 10-mg dose is the dose registered.

The durability of the response after withdrawal of treatment is now becoming known. Of 60 patients undergoing HBe seroconversion on adefovir, 91% were still HBe antigen-negative after 1 year of follow-up. All the patients that relapsed were genotype C.[29] However, cessation of therapy in some patients without HBe seroconversion was associated with relapse, therefore maintenance therapy is recommended. Preliminary results suggest that the antiviral effect is maintained and the rates of virological response with HBe seroconversion increase with the duration of therapy.[30] However, a longer follow-up is planned (up to 5 years) to answer the question of the durability of the response under treatment and of the possible increased efficacy of long-term treatment.

An extensive genotyping study has been carried out in all patients with detectable HBV DNA (by PCR assay). Systematic sequencing did not show any case of emergence of a mutant HBV resistant to adefovir after 48 weeks of treatment with adefovir.[31] Large-scale studies of cohorts of patients undergoing adefovir therapy are in progress to assess the incidence of resistance in the long term. The explanation for the high threshold for resistance to adefovir dipivoxil may reside in the structural features of adefovir that distinguish it from nucleoside analogues: specifically, its minimal flexible acyclic linker that closely resembles the natural substrate and the fact that it is a nucleotide, containing a phosphorus atom, not a nucleoside.

### *HBeAg-negative chronic hepatitis B*

A large randomized, placebo-controlled study of adefovir dipivoxil has been performed in 185 patients with HBeAg-negative chronic hepatitis B.[32] Patients were randomized at a ratio of 2:1 to receive either adefovir dipivoxil 10 mg (n = 123) or placebo (n = 62) for 48 weeks. Adefovir 10 mg once daily resulted in a significant reduction in serum HBV DNA levels at week 48 compared with placebo, with a median decrease of 3.9 $\log_{10}$ copies/mL versus 1.3 $\log_{10}$ copies/mL ($p$ <0.001). 51% of the patients treated with adefovir dipivoxil had no detectable HBV DNA as measured by PCR compared with none in the placebo group ($p$ <0.001) (Fig. 20.7).[32] ALT normalization was achieved in 72% compared with 29% ($p$ <0.001). Significantly more patients in the adefo-

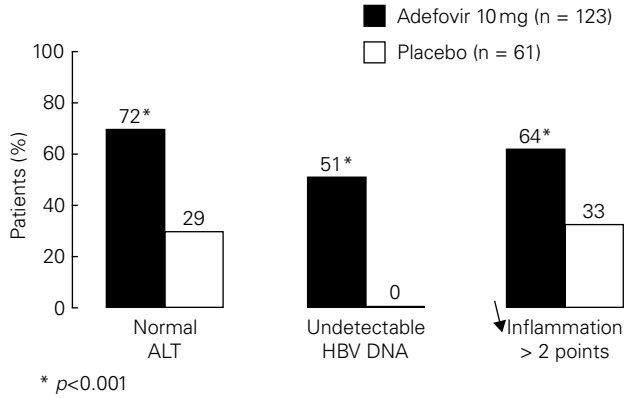

**Figure 20.7** Adefovir dipivoxil in the treatment of HBeAg-negative chronic hepatitis B (from Hadziyannis *et al*., *NEJM* 2003[32]). In this randomized controlled trial, at 48 weeks of therapy, the rates of normal ALT, undetectable HBV DNA and histological improvement were higher in the group of patients receiving adefovir, at the dose of 10 mg daily, as compared with the group receiving a placebo.

vir group had histological improvement from baseline to week 48 compared with the placebo group (64% versus 33%, $p$ <0.001).

At 144 weeks of therapy with 10 mg of adefovir daily, the antiviral effect was maintained with, in a subgroup which had a repeat liver biopsy at 96 weeks, a maintained histological improvement. After 144 weeks of therapy, tolerability was good without significant side-effects and without the occurrence of nephrotoxicity.[33] The incidence of resistance related to the occurrence of specific mutations (rt N236T and rt A181V) was low (3% at 96 weeks and 5.9% at 144 weeks). It seems that the HBV strains resistant to adefovir are sensitive to lamivudine.

### *Special groups*

An open-label efficacy and safety study of adefovir dipivoxil 10 mg has been performed in 324 chronic hepatitis B patients before and after liver transplantation (n = 128 and 196, respectively) with clinical evidence of lamivudine-resistant HBV.[34,35] Patients have received adefovir dipivoxil for varying lengths of time up to a maximum of 72 weeks (before liver transplantation) and 129 weeks (after liver transplantation), respectively. Serum HBV DNA was reduced by approximately 4 $\log_{10}$ copies/mL in both groups, and ALT level normalized in 76% and 49% of patients in the two groups, respectively. Patients also had significant improvement of liver function. Kaplan–Meier survival curve estimates by week 48 were 84% and 93% in the pre- and post-transplantation groups, respectively. These 1-year survival rates are significantly better than survival rates observed in historical groups of patients with no treatment. It is noteworthy that, in a significant number of patients who improved, the liver transplantation was postponed.

Although many of the patients (all of whom had lamivudine-resistant HBV) were medically compromised as a result of advanced liver disease and co-morbidities, there was a low rate of adverse events leading to drug discontinuation in pre- and post-liver transplantation patients (5% and 6%, respectively). A total of 42 deaths (11%) was reported in pre- and post-transplantation patients (24 and 18 patients, respectively). The deaths were considered to be due to complications of progressive liver disease or liver transplantation surgery.

In an open-label pilot study conducted in 35 HIV-HBV co-infected patients with lamivudine-resistant HBV and controlled HIV infection, adefovir therapy, at the dose of 10 mg, induced a 4 log decrease in serum HBV DNA levels at 48 weeks.[36] Two patients underwent HBe seroconversion. A transient increase in serum ALT levels was observed in 15 patients without consequence for liver function. The explanation for this observation is unclear. No HBV DNA breakthrough and no viral resistance was observed through week 48. In addition, no significant changes in either HIV RNA or CD4 cell count were observed.

## New treatments

### Pegylated IFN

More recently, the efficacy of IFN has been improved with the replacement of standard IFN by IFN conjugated with polyethylene glycol (PEG IFN). This new form of IFN reduces elimination of IFN by the kidneys, thus significantly increasing its half-life and resulting in more stable plasma concentrations of IFN. Moreover, pegylation reduces the immunogenicity of the protein (reduction of the production of anti-IFN antibodies). Finally, the number of injections has been reduced from three times to once weekly, thanks to improved pharmacokinetics, which is obviously more comfortable for the patient.

Two PEG IFNs which differ in the quality and quantity of conjugated PEG to IFN have been produced: 12 kD of linear PEG for IFN alpha-2b and 40 kD branched PEG for IFN alpha-2a. In both cases, PEG IFNs have been shown to be twice as effective overall as the corresponding non-pegylated IFNs in chronic hepatitis C.[37,38] Therefore, the efficacy of PEG IFNs has been assessed recently in the treatment of chronic hepatitis B.

A first randomized controlled study of PEG IFN alpha-2a has been performed in patients with HBeAg-positive chronic hepatitis B.[39] Treatment duration and follow-up were each 24 weeks. At the end of follow-up, treatment response defined by loss of HBeAg with serum HBV DNA level <500 000 copies/mL with normal ALT was observed in 19–28% of patients receiving PEG IFN alpha-2a (at a dose of 90 µg, 180 µg or 270 µg per week) versus 12% of patients who received standard IFN al-

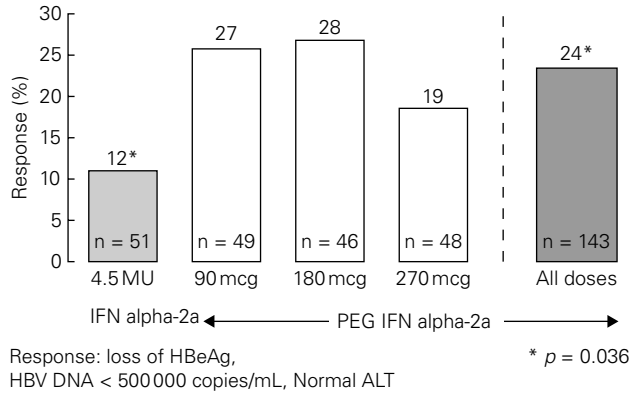

**Figure 20.8** Pegylated interferon (PEG IFN) alpha 2-a in HBeAg-positive chronic hepatitis B (from Cooksley *et al.*, *J Viral Hepat* 2003[39]). In this randomized controlled trial, 24 weeks after therapy, the rates of response were higher in the three groups which received PEG IFN alpha 2a as compared with the group which received conventional IFN alpha 2a; however, the difference was not significant. When the three PEG IFN groups were pooled retrospectively, there was a significant difference as compared with the IFN group (24% versus 12%; p = 0.036).

pha-2a (Fig. 20.8).[39] Side-effects associated with PEG IFN were comparable to those observed with standard IFN. The safety profile of PEG IFN was comparable to that of conventional IFN with the same frequency of adverse events or laboratory abnormalities.

This study does not prove the superiority of PEG IFN alpha-2a as compared with standard IFN alpha-2a, as the dose of IFN alpha-2a used was relatively low (4.5 million units, three times a week) and the differences observed between each of the three PEG IFN alpha-2a treatment groups and the standard IFN alpha-2a group were not significant. However, the overall rate of response in patients who received PEG IFN alpha-2a was higher than that observed in the IFN alpha-2a group. A retrospective analysis showed that the rates of response were higher with the PEG IFN among the most difficult to treat patients (with high HBV DNA level or low ALT levels). Therefore, this study strongly suggests that PEG IFN alpha-2a is more effective than standard IFN alpha-2a for the treatment of chronic hepatitis B.

Three large randomized controlled trials have confirmed the efficacy of PEG IFNs in HBeAg-positive (one trial with PEG IFN alpha-2b and one trial with PEG IFN alpha-2a) and HBeAg-negative chronic hepatitis B (one trial with PEG IFN alpha-2a). These studies, which compared PEG IFN monotherapies to the combination of PEG IFN and lamivudine (three studies) and lamivudine (two studies), are detailed in the next chapter.

## Combination of PEG IFN with lamivudine

Previous studies on the combination of IFN and lamivudine suggested that this combination could be more effective than lamivudine monotherapy.[40] However, the results of different studies were discordant, which could be due to different treatment regimens that may not have been optimal.

### *HBeAg-positive chronic hepatitis*

In a large randomized controlled study, 307 patients with HBeAg-positive chronic hepatitis B were randomized to receive either the combination of PEG IFN alpha-2b 100 µg per week for 32 weeks then 50 µg for 20 weeks and lamivudine 100 mg per day or PEG IFN alpha-2b at the same dose with placebo.[41] At the end of the 26-week post-treatment follow-up, there was no difference in response rates between the two treatment groups: serum HBV DNA was undetectable by PCR (<400 copies per mL) in 7% and 9%; HBeAg loss was observed in 36% and 35%; normal ALT was obtained in 32% and 35% in the PEG IFN monotherapy and the PEG IFN with lamivudine combination therapy groups. Interestingly, a relatively high rate of HBsAg loss was observed (7% in both groups).

This study shows that in patients with HBeAg-positive chronic hepatitis B, 26 weeks after therapy, the combination of PEG IFN alpha-2b with lamivudine (with the simultaneous regimen used) is not superior to PEG IFN alpha-2b used in monotherapy.

Main predictors of response were HBV genotype and pretreatment ALT level. Response was 34% for those with ALT levels under three times the upper limit of normal and 50% for those with ALT levels above five times the upper limit of normal. Response was 60% for genotype A versus 42% for genotype B, 32% for genotype C and 28% for genotype D.

Another large randomized controlled trial of the combination of PEG IFN alpha-2a with or without lamivudine versus lamivudine showed similar results.[42]

Patients were randomized to one of the following treatments: PEG IFN alpha-2a, 180 µg once weekly plus oral placebo once daily for 48 weeks; PEG IFN alpha-2a, 180 µg once weekly plus lamivudine 100 mg once daily for 48 weeks; lamivudine 100 mg once daily for 48 weeks. In total, 814 patients were enrolled in the study. At the end of the 24-week post-treatment follow-up, the two PEG IFN treatment arms (with or without lamivudine) showed the same efficacy, which was superior to that observed in the lamivudine treatment arm. HBe seroconversion was observed in 32%, 27% and 19% of the patients, respectively, and a virological response (serum HBV DNA <100 000 copies per mL by quantitative PCR) in 32%, 34% and 22% of the patients, respectively.

HBsAg loss was observed in patients who received PEG IFN alpha-2a (4% and 3% versus 0% in the lamivudine group).

### *HBeAg-negative chronic hepatitis*

A phase III, partially double-blinded study has evaluated the efficacy and the safety of PEG IFN alpha-2a alone or in combination with lamivudine versus lamivudine in patients with HBeAg-negative chronic hepatitis B.[43]

Patients were randomized to one of the following treatments: PEG IFN alpha-2a, 180 µg once weekly plus oral placebo once daily for 48 weeks; PEG IFN alpha-2a, 180 µg once weekly plus lamivudine 100 mg once daily for 48 weeks; lamivudine 100 mg once daily for 48 weeks. In total, 552 patients were enrolled in the study. At the end of the 24-week post-treatment follow-up, the two PEG IFN treatment arms (with or without lamivudine) showed the same efficacy, which was superior to that observed in the lamivudine treatment arm: a biochemical response (normal ALT) was observed in 59%, 60% and 44% of the patients, respectively, and a virological response (serum HBV DNA <20 000 copies per mL by quantitative PCR) in 43%, 44% and 29% of the patients, respectively (Fig. 20.9). Interestingly, taking into account that HBsAg loss is rarely observed in HBeAg-negative patients, a substantial rate of HBsAg loss was observed in this study in patients who received PEG IFN alpha-2a (4% and 3% versus 0% in the lamivudine group).

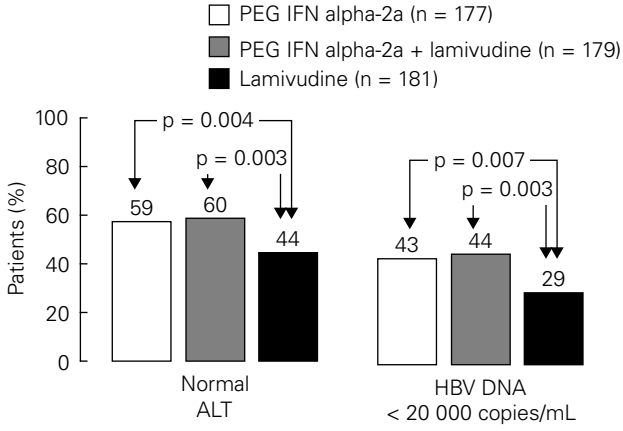

**Figure 20.9** Pegylated interferon (PEG IFN) alpha-2a in HBeAg-negative chronic hepatitis B (from Marcellin *et al.*, AASLD 2003). In this randomized controlled trial, 24 weeks after therapy, the rates of response (normal serum ALT level and serum HBV DNA <20 000 copies per mL) were higher in the two groups which received PEG IFN alpha-2a (with or without lamivudine) as compared with the group which received lamivudine. There was no difference in response rates between the group which received PEG IFN alpha-2a alone and the group which received the PEG IFN alpha-2a plus lamivudine combination.

It is noteworthy that, at the end of the 48-week treatment period, there was a higher incidence of lamivudine resistance in the lamivudine monotherapy group as compared with the PEG IFN alpha-2a plus lamivudine combination group (18% versus <1%), which confirms previous studies suggesting that IFN decreases the risk of lamivudine resistance.[40]

The adverse events associated with PEG IFN alpha-2a therapy were similar to those observed in previous trials in patients with chronic hepatitis C. Interestingly, the frequency of the adverse events was lower than that observed in patients with chronic hepatitis C. In particular, the frequency of depression was much lower: 3–4% as compared with 16–20% in patients with chronic hepatitis C.

This study shows that in patients with HBeAg-negative chronic hepatitis B, (1) the efficacy, as assessed at 24 weeks post-treatment, of PEG IFN alpha-2a monotherapy is superior to lamivudine monotherapy, and (2) the combination of PEG IFN alpha-2a with lamivudine (with the simultaneous regimen used) is not superior to PEG IFN alpha-2a used in monotherapy. However, longer follow-up is needed to assess the durability of response.

## Combination of adefovir with lamivudine

The concept of improving the efficacy by combining two analogues is based on the hypothesis that the combination would maximize the viral suppression and would decrease the occurrence of viral resistance.

One randomized study evaluated the efficacy of the combination of adefovir with lamivudine as compared to lamivudine alone or adefovir alone in 59 patients with HBeAg-positive chronic hepatitis B with lamivudine-resistant HBV.[44] There was no significant difference in median serum HBV DNA reduction (–3.59 and –4.04 log copies/mL), rates of ALT normalization (53% and 47%) and HBeAg loss (three patients in each group) between the adefovir-lamivudine combination group and the adefovir monotherapy group. Notably, serum HBV DNA level remained stable, and there was no significant biochemical or serological change during the study in the patients who remained on lamivudine monotherapy. Therefore, the clinical benefit of continuing lamivudine therapy, once resistance develops, appears to be questionable. However, it seems reasonable, at least in patients with bridging fibrosis or cirrhosis, to continue lamivudine administration after initiation of adefovir since a significant decrease of serum HBV DNA and serum ALT has been obtained.

Another study compared the efficacy of the combination of adefovir with lamivudine versus lamivudine used in monotherapy in 112 treatment-naïve patients (107 HBeAg-positive).[45] There was no significant differ-

ence in median serum HBV DNA reduction (–5.41 and –4.80 log copies/mL), rates of undetectable HBV DNA with PCR (39% and 41%) and HBeAg loss (19% and 20%) between the adefovir-lamivudine combination group and the adefovir monotherapy group. Interestingly, there was a lower incidence of lamivudine resistance in the combination group (2%) than in the lamivudine monotherapy group (20%) ($p$ <0.003).

These two studies do not answer the question of the benefit of the long-term treatment with the combination of adefovir and lamivudine as compared to adefovir monotherapy. Large randomized controlled trials with a long follow-up are needed to address this issue.

## New antivirals

Many new nucleoside analogues are under evaluation for the treatment of chronic hepatitis B. Entecavir, emtricitabine and telbivudine phase III studies have been or will soon be achieved. Other interesting nucleoside analogues like clevudine are still in phase II.

### Entecavir

Entecavir, a cyclopentyl guanosine analogue, is a potent inhibitor of HBV DNA polymerase, inhibiting both the priming and elongation steps of viral DNA replication. Entecavir is phosporylated to its triphosphate, the active compound, by cellular kinases. It is a selective inhibitor of HBV DNA and is less effective against lamivudine-resistant mutants than against wild-type HBV.[46–48]

In a 24-week, double-blind, randomized trial, the safety and efficacy of three different doses of entecavir (0.01 mg/day, 0.1 mg/day or 0.5 mg/day) was compared to lamivudine (100 mg daily); 169 patients were included.[49] Compared with lamivudine, entecavir reduced HBV DNA by an additional 0.97 log at the 0.1-mg dose and 1.28 at the 0.5-mg dose ($p$ <0.0001). At 22 weeks of therapy, in patients treated with entecavir 0.5 mg, 83.7% had an HBV DNA level below the lower limit of detection of the assay (0.7 ME/mL) compared with 57.5% treated with lamivudine ($p$ = 0.008). However, very few patients achieved HBeAg loss (0% and 6% in both groups, respectively. A dose-response relationship was observed.[50] Entecavir was well tolerated at all doses. Most adverse events were mild to moderate and transient with no significant differences observed between the different doses of entecavir and lamivudine. This study indicates that the 0.5-mg dose of entecavir could be the optimal dose.

Entecavir also showed activity in patients with lamivudine-resistant HBV. In one trial including 181 patients with lamivudine-resistant HBV, different doses (0.1, 0.5 and 1 mg daily) of entecavir were tested and compared with lamivudine.[51] At week 24, the percentage of patients with undetectable HBV DNA (<0.7 ME/mL) was 19% with 0.1 mg, 53% with 0.5 mg and 79% with 1 mg of entecavir versus 13% in the group receiving lamivudine ($p$ <0.0001).

Results of phase III studies of entecavir given for 48 weeks as compared with lamivudine in HBeAg-positive and HBeAg-negative patients and in patients with lamivudine-resistant HBV confirmed the efficacy and safety of entecavir. In one study, 709 patients with HBeAg-positive chronic hepatitis were randomized to receive entecavir or lamivudine. Mean HBV DNA level decreases were 7.0 and 5.5 $\log_{10}$ copies/mL ($p$ <0.0001), percentages of patients with undetectable HBV DNA (PCR) were 91% and 65% ($p$ <0.0001) and histological improvement was observed in 72% and 65% ($p$ = 0.008) of patients, respectively.[52]

In another study, 638 patients with HBeAg-negative chronic hepatitis were randomized to receive entecavir or lamivudine. Mean HBV DNA level reductions were 5.2 and 4.7 $\log_{10}$ copies/mL ($p$ <0.0001), percentages of patients with undetectable HBV DNA were 91% and 73% ($p$ <0.0001), histological improvement was observed in 70% and 61% of patients ($p$ = 0.014), respectively.[65] Resistance to entecavir (mutations at positions nt 184, 202 and nt 250) was observed in none of the 432 patients who were not previously treated with lamivudine and in 5.8% of the 172 patients who had previously received lamivudine.[53]

### Emtricitabine

Emtricitabine (FTC) is a cytosine nucleoside analogue with antiviral activity against both HBV and HIV.[46] It differs from lamivudine by a fluorine at the 5-position of the nucleic acid. In a pilot study, 49 patients with HBeAg-positive chronic hepatitis B received five different doses of emtricitabine: 25, 50, 100, 200 or 300 mg daily for 8 weeks. At the end of treatment, serum HBV DNA levels decreased by 2–3 logs in patients receiving the highest doses.

In a randomized, double-blind study, 98 Asian patients (77 HBeAg-positive and 21 HBeAg-negative) were randomized to receive 25, 100 or 200 mg of emtricitabine daily for 48 weeks.[54] At 48 weeks, the median decreases in viral load were 2.6 $\log_{10}$, 3.1 $\log_{10}$ and 2.9 $\log_{10}$ copies/mL, respectively, for the three doses. The proportions of patients with undetectable HBV DNA (<4700 copies per mL) were 38%, 42% and 61%, respectively, for the three doses. HBeAg loss was observed in a high proportion (40%) of the HBeAg-positive patients (ranging from 32% to 50% depending on the dose). Emtricitabine has a comparable efficacy in HBeAg-negative chronic hepatitis B.[55] The results of this study suggest that the optimal dose of emtricitabine is 200 mg once

daily. Genotypic analysis performed at week 48 showed that 12% of patients treated with 100 mg of emtricitabine and 6% of those treated with 200 mg developed drug-resistant HBV.

Phase III clinical trials are under way to determine the long-term safety and efficacy of emtricitabine. However, the role of emtricitabine as a monotherapy may be limited by its structural similarity to lamivudine, with the risk of development of drug resistance.

## Telbivudine

The natural nucleosides in the β-L-configuration (β-L-thymidine [LdT], β-L-2-deoxycytidine [L-dC] and β-L-2-deoxyadenosine [L-dA]) represent a newly discovered class of compounds with potent, selective and specific activity against hepadnavirus.[56] *In vitro* studies have shown that these compounds have marked effects on HBV replication.[46] Telbivudine (LdT) is at the most developed stage of clinical investigation. A phase I study showed a safe preclinical toxicology profile with no mitochondrial toxicity and no mutagenic effect.[57,58]

A phase II study including 104 HBeAg-positive patients compared different therapeutic schedules for 52 weeks: LdT 400 mg daily, LdT 600 mg daily, LdT 400 mg and lamivudine 100 mg daily, LdT 600 mg and lamivudine 100 mg daily or lamivudine 100 mg daily.[59] Median HBV DNA reduction was –6.01, –5.99 and –4.57 in the patients who received telbivudine, the combination of telbivudine and lamivudine, and lamivudine, respectively. Percentages with undetectable HBV DNA by PCR were 61%, 49% and 32%. Percentages of patients with HBeAg loss were 33%, 17% and 28%. YMDD HBV mutants were found in 4.4%, 12.2% and 21.1% of the patients. The safety profile of telbuvidine appeared similar to placebo. Thus, this study confirms the marked antiviral effect of telbivudine with a safe profile. However, there was also a 1-year resistance rate of 4.4%. The combination of telbivudine with lamivudine was not superior to telbivudine alone. On the basis of these data, phase III studies have been initiated.

Another promising β-L-nucleoside compound is val-LdC. It is in phase II testing and preliminary results indicate interesting antiviral activity with a good safety profile. A combination of these two compounds which act at different levels of HBV replication could be of interest.

## Clevudine

Clevudine (L-FMAU;1-[2-fluoro-5methyl-β-L-arabinosyl uracil]) is a pyrimidine analogue with marked *in vitro* activity against HBV but not HIV.[60] The active triphosphate inhibits HBV DNA polymerase but is not an obligate chain terminator. *In vitro* studies suggest that it may also be effective against lamivudine-resistant HBV mutants. In the woodchuck model, a daily dose of 10 mg/kg of clevudine resulted in a 9 $\log_{10}$ decrease in viral load. Interestingly, a delayed reincrease of viral load after cessation of drug administration in a dose-dependent manner was observed.[61] No evidence of drug-related toxicity was observed in treated animals.

An open-label phase I/II, non-randomized, dose escalation study was performed in 35 patients who received clevudine for 28 days at the daily dose of 10 mg (n = 10), 50 mg (n = 10), 100 mg (n = 10) or 200 mg (n = 5) followed by a 20-week post-treatment period.[63] At the end of the dosing period, the median reduction in serum HBV DNA was 2.48 $\log_{10}$, 2.74 $\log_{10}$ and 2.95 $\log_{10}$ in the 10 mg, 50 mg and 100 mg groups, respectively. Interestingly, as in the woodchuck model, there was a slow and delayed reincrease of serum HBV DNA levels with, at the end of the post-treatment follow-up, lower median HBV DNA levels as compared with baseline. Clevudine was well tolerated without serious adverse events. An additional trial with clevudine administered for 12 weeks showed comparable results and confirmed safety.

These preliminary results show that clevudine might be one of the most potent antiviral agents available for the treatment of HBV. Further studies are needed to assess the long-term efficacy and safety of this drug.

## Summary

In recent years, marked progress has been made in the treatment of chronic hepatitis B. The efficacy of lamivudine, the first nucleoside analogue available, is limited by the high incidence of resistance. Adefovir, which was recently approved, has a comparable efficacy with a very low frequency of resistance. However, adefovir needs to be indefinitely administered, as withdrawal of therapy is generally associated with reactivation and sustained response is uncommon.

Preliminary results suggest that PEG IFNs are at least as effective as conventional IFNs. So far, the combination of PEG IFN with lamivudine, used simultaneously, has been disapointing. However, long-term efficacy needs to be assessed and different schedules of combination (for example sequential) need to be evaluated.

A number of nucleoside analogues, with favourable toxicity profiles and a promise of increased effectiveness against HBV, are at various stages of clinical development. Results of phase III trials of entecavir and emtricitabine confirmed their efficacy. However, while entecavir is associated with a low incidence of resistance, emtricitabine is associated with a relatively high incidence of resistance, which limits its use as a monotherapy. The efficacy and safety of new and more potent drugs like telbivudine and clevudine need to be confirmed.

The future of chronic hepatitis B therapy seems to be in the combination of different drugs. Ideally, the optimal drugs to combine would meet the following criteria. They should have different sites of action on HBV DNA replication, a potent antiviral effect, an excellent safety profile and they should induce a sustained response with a limited duration of therapy. Indeed, the concept of combination therapy has been developed recently to increase efficacy and to decrease the occurrence of viral resistance. However, so far few combinations have been evaluated. No combination therapy demonstrated a benefit as compared with monotherapy. More potent drugs and new combinations together with the understanding of the mechanisms of resistance to therapy are important challenges to improve the efficacy of treatment and decrease the global burden related to chronic hepatitis B in the future.

# Chapter 21
# Management of drug-resistant mutants

Yun-Fan Liaw

## Summary

Lamivudine is a nucleoside analogue with potent inhibitory effects on hepatitis B virus (HBV) replication. Prolonged therapy is required for sustained suppression. However, HBV species with mutations in the tyrosine-methionine-aspartate-aspartate (YMDD) locus of the HBV RNA-dependent DNA polymerase (rt M 204 I/V) conferring resistance to lamivudine may emerge after 9–10 months of therapy with an incidence of 38% and 67% after 2 and 4 years of lamivudine therapy, respectively. During continued lamivudine therapy, patients with rt M 204 I/V HBV usually show serum alanine aminotransferase (ALT) and HBV DNA elevations at lower median levels than their baseline. Marked flare of serum ALT or acute exacerbation may occur as the result of cytotoxic T-lymphocyte (CTL)-mediated immune response directed against the YMDD mutant. Although viral clearance with or without emergence of distinct lamivudine-resistant mutants may occur after such exacerbations, 20% of the exacerbations are complicated with decompensation or even fatality. The exacerbations appear to be more severe than those that occur during the natural course of wild-type HBV chronic infection. The conventional practice of continuing lamivudine therapy therefore seems inappropriate. Studies suggest that there is no benefit in continuing lamivudine therapy in such patients. Limited data show that interferon therapy seems ineffective. Switching to adefovir monotherapy is as effective as adefovir/lamivudine combination therapy, and is safe even in decompensated patients. To develop strategies of enhancing therapeutic response and shortening duration of therapy to avoid drug resistance is more important.

## Introduction

Lamivudine is a cytosine nucleoside analogue with potent inhibitory effects on hepatitis B virus (HBV) polymerase/reverse transcriptase activity.[1] Although it can block new covalently closed circular DNA (cccDNA) synthesis, a residual amount of stable pre-existing cccDNA remains.[2] Therefore, the suppressive effect was usually not sustained after stopping lamivudine therapy[3–6] even after hepatitis B e antigen (HBeAg) had seroconverted to its antibody (anti-HBe) in association with HBV DNA clearance.[6–9] In addition, studies have shown that the HBeAg seroconversion rate in patients treated with lamivudine 100 mg daily for 1 year was <20%.[10,11] These findings suggest that prolonged lamivudine therapy is required for most of the patients. However, HBV with reverse transcriptase mutations conferring drug resistance start to emerge after 6–9 months of lamivudine therapy and create a great challenge for long-term lamivudine therapy. Adefovir dipivoxil (ADV) is another licensed direct antiviral agent with potent suppressive effect on HBV. Resistant mutations (N236T and A181V) may also emerge upon prolonged ADV therapy at a low incidence (<6% up to 3 years) and were responsive to lamivudine. However, its long-term consequences are not clear yet, therefore they will not be covered in this chapter.

## YMDD mutation and its incidence

The lamivudine-resistant HBVs have a characteristic amino acid substitution over the tyrosine-methionine-aspartate-aspartate (YMDD) motif of the RNA-dependent DNA polymerase.[12] According to the new consensus reverse transcriptase domain numbering system,[13] the methionine at position 204 is either replaced by an isoleucine (rt M 204 I) or a valine (rt M 204 V).[14–16] In addition, the rt 204 mutations are frequently accompanied by a leucine-to-methionine substitution at position rt 180 (rt L 180 M).[17,18] While rt M 204 I and rt L 108 M/M 204 V are the two most commonly identified mutants, many other mutants have been reported.[19,20]

Although a mutation in the rt YMDD motif may be detected before therapy,[21] it usually emerges after lamivudine therapy for 6–9 months. One study showed that the genotypic resistance appeared as early as 49 days.[22] The incidence varies from report to report. Based on the results of the largest series, the 1-year incidence was 14% of 285 HBeAg-positive Asian patients,[11] 32% of 44

HBeAg-positive Caucasian patients[10] and 27% of 41 HBeAg-negative Caucasian patients.[23] It was reported that patients with higher serum transaminase, higher HBV DNA or HBV with core promoter mutations select rt YMDD mutations more rapidly.[11,22,24] Data also show that the incidence in Oriental patients is lower than in Caucasians.[10,11] Combined data from four multicentre, controlled phase 3 studies showed that the 1-year incidence was 24% and that sex, baseline body mass index and HBV DNA level were associated with emergence of YMDD mutants.[25] As there is distinct variation in the genotypes of HBV in different geographical regions, it has been questioned whether there is genotype-related incidence of YMDD mutations. One study showed that patients infected with adw subtype HBV had a 20-fold increase in the risk of lamivudine resistance during a mean period of 12 months' therapy as compared with patients with the ayw subtype.[26] A study of longer treatment periods (12–36 months, mean 24 months) showed that the 1-year incidence of YMDD mutation was higher in genotype A (adw) than in genotype D (ady) (43% vs 18%) but the 2-year incidence was similar (53% vs 55%).[27] There was also no significant difference in the cumulative incidence among genotypes A, B and C infection in Japanese patients.[28]

The incidence of rt M 204 I/V increases with increasing duration of lamivudine therapy. In Asian lamivudine studies, it increases from 14% at 1 year to 38%, 55%, 67% and 69%, respectively, at the end of 2, 3, 4 and 5 years.[5,11,29–31] The cumulative rate increases to 56% at 2 years in HBeAg-negative Italian patients,[24] and reaches 91% at 4 years of lamivudine therapy, or 20% per year, in human immunodeficiency virus (HIV)-infected patients with chronic HBV infection.[32] It appears that rt M 204 I/V will ultimately emerge in most, if not all, patients with continuing lamivudine therapy.

## Viral consequences after emergence of YMDD mutations

It has been shown that the replication competency of HBV with rt M 204 I/V is defective.[33] On the other hand, the mutations exert configuration hindrance to the incorporation of lamivudine and therefore confer drug resistance.[34] Upon longer therapy, additional P gene mutations may occur and restore the replication fitness of HBV with rt M 204 I/V.[17,20,24,35] Site-directed mutagenesis experiments have further shown that the defective replication competency of some mutants may be completely restored after addition of lamivudine.[20,36,37] Some P gene mutations may influence or be related to other HBV genes. One study showed reversion of precore stop codon mutation in three HBeAg-negative patients and amino acid substitution in the coding sequence of the overlapping S gene in approximately half of the P gene changes.[24] The functional consequences of such S gene mutations have not been clearly defined and their potential effects are unpredictable but may affect viral envelopment, secretion, antigenicity and infectivity.[38] S gene truncation impairing the secretion of HBsAg has been found in some P gene mutations.[20,36] Of note is that the truncation point in the A529T (rt A 181 T) mutant was located just at the border of the previously defined 'transactivity-on-region'.[20,39] The pre-S2/S mutant with such truncation, as identified in the HBV integrant of a human HCC,[40] is capable of transactivating several promoters including those of oncogenic proteins.[39–41]

## Clinical impact of YMDD mutations during continuing lamivudine therapy

The emergence of rtYMDD mutations is initially silent but is followed by phenotypic resistance or viral breakthrough, after a time lag of 3–4 months.[22] Although the emergence of rtYMDD mutations is followed by viral breakthrough and ALT elevation in >90% of the patients,[25,42,43] it has invariably been reported that patients with YMDD mutations maintain a significantly lower 'median' HBV DNA and ALT level than at baseline.[5,10,11,25,29] However, hepatitis flare with serum ALT over five times the upper limit of normal (ULN) occurred in around 40% of HBeAg-positive patients[22,42] and around 50% of HBeAg-negative patients during continued lamivudine therapy after emergence of rtYMDD mutations (Table 21.1).[22,44–48] These hepatitis flares, usually preceded by a rapid resurgence of HBV DNA,[49] as shown in Fig. 21.1, were considered to be the results of CTL-mediated immune response against rt M 204 I/V.[42] Although such hepatitis flares may be followed by HBeAg seroconversion and/or immune clearance of the mutant virus,[42,43] new and distinct mutant may be selected and elicit another exacerbation and then select another mutant.[20] Whereas patients harbouring HBV with rt M 204 I/V continue to achieve HBeAg seroconversion,[5,29,42,43] the seroconversion rates are much lower than in patients without YMDD mutation.[25] In addition, severe hepatitis with hepatic decompensation or even fatality may occur, particularly in patients with advanced underlying liver disease[42,43,50,51] or in a post-transplantation setting[14,37,52–57] (Table 21.2). Compared with the hepatitis flare or exacerbation occurring in the natural history of untreated chronic HBV infection,[58] hepatitis flares during continued lamivudine therapy in patients with YMDD mutations appear to be more severe in terms of the incidence of hepatic decompensation.[59] The liver damage associated with these hepatitis flares[50] may explain the observation that the hepatitis activity index worsened after initial improvement in patients with rtYMDD mutations.[29,60] One study showed that cirrhotic patients with initial increases in serum albumin dur-

ing lamivudine therapy developed a highly significant and rapid decline in serum albumin after emergence of rtYMDD mutations.[61,62] It is clear, then, that the possible adverse effects of rtYMDD mutants (Table 21.3) do cause concern and are a challenge, and that the benefits versus risks of prolonged lamivudine therapy must be carefully weighed.

## Better to avoid than to contend with YMDD mutants

Given the problems associated with YMDD mutations, it is better to prevent the occurrence of such a difficult issue. One strategy is not to treat or to postpone the treatment, if the risk is sufficiently low or spontaneous

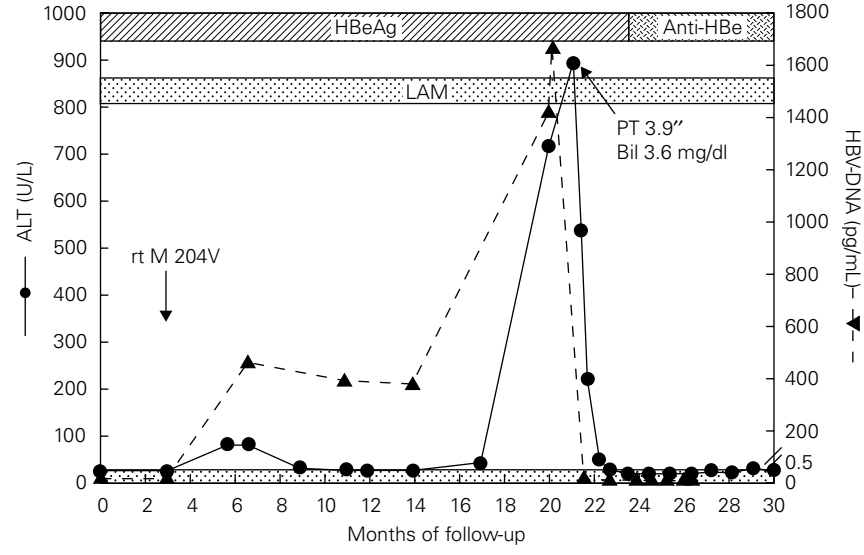

**Figure 21.1** Clinical course of a patient with chronic hepatitis B virus (HBV) infection who developed hepatitis flare after emergence of rt M 204 V during prolonged lamivudine (LAM) 100 mg daily therapy. Note that serum HBV DNA level increased gradually to a high level and was followed by a severe hepatitis flare with high serum alanine aminotransferase (ALT), increased serum bilirubin (Bil) and prothrombin time (PT) prolongation. The hepatitis flare was followed by precipitous decline of serum HBV DNA, subsequent hepatitis B e antigen (HBeAg) seroconversion to its antibody (anti-HBe) and normalization of ALT.

**Table 21.3** Problems of YMDD mutants during continuing lamivudine therapy

| | |
|---|---|
| I Viral | Incidence increases with duration of therapy.<br>Defective replication competency of the mutants restored in the presence of additional compensatory mutations and lamivudine.<br>Viral breakthrough, although 'median' HBV DNA level lower than baseline level. |
| II Clinical | Biochemical breakthrough in >90% of the patients.<br>Hepatitis flares (ALT >5 × ULN) occur in up to 50% of the patients.<br>Severe hepatitis/decompensation may occur, mortality in patients with cirrhosis.<br>Histological benefit diminishes. |

viral clearance is likely to occur. For example, around 70% of hepatitis flares with bridging hepatic necrosis or a serum alpha-fetoprotein level over 100 ng/mL are followed by spontaneous HBeAg/HBV DNA clearance within 3 months.[63] Therefore, a 3-month observation period is acceptable if there is no concern as regards hepatic decompensation.[64,65]

If the patients do need treatment, strategies should be applied to minimize the incidence of YMDD mutation. As was documented with the therapy for HIV infection, combination therapy to completely suppress ongoing replication is required to arrest the emergence of drug resistance. Currently, adefovir dipivoxil (ADV) has been approved and entecavir (ETV), emtricitabine (FTC), clevudine (L-FMAU), telbivudine (LdT) and other new nucleoside analogues, as well as immunotherapeutic approaches, are undergoing appraisal and the preliminary results are encouraging. Combination therapy with some of these agents is a possible strategy to avoid the emergence of YMDD mutants. However, this requires confirmation by controlled studies.

Another strategy is to treat more effectively and thereby shorten the duration of therapy. Studies have shown that patients with high pre-therapy ALT level (>5 × ULN) had a much higher HBeAg seroconversion rate, up to 65% at 1 year[66,67] and 80% at 2 years, [5] suggesting that antiviral agents are more effective in patients who have mounted a stronger endogenous immune response to HBV. With the concern of YMDD mutations, it was recommended to select patients with higher ALT (>5 × ULN) for lamivudine therapy, which should be discontinued as soon as possible after HBeAg seroconversion and/or HBV DNA loss had been documented on two separate occasions at least 1 month apart.[65] Considering the durability of such a response,[6–9] a more recent recommendation is to stop lamivudine therapy after an additional treatment for 6 months after HBeAg seroconversion.[65] This strategy is best demonstrated by a representative case with durable response to a short course of lamivudine therapy (Fig. 21.2).

The strategy for patients with lower ALT level (2–5 × ULN) is to postpone lamivudine treatment until ALT rises over 5 × ULN. Alternatively, to induce ALT flare may be a workable approach, as a pilot study of prednisolone priming has shown an enhanced Th1 response and increased efficacy of a subsequent 9-month period of lamivudine therapy.[68] Enhanced response has also been documented in such patients who received 100 mg of lamivudine daily for 8 weeks followed by combination therapy of 100 mg lamivudine daily with 10 MU IFN-α2b three times weekly for 16 weeks.[69] Studies are required to test whether manipulation of the host immune response against HBV using other immunomodulating agents, such as thymosin $\alpha_1$, before or during lamivu-

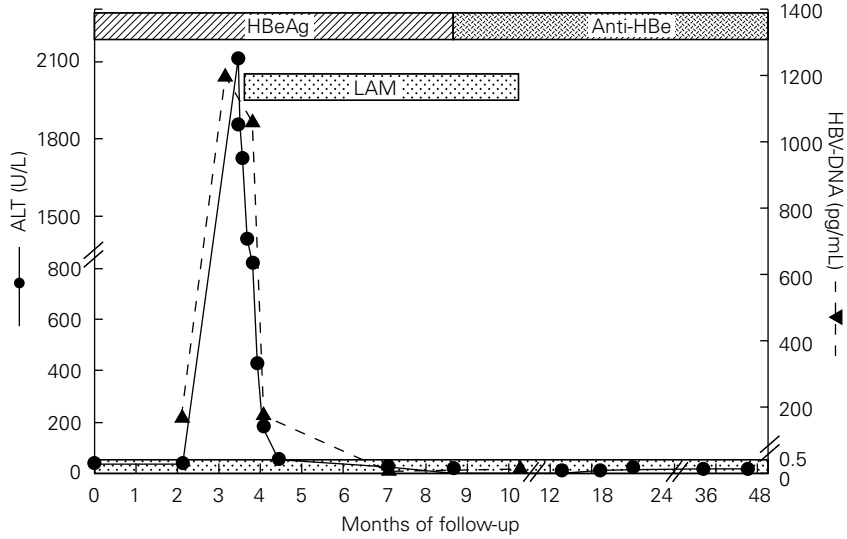

**Figure 21.2** Clinical course of a patient with chronic hepatitis B virus (HBV) infection showing durable response after a short course (6 months) of lamivudine (LAM) therapy. LAM therapy started after serum alanine aminotransferase (ALT) increased over 1500 U/L. Note that serum HBV DNA declined rapidly and was followed by hepatitis B e antigen (HBeAg) seroconversion to its antibody (anti-HBe). The response was sustained for more than 3 years of therapy. No YMDD mutation was detected.

dine therapy, could also enhance efficacy and thereby shorten the duration of therapy.

## Management of patients with YMDD mutations

### Conventional practice: to continue lamivudine therapy

Until effective drug(s) against HBV with rt M 204 I/V are available, patients with YMDD mutations are very difficult to treat. The general recommendation for such patients is to continue lamivudine therapy[64,67] in order to further suppress or to prevent the return of wild-type HBV,[70] which is more replication-competent than HBV with rt M 204 I/V.[33] Another rationale is based on the clinical experience that patients with YMDD mutations maintain lower 'median' serum HBV DNA and ALT levels than their baseline values and continue to achieve HBeAg seroconversion during continuing lamivudine therapy.[5,11,25,29] However, this strategy seems ineffective, and is associated with many problems, as discussed earlier (Table 21.2).

### Discontinue lamivudine therapy

HBV with rt M 204 I/V is not only resistant to lamivudine therapy, experiments have also shown that the defective replication competency of some YMDD mutants was completely restored upon addition of lamivudine.[20,36] This may argue against the practice of continuing lamivudine therapy after emergence of YMDD mutations. Consistent with earlier experimental findings, a recent study on severe recurrent hepatitis B with rt M 204 I/V after liver transplantation also showed enhanced replication of the HBV with rt M 204 I/V *in vitro* in the presence of lamivudine.[37] Similar to the repeatedly reported fatality during continuing lamivudine therapy after emergence of rt M 204 I/V,[43,50–57] two patients in that study died of hepatic failure during continuing lamivudine therapy. In contrast, one patient with hepatic decompensation showed decreasing HBV DNA levels with subsequent clinical improvement and survival after stopping lamivudine therapy. It was therefore concluded that the lamivudine-enhanced replication of HBV with rt M 204 I/V during continuing therapy could be deleterious and that lamivudine therapy should be stopped in the setting of lamivudine-dependent mutants.[37] One Asian study in patients with rt M 204 I/V showed that hepatic flare and decompensation occurred in 67% and 11%, respectively, in patients who continued lamivudine therapy for 12 months as compared with 54% and 7% in those who were followed up for 12 months after stopping lamivudine therapy. In addition, serum HBV DNA increased in 64% and decreased in 36% of the patients who continued lamivudine therapy, but increased in 11% and decreased in 89% of the patients who stopped lamivudine therapy ($p$ <0.001) The study therefore concludes that there is no benefit to continue lamivudine therapy after emergence of rt M 204 I/V.[71] Another Asian study has shown that stopping therapy in this setting is generally safe.[72] All these findings suggest stopping lamivudine therapy even if effective drug(s) for YMDD mutant HBV are not available.

### Switch to drugs able to suppress rt M 204 I/V

Small studies showed that IFN therapy had limited efficacy in treating patients with rt M 204 I/V.[59,73,74] In contrast, studies have shown that ADV and ETV are effective against HBV rt M 204 I/V.[75–78] ADV added to lamivudine in decompensated patients with rt M 204 I/V HBV may suppress HBV DNA level by 2–5 logs and restore their Child Pugh status.[75–77] The clinical course of a representative patient is shown in Fig. 21.3. Switching from lamivudine to ADV monotherapy is as effective as ADV/lamivudine combination therapy in patients with rt M 204 I/V, although hepatitis flare without increase of HBV DNA developed in one-third of the 19 patients after switching to ADV monotherapy.[77] A recent control study in 42 Korean patients with decompensated liver disease[79] and a cohort study in 20 Taiwanese cirrhotic patients with or without decompensation (Liaw *et al*. 2005, unpublished data), however, showed that switching to ADV monotherapy was effective and safe and not associated with significant hepatitis flare. Similarly, switching from lamivudine to ETV monotherapy is safe, has no risk of hepatitis flare and is highly effective.[78] It seems likely that with these drugs, we are able to cope with the problems associated with rt M 204 I/V.

## Conclusions

There is no doubt that chronic HBV infection is difficult to treat, and that even agents with potent suppressive effect on HBV require prolonged therapy to achieve a durable response. Then, drug-resistant mutants will inevitably emerge and create virological and clinical consequences or problems. Although we now have agents able to suppress such mutants, the long-term outcomes are still unknown. To develop strategies for enhancing therapeutic response and shortening the duration of therapy is our ultimate goal to avoid the problems of drug-resistant mutants.[80] For the existing patients suffering from problems with such mutants, it seems more reasonable to switch to a drug that is able to suppress the mutant than to combine with that drug in terms of cost and effectiveness.

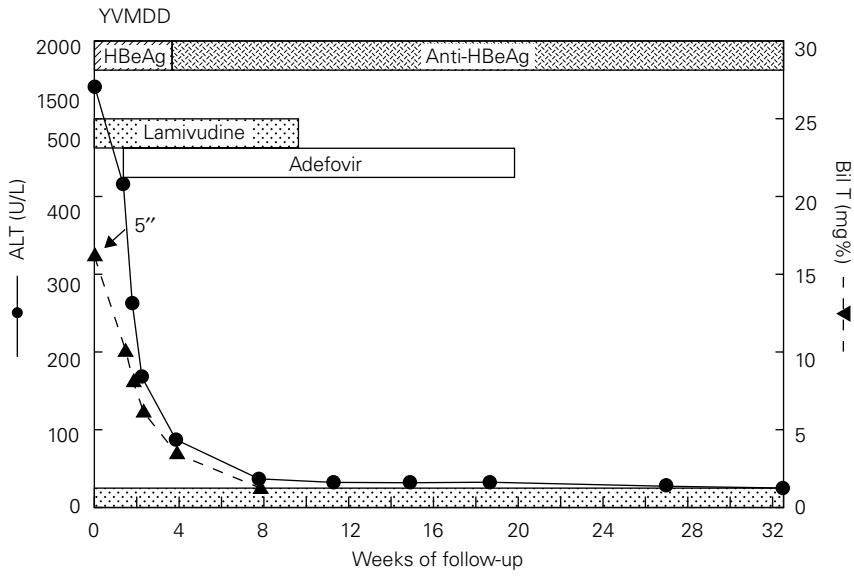

**Figure 21.3** Clinical course of a patient with severe hepatitis flare and decompensation after emergence of YMDD mutants during continued lamivudine (LAM) therapy. After addition of adefovir dipivoxil (ADV), her serum bilirubin (Bil) decreased from 16 mg/dL and alanine aminotransferase (ALT) decreased from 418 U/L to normal levels. Hepatitis B e antigen (HBeAg) seroconversion to its antibody (anti-HBe) also followed. The responses were maintained after stopping LAM therapy and sustained after stopping ADV therapy.

# Chapter 22
# Liver transplantation in the management of chronic viral hepatitis

Marina Berenguer, Teresa L Wright

## Introduction

Liver transplantation has revolutionized the care of patients with end-stage liver disease. Indeed, due to significant improvements in immunosuppressive therapy and surgical techniques over the past decades, excellent survival rates and quality of life should now be expected.[1] Among several circumstances that may pose a threat to long-term survival, the greatest is probably the recurrence of the original liver disease.[2–4] This complication may occur for most of the primary causes of liver failure, and more specifically with those of viral origin. While recent advances, predominantly the development of strategies to prevent or effectively treat hepatitis B, have led to substantial improvements in the post-transplantation outcome of hepatitis B candidates,[2] there is a great need for interventions that alter the natural history of recurrent hepatitis C.[3]

This chapter reviews the indications for liver transplantation for viral-related liver diseases, the mechanisms involved in viral reinfection, and the natural history, pathology, methods for prevention and treatment of recurrent viral hepatitis.

## Recurrent hepatitis B virus (HBV) infection

HBV disease, once considered a relative or even absolute contraindication for liver transplantation in many centres, is now considered an excellent indication, accounting for 6–10% of liver transplantations performed annually in the United States and Europe.[1,2] Comparable and even better results than those obtained for other indications can now be obtained, largely due to effective interventions to prevent post-transplantation recurrence – namely high doses of hepatitis B immune globulin (HBIg) in combination with antiviral agents. Historically, rates of HBV recurrence were high (90%) resulting in graft loss in >70% of patients. In fact, the rapid recurrence of hepatitis B with ensuing graft loss was frequent enough for most third party payers to withdraw hepatitis B infection as an acceptable indication for liver transplantation. A number of approaches were developed during the 1990s, and with each intervention, there has been a step-wise reduction in the likelihood of recurrence, down to 5–10% with HBIg plus lamivudine.[2] Currently, the debate has shifted from whether liver transplantation is an option for this patient subgroup to selecting the most cost-effective and applicable strategies to prevent reinfection and treat disease before and after transplantation. Indeed, at present, the main unanswered questions are to define (1) the best long-term prophylactic strategy, with the highest success rate and the lowest cost, and (2) the optimal regimen and timing of pre-transplantation antiviral therapy.

### Indications for liver transplantation

Cirrhosis caused by chronic HBV infection is associated with reduced survival, due to the development of hepatic complications, namely clinical decompensation and hepatocellular carcinoma (HCC). While in the absence of decompensation, the 5-year survival reaches 84%, it drops to 14% once decompensation occurs.[5] The indications and contraindications for transplantation in these patients do not differ from those applied to other forms of liver diseases and typically include liver failure, complications from portal hypertension, or the development of HCC. Criteria for selecting patients with HCC do not differ from those uninfected with co-existent HCC and include a solitary nodule smaller than 5 cm or no more than three nodules, each one smaller than 3 cm in diameter, without macroscopic vascular involvement or extra-hepatic spread.[6]

Studies of the natural history of advanced HBV disease have demonstrated that patients with active viral replication, defined as the presence of detectable HBV DNA using a non-polymerase chain reaction (PCR)-based assay (>$10^5$–$10^6$ copies/mL) or hepatitis B e antigen (HBeAg), are at increased risk of disease progression.[5,7] Suppression of HBV replication in these patients, either spontaneously or with antiviral treatment, measured

by the disappearance of HBV DNA from the serum and seroconversion from HBeAg to anti-Hbe, may result in significant clinical improvement, including improvement in the Child Pugh score of the patient.

## Recurrence of HBV infection

In the absence of preventive measures, most cases of HBV reinfection occur during the first 1–3 years post-transplantation and rarely thereafter.[8] Reinfection is characterized by the reappearance of HBsAg in serum and high levels of HBV DNA.

HBV DNA level before transplantation is the best predictor of the risk of HBV recurrence, with the highest rates reported in HBsAg-positive cirrhotic patients with evidence of active viral replication and the lowest in patients with fulminant hepatitis, HDV co-infection and chronic HBV infection without detectable HBeAg or HBV DNA.[2,8,9] In the absence of effective prophylactic therapies, HBV recurs in 75–90% of patients with a 2-year actuarial risk of 67% in HBV-cirrhotic patients, 32% in cirrhotic patients co-infected with hepatitis D virus (HDV) and 17% in those undergoing transplantation for fulminant hepatitis.[2,8,9] When long-term HBIg was used for HBV prophylaxis, with doses of HBIg used to produce anti-HBs titres higher than 100 UI/L, recurrence was reduced in those without active HBV replication to 17–38% at 2 years but remained at approximately 70–96% for those undergoing transplantation who were HBV DNA-positive (by hybridization methods)[2,8–10] (see below).

## Pathogenesis

Graft reinfection may occur from circulating viral particles in blood immediately post-transplantation or alternatively from virus present in extrahepatic sites, particularly the peripheral blood mononuclear cells (PBMCs). In patients receiving HBIg, circulating Dane particles are presumably neutralized by immune globulins, although the true mechanism by which passive prophylaxis reduces the rate of recurrent HBV infection is unknown. Hypotheses include the binding of antibody to virus in the serum which thereby limits viral entry into the new graft, and the control of horizontal spread of virus within the liver. The specific antibody preparation used for prophylaxis may alter efficacy.[10]

Reinfection in HBIg-treated patients may occur due to one or more of the following causes: (1) viral mutations in the 'a' determinant region; (2) titres of anti-HBs antibody that are too low to provide adequate protection; and/or (3) overproduction of HBV in the extrahepatic sites.[10–15] The 'a' determinant is the region of the surface protein where anti-HBs binds, and mutations in the surface gene encoding this region have been reported in association with monoclonal and with polyclonal HBIg therapy. These mutations, which occur in approximately half of the patients failing HBIg prophylaxis,[12] are associated with detectable HBsAg and HBeAg in serum, increase in HBV DNA levels and disease recurrence, and thus are termed 'escape mutants'. They typically occur after 6 months of treatment. The most common mutation is a substitution of glycine for arginine at amino acid position 145. Discontinuation of HBIg results in reversion of the mutation to the wild-type virus in the majority of patients.[14] In contrast, in the early post-transplant period, failure of HBIg to prevent reinfection is probably due to inadequate post-transplantation anti-HBs titres in the context of high levels of viraemia and/or production of virus from extrahepatic sites. In one study of a patient with HBV reinfection despite anti-HBs Ig prophylaxis, it was shown that the predominant HBV strain after transplantation was the predominant strain present in lymphocytes before transplantation. Interestingly, this strain was different from the predominant strain present in serum and liver, suggesting an immune pressure selection of HBV strain by anti-HBs Ig and demonstrating the role of extrahepatic lymphocytes as a source of HBV reinfection after transplantation.[11]

The mechanisms by which HBV leads to liver injury are incompletely understood. Increased levels of HBV replication are typically observed, probably related to the use of immunosuppressive drugs, particularly corticosteroids. This enhanced replication with excess production of viral proteins in conjunction with the altered host immune responsiveness probably contributes to the pathogenesis of liver damage, particularly to pathogenesis of severe progressive disease of the grafted liver.[16]

## Natural history of HBV recurrence

The natural history of recurrent hepatitis B in the absence of therapeutic intervention is more aggressive than that observed in the immune competent population. Less than 5% of patients developing HBV recurrence maintain a normal graft in the medium to long term.[8,17–19] Typically, patients develop acute hepatitis after detection of HBsAg in serum, with progression to chronic hepatitis and cirrhosis within 2 years of transplantation. One particular entity initially described in these patients is known as fibrosing cholestatic hepatitis, characterized by extensive cytoplasmic HBsAg expression, variable degrees of HBcAg cytoplasmic and nuclear expression.[16] The combined features of high cytoplasm expression of viral antigens and paucity of inflammatory infiltrate suggest a direct cytopathic effect of the virus. The clinical course is rapidly progressive with severe cholestasis, hypoprothrombinaemia, and liver failure within weeks of onset. Patients at risk for this syndrome include those with high levels of viraemia pre-transplantation and

those infected with precore mutants.[20,21] Fortunately, with currently available effective therapies, this syndrome is rarely if ever seen in patients undergoing liver transplantation for HBV disease today.

## Prevention of HBV graft reinfection

### *Hepatitis B immunoglobulins*

In order to prevent reinfection with HBV, lifelong passive immunization with high-dose hepatitis B immunoglobulins is used in most transplant centres and was considered, until very recently, the 'standard of care'.[2,10]

#### *Efficacy*

The administration of HBIg for more than 6 months has been shown to reduce dramatically the rate of HBV recurrence. In a large European multicentre study, the recurrence rate was 75% in patients receiving no or short-term HBIg versus 33% in those receiving long-term HBIg ($p$ <0.001).[9] Long-term administration of HBIg reduced the rate of recurrence in patients with fulminant HBV hepatitis to <10%, in HDV co-infected patients to 10–15%, and in HBV DNA-negative cirrhotic patients to <30%. Yet it did not reduce the rate of recurrence in patients with HBV DNA-positive cirrhosis. A more recent analysis of the long-term results of HBIg administration in 271 patients shows an actuarial rate of HBV recurrence of 26.8%, 34.6%, 40% and 41.6% at 1, 2, 5 and 10 years, respectively.[8] Substantial differences were again observed between patients who were HBV DNA-positive and those who were negative pre-transplantation with 5-year actuarial recurrence rates of 76.7% and 33%, respectively. Interestingly, almost no new cases of recurrence were observed after 5 years.

The adverse prognostic characteristic of active viral replication pre-transplantation may be overcome with more aggressive use of HBIg maintaining titres over 500 IU/L, or by the use of HBIg in combination with antiviral agents.[2,10] With the first alternative, at least during the first 6 months, recurrence in HBV DNA-positive patients may be reduced to approximately 16–35%.[8,22,23] In addition, these aggressive regimens have also been shown to improve outcome in patients re-transplanted for fibrosing cholestatic hepatitis (see above). The second alternative is to use combination prophylactic therapy with HBIg in association with pre- and/or post-transplantation antiviral therapy (see later).

#### *Administration*

Various regimens have been described, with most including the administration of 10 000 IU HBIg intravenously during the anhepatic phase and 10 000 IU HBIg daily for the first week post-transplantation.[2,10] The subsequent dosing is either given on a fixed schedule (generally on a monthly basis)[23] or based on anti-HBs titres (re-administration when antiHBs titre is <100–500 IU/L).[8,22] Individualized immunoprophylaxis based on the administration of variable amounts of HBIg is possibly the best approach. Indeed, there is a great variability in the pharmacokinetic profile of immunoglobulins between patients. In addition, variations are also common in the same individual based on the time since transplantation. The individualized approach is aimed at achieving pre-defined anti-HBs level in the serum known to minimize the risk of recurrence while at the same time reducing the number of infusions and, subsequently, the cost. Based on previous studies, HBIg should be given so as to obtain anti-HBs titres >500 IU/L during the first week after transplantation, >250 IU/L between days 8 and 90 and >100 IU/L thereafter.[2,10]

#### *Safety profile*

HBIg has a very satisfactory safety record with adverse events being typically minor. Mercury poisoning has been reported anecdotally in patients receiving an intramuscular form of the intravenous HBIg.[2,10]

#### *Disadvantages*

Despite the clear efficacy of prophylactic HBIg as a single agent, this therapy has limitations, including the high cost, limited availability, selection of pre-S/S-resistant mutants,[12–15] and overall failure in 20–30% of treated recipients.

A specific limitation is the need for lifelong therapy, given the risk for reinfection associated with discontinuation of this product. Recurrent infection has been documented in patients stopping prophylaxis with HBIg after 1 year. Furthermore, HBV DNA has been detected by highly sensitive molecular techniques in the serum, liver and PBMCs of 50% of HBsAg-negative patients on HBIg ± lamivudine prophylaxis,[23–26] although it is unclear whether these viral sequences represent infectious viral particles capable of reinfecting the graft. Nevertheless, detection of HBV DNA suggests that indefinite treatment is required.

### *Alternatives to HBIg mono-prophylaxis*

In order to overcome the limitations of HBIg, several alternatives are currently being evaluated (Table 22.1)

#### *Pre-transplantation antiviral therapy*

The first alternative is the use of antiviral treatment prior to transplantation to inhibit viral replication.[5,27–36]

**Table 22.1** Strategies in patients undergoing liver transplantation for HBV-related liver disease

| Stage | Goals of therapy | Available drugs | Unsolved questions |
|---|---|---|---|
| Pre-transplantation therapy | Inhibition of viral replication:<br>Inclusion in the waiting list<br>Reduction of the risk of recurrence<br>Stabilization of liver function | Interferon (?)<br>Lamivudine<br>Adefovir | Time of initiation of lamivudine<br>Lamivudine vs adefovir vs combination therapy |
| Post-transplantation pre-emptive therapy | Prevention of recurrence | HBIg<br>Adefovir (?)<br>HBIg + lamivudine<br>HBIg + adefovir | Long-term prophylaxis<br>Lamivudine vs adefovir |
| Treatment of established disease | Histological improvement<br>Inhibition of viral replication | Lamivudine<br>Adefovir<br>Entecavir | Combination therapy vs monotherapy |

HBIg, hepatitis B immune globulins.

Interferon (IFN) is not recommended in patients with decompensated HBV cirrhosis, due to the low tolerability, the risk of triggering life-threatening complications such as bacterial infections and/or the risk of precipitating flares of underlying liver disease leading to worsening liver failure and even death. In contrast, nucleoside analogues are very well tolerated, are orally administered, and have a potent antiviral effect, inducing rapid suppression of HBV DNA in serum. Recent experience with these drugs in cirrhotic patients awaiting liver transplantation is encouraging.[28–36] Most of the experience published to date is with lamivudine, with data on >500 cirrhotic patients treated with this drug while on the waiting list for liver transplantation. With lamivudine, HBV replication is suppressed below the level of detection of standard assays within 2–3 months of initiating therapy, allowing liver transplantation to be performed in conditions of low risk of HBV recurrence. In most published studies, pre-transplantation lamivudine results in loss of HBV DNA by molecular hybridization in 90% (range 62.5–100%) of patients with detectable serum HBV DNA prior to beginning nucleoside therapy, including those infected with the e-minus strain.[28–36] However, viraemia will recur in >80% of patients following treatment discontinuation, and thus treatment should be administered indefinitely in these patients with advanced HBV cirrhosis. Unfortunately, prolonged therapy is associated with development of mutations in the YMDD motif of the HBV DNA polymerase gene. Moreover, development of resistance has been associated with progression of liver disease, and even fatal flares of HBV disease.[28–36]

Suppression of HBV replication has resulted in improvement in hepatic synthetic function as well as in Child Pugh score, in some cases delaying or even obviating the need for liver transplantation.[28–34,36] In these cases, clinical and biochemical improvement, defined by normalization of serum aminotransferases, decrease in serum bilirubin, increase in albumin levels and a >2–3 point improvement in the Child Pugh scores occur gradually, typically after 6–9 months of therapy.[35,37] Unfortunately, not all decompensated cirrhotic patients with active viral replication who are treated with lamivudine will benefit from this drug. Indeed, progression of the disease and even death may occur, particularly in the subset of patients with severely advanced liver failure with increased serum bilirubin and creatinine levels and elevated Child Pugh and model for end-stage liver disease (MELD) scores.[37,38] As deaths tend to occur early after the initiation of therapy, generally within the first 6 months, patients with the above characteristics, who most likely have presented late in their disease course, should be prioritized for urgent liver transplantation, irrespective of the antiviral response to lamivudine.

The major downside of lamivudine is the emergence of 'drug resistance' with HBV DNA reappearance, and generally, modest increase in serum aminotransferase levels. This complication, which is strongly linked to the duration of therapy, develops in 0–27% of patients, with the risk increasing substantially after 6 months of treatment.[28–38] Although the clinical course after the development of drug resistance is often benign,[39] fatal flares of hepatitis and rapidly worsening liver failure have been reported.[40–42] In addition, development of resistance while on the waiting list may lead to reluctance to transplant an HBV DNA-positive patient known to have lamivudine-associated HBV mutants.[43–45] Indeed, it has been recently shown that the risk of postoperative HBV recurrence may be relatively high in these patients, despite the use of high doses of HBIg in combination with lamivudine in the post-transplantation period.[44,45] Hence, for the last few years, the dilemma has been to decide the optimal timing of initiation of lamivudine in potential liver transplant candidates. Against the concept of delaying lamivudine therapy has been the observation that some patients with decompensated cirrhosis have improvement in the hepatic synthetic function with treatment-related viral suppression. In contrast,

against the concept of early antiviral therapy is the fear of emergence of lamivudine resistance with prolonged therapy and the potential for worsening liver disease and increased risk of HBV recurrence. One approach to minimizing the risk of progressive liver disease resulting from viral resistance has been to give other oral agents that carry a lower risk of resistance.

Adefovir dipivoxil, a prodrug of adefovir, is a phosphonate nucleotide analogue of adenosine monophosphate, which appears to be, at least in part, the solution to this problem. The major advantage of this recently approved oral antiviral agent is the potential to treat effectively HBV infection in patients who have previously developed lamivudine resistance. This drug has demonstrated activity *in vitro* and *in vivo* against HBV strains resistant to lamivudine. Recent data from 128 patients with decompensated cirrhosis treated with adefovir at doses of 10 mg daily demonstrated that this drug is safe and effective in treating lamivudine-associated breakthrough, significantly suppressing serum HBV DNA levels. As with lamivudine, normalization of ALT is achieved in most treated patients (approximately 60%), with improvement in serum bilirubin, albumin and prothrombin time.[46] The one concern with this drug is the potential for renal toxicity, which may be of particular importance in patients with hepatic decompensation. The dose of adefovir should be adjusted based on creatinine clearance and careful monitoring of renal function is warranted. As elevations of serum creatinine are mostly observed in patients with pre-existing renal insufficiency, dose reductions of adefovir have been recommended for patients with creatinine clearances of <50 mL/min.

In summary, adefovir dipivoxil appears to be an excellent rescue therapy for patients with advanced decompensated HBV-related cirrhosis who develop lamivudine resistence while awaiting liver transplantation. While polymerase gene mutations associated with long-term adefovir have been recently reported, their incidence appears to be extremely low (2% after 2 years of continuous use), and other nucleoside analogues that are in various phases of development offer hope as rescue therapy for viral resistance.[47] The observation that lamivudine-resistant variants are sensisitive to adefovir dipivoxil, and conversely that adefovir-resistant variants are sensitive to lamivudine provides scientific rationale for combination therapy with both of these agents in treating patients with advanced liver disease awaiting transplantation.

Several questions remain unanswered at present. For instance, the best post-transplantation prophylaxis in patients with lamivudine-resistant mutants is not known. Theoretically, a triple therapy with lamivudine, adefovir dipivoxil and high dose HBIg may be the best approach, but data are lacking. In addition, it is unclear whether there is a need to continue with lamivudine once adefovir is started. Finally, what is the appropriate management for patients with improved hepatic function in response to antiviral therapy while awaiting transplantation? Should these patients be removed from the waiting list? Should an HCC surveillance programme be adapted to these patients? Is the risk of HCC development the same as it is for HBV carriers or is it higher? Will the risk of adefovir resistance increase significantly with prolonged therapy? And finally, will combination therapy with two or more oral agents (such as lamivudine plus adefovir) reduce the rate of emergence of resistant HBV variants, which poses a risk of hepatic decompensation for these patients with advanced liver disease?

### *Post-transplantation antiviral therapy*

Once liver transplantation has been performed, there are several alternatives to long-term HBIg. The first is to continue therapy with lamivudine as a single agent that was begun prior to transplantation. Although this approach is initially effective and patient compliance is good given the few side-effects of this drug,[25,34,48,49] therapy is limited by the emergence of HBV mutants with prolonged treatment.[25,34,48,49] The rate of recurrence due to the emergence of escape mutations, mainly in patients with a high level of viral replication before starting lamivudine, may reach as much as 40% and 60% at 1 and 3 years, respectively. It is presently unknown whether these results may be improved when combining lamivudine with other oral antiviral agents, such as adefovir.

### *Combination therapy*

As treatment failures occur with both HBIg and with lamivudine given as single agents, the second alternative is the use of the two in combination. The advantages over a single agent are the following: (1) possibility of administering lower doses of HBIg (400–2000 IU), which results in significant cost reduction; (2) potential reduction of development of resistant mutants, which is a frequent event when either drug is given as a single agent; and (3) synergistic effect with lower rates of treatment failures. The potential mechanisms for the observed synergistic protection of these two agents against graft reinfection are not completely known but include (1) reduction of lamivudine resistance due to reduction of circulating virions by HBIg, and (2) reduction of surface gene mutations due to the decrease in viral load induced by lamivudine. In a preliminary report, lamivudine in combination with high doses of HBIg was shown to be safe and highly effective.[50] In this study, 13 patients were treated prophylactically with lamivudine (150 mg daily) and high-dose HBIg starting with 10 000 IU during the anhepatic phase. No treatment failures were observed

after 1 year of treatment and 1-year patient survival reached 92%.[50] Combination prophylaxis with low doses of intramuscular HBIg and lamivudine has also been shown to be highly effective (Table 2.2) with recurrence rates of <10% in most studies.[24,34,44,51–55] Higher rates of recurrence are typically found in patients who have developed lamivudine resistance prior to transplantation.[44] This strategy is becoming the standard of care in most transplant programmes. However, the best protocol is still unknown as doses, routes, type and lengths of administration vary substantially from centre to centre. Moreover, the amount of HBIg infused ranges from 2800 to 80 000 IU during the first week, and from 7600 to 200 000 IU during the first year. Some centres continue to use the intravenous (i.v.) route while others switch to the intramuscular (i.m.) injection. Fixed i.m. or i.v. HBIg doses are utilized in some centres, while others prefer to individualize this therapy to achieve predefined serum anti-HBs concentrations. Finally, some centres continue HBIg indefinitely, while others stop HBIg at different time intervals from transplantation. Future studies are needed to assess these aspects, in particular the benefits of fixed versus individualized therapy and the need for indefinite versus limited durations of HBIg therapy.

### *Long-term prophylactic therapy*

At present, the main unanswered question relates to long-term prophylaxis. In patients receiving combination therapy, there is a need to define the optimal duration of HBIg. Two different approaches have been investigated. The first is *active HBsAg vaccination* with the aim of inducing active immunity against HBV without the need for additional antiviral treatment. Results from preliminary studies are disparate,[56–59] with good results being achieved in some studies, and poor response to HBV vaccination observed in others. Reasons for these apparently discrepant results likely include differences in study populations, differences in methodologies and differences in definitions of seroprotection. In the first study by Sanchez-Fueyo *et al*.,[56] 17 patients at low risk for HBV recurrence (non-replicative before transplantation, HBIg for at least 18 months without evidence of allograft HBV infection, and on low immunosuppressive doses) were vaccinated against HBV at a median of 30 months post-transplantation. The maintenance dose of HBIg prior to vaccination was approximately 2000 IU given i.m. every 1–2 months so as to maintain anti-HBs titres >100 IU/L. Then 1–4 weeks after the last dose of HBIg, three i.m. doses of 40 μg of recombinant HBsAg were given at 0, 1 and 6 months. Seroconversion to anti-HBs (antiHBs titres >10 IU/L) occurred in 82% of the patients (six after the first three doses, eight after a second course of three additional doses). A recently updated report showed that among 22 vaccinated transplant recipients, the percentage of seroconversion decreased to 64%.[57] In contrast to this initial study, a second study by Angelico *et al*. did not confirm these findings and the rate of seroprotection (defined as anti-HBs titres >10 IU/L) was only 23%.[58] The main differences between these two studies include the differences in the study population (all patients in the Italian study underwent transplantation for cirrhosis) and the use of lamivudine following HBIg discontinuation (in the Italian study). More recently, a third group has reported the results of HBV vaccination using a more immunogenic vaccine.[59] In that study, 10 patients received repeated doses of recombinant HBV vaccine (20 μg) in combination with a new adjuvant, monophosphoryl lipid A. Vaccination was performed at least 2 days prior to HBIg administration and titres of anti-HBs concentrations were determined before HBIg injections. HBIg was then discontinued whenever levels were >500 IU/L. Five of the 10 patients developed anti-HBs levels ranging from 721 to 45 800 IU/L, thus allowing HBIg withdrawal. After 1 year of follow-up, all responders had serum anti-HBs concentrations >900 IU/L. Larger

trials using different vaccination protocols over a longer observation period are needed to determine the real efficacy of this approach, particularly in low-risk patients without active viral replication pre-transplantation. Once established in this group, the applicability of this approach will have to be tested in patients at high risk for treatment failure. Other issues will need to be addressed, including the optimal vaccine doses, the timing of booster injections, as well as the potential benefit of using more immunogenic vaccines. Finally, the scientific basis for this approach may be questioned, as these patients with previous chronic HBV cirrhosis have already been exposed to high levels of naturally occurring HBsAg and have failed to develop protective immunity to HBV. It is therefore unclear why vaccination of these immunocompromised individuals would be likely to now result in immune protection.

A less risky alternative may be to *substitute HBIg with lamivudine in the long term*. Successful results using this alternative have already been reported by some authors in low-risk patients without markers of viral replication prior to transplantation.[25,60,61] More data are needed to define the optimal timing for HBIg withdrawal and the potential applicability in high-risk individuals.

In summary, an individualized multi-step prophylactic regimen may be used to prevent HBV recurrence. In patients at low-risk for recurrence, i.e. those undergoing transplantation for HBV HDV cirrhosis, fulminant hepatitis B and HBV cirrhosis with undetectable HBV DNA by PCR assays, there may be no need for pre-transplantation antiviral therapy. In contrast, for those with detectable HBV DNA prior to transplantation, suppression with oral antiviral appears to be appropriate. Following transplantation, three alternatives may be proposed: (1) indefinite high-dose HBIg starting with i.v. HBIg 10 000 UI in the anhepatic phase and daily during the first week, followed by the administration of variable amounts of HBIg aimed at achieving anti-HBs titres >100–150 UI/L; (2) indefinite low-dose HBIg in association with lamivudine (100 mg/day) using the same dose of HBIg during the first week followed by i.m. monthly administration of low-dose HBIg (2000–4000 UI/L); (3) high-dose HBIg in association with lamivudine (100 mg/day) during the first 6–12 months, followed by lamivudine alone for up to 2–3 years, and subsequently active HBV vaccination. In those who develop protective immunity, lamivudine may be stopped, and booster doses may be administered to maintain anti-HBs levels (at least, >100 UI/L). If there is no response to vaccine, the prophylaxis should continue with lamivudine. In high-risk patients, i.e. those with detectable HBV DNA by hybridization assay and/or HBeAg, pre-transplantation antiviral therapy with lamivudine is required for at least 1 month. Following transplantation, two alternatives may be proposed: (1) indefinite high-dose HBIg in association with lamivudine (100 mg/day) starting with i.v. HBIg 10 000 UI in the anhepatic phase and daily during the first week, followed by the administration of variable amounts of HBIg aimed at achieving anti-HBs titres >500 UI/L during the first 3 months, and 100–150 IU/L subsequently; (2) high-dose HBIg in association with lamivudine (100 mg/day) during the first 12–24 months, followed by lamivudine alone for up to 2–3 years, and subsequently active HBV vaccination. HBIg discontinuation should only be proposed for patients with undetectable serum HBV DNA by PCR assay.

## Treatment of HBV disease of the graft

There are three categories of patients who are potential candidates for HBV therapy after liver transplantation: (1) those who have undergone liver transplantation in the pre-HBIg and/or lamivudine era; (2) those who have undergone liver transplantation in the post-HBIg/lamivudine era and who have broken through treatment; (3) those with apparent '*de novo*' acquisition of HBV. Selection of therapy likely depends on the category to which the patient belongs. For example, treatment options for patients in the first category include lamivudine, entecavir or adefovir. These patients may have developed 'vaccine escape mutants', but they are likely to be sensitive to all three antiviral agents. The proportion of patients falling into the second category today is small, yet if these patients have 'broken through' both HBIg and lamivudine, they are likely to have developed resistance and as such may be appropriate candidates for antiviral agents such as adefovir or entecavir that have activity against resistance variants. Finally, patients that fall into the third category with '*de novo*' infection, are likely to be infected with virus that is sensitive to all currently available agents.[27,62]

Lamivudine is the most widely used nucleoside analogue. In most studies, liver transplant recipients with documented HBV recurrence (elevated serum ALT levels, and detectable HBsAg and HBV DNA) have been treated with lamivudine 100 mg daily (adjusted for renal function) with good tolerance and rapid loss of HBV DNA in serum.[27,62–66] Good biochemical and virological responses have been achieved not only in patients with chronic hepatitis B following transplantation but also in the setting of acute hepatitis B of the graft and in the most severe cases of fibrosing cholestatic hepatitis. Histological improvements in the inflammatory grade are also achieved with therapy. In a multicentre study based on 52 patients with detectable DNA after liver transplantation, lamivudine therapy for 1 year resulted in 60% loss of HBV DNA in serum and 31% 'e' seroconversion.[63] Other studies have confirmed these results, showing HBV DNA loss in 68–100% of patients treated for periods of 12–36 months.[27,64–66] The downside of this agent is

the need for continuous treatment, as relapse is the rule once the drug is discontinued. Prolonged therapy is, in turn, associated with the development of breakthrough due to the emergence of HBV escape mutants, which has been shown to reach 50% with long-term therapy.[62–68]

Famciclovir (500 mg three times daily with dosing adjusted to renal function) has also been used to treat liver transplant recipients with HBV recurrence.[64,67] Although initially good results were obtained with this drug both in terms of HBV DNA reduction and transaminase normalization, viral clearance was observed in a lower percentage of patients than has been seen for lamivudine. In addition, famciclovir-resistant virus may not be sensitive to lamivudine, a situation recently described in several patients.[42]

### *Emergence of nucleoside analogue resistance*

Monotherapy with both lamivudine and famciclovir has resulted in the emergence of HBV variants that are resistant to these compounds. This resistance generally occurs after prolonged therapy (>6 months).[27,62–68] In both instances, the appearance of resistant mutants is associated with a rise in serum HBV DNA and ALT levels, indicating a breakthrough in therapy. Molecular analysis has shown mutations in the gene encoding the viral DNA polymerase. Because of the overlapping nature of the HBV open reading frames (ORFs), nucleotide changes in the polymerase may result in amino acid changes not only in the polymerase protein but also in the surface protein, which could in turn theoretically alter binding of HBIg at the time of transplantation.[42]

When the antiviral drugs are stopped, the wild-type variant re-emerges as the dominant viral population, but retreatment is again associated with the development of resistant mutants at an accelerated rate. Drug-resistant mutants are not consistently associated with hepatic disease progression. *In vitro* studies have shown that the M 204 V/I mutants have decreased replication fitness compared with wild-type HBV.[39] However, in some cases, severe and fatal hepatitis B infection can occur during lamivudine therapy and may be associated with certain HBV mutants selected during sequential nucleoside and HBIg treatment.[42] It has been suggested that these changes may represent compensatory mutations that restore the replication fitness of HBV. The lamivudine-enhanced replication shown by these mutants suggests that continuation of therapy with lamivudine could be deleterious in some patients. From a clinical point of view, patients who are maintained on lamivudine therapy after the emergence of lamivudine resistance should be closely monitored to detect flares of the underlying disease. Fortunately, the availability of new hepatitis B antivirals such as adefovir has resulted in viral suppression of lamivudine-resistant variants.[46] Thus far, resistance to adefovir is unusual (<2% after 2 years). It is not yet known whether patients who are treated for lamivudine resistance with adefovir post-transplantation need to continue on lamivudine, but given the potential for progressive liver disease with overt recurrence, it seems prudent to continue both drugs for some period after the institution of adefovir.

For patients who have become HBsAg-positive after liver transplantation despite therapy in the pre- and/or peri-transplantation period, possible interventions include adefovir or entecavir. Experience with adefovir (at a dose of 10 mg per day) has shown that this drug is viral suppressive but that treatment may be limited by toxicities, possibly associated with impaired renal function.[46] Experience with entecavir is limited. As this nucleoside is devoid of renal toxicity, it may play an important role in the future management of these recipients.

## Prevention and treatment of *de novo* HBV infection

The prevalence of *de novo* HBV hepatitis ranges from 2% to 8%, and is generally related to transmission from an HBsAg-negative, anti-HBc-positive donor to an uninfected recipient. The most significant factor associated with transmission is the serologic status of the recipient, so that the risk is almost null in patients who are anti-HBs-positive, minor (≅ 10%) in those who are anti-HBs-negative but anti-HBc-positive, and high (≅ 50–70%) in those without markers of previous exposure to HBV.[69,70] Although there have been reports of severe progression, the natural history of *de novo* hepatitis B is generally more benign than that described for recurrent hepatitis B.

In order to avoid *de novo* HBV infection, two complementary approaches may be undertaken. (1) HBV vaccination prior to liver transplantation of all anti-HBs-negative candidates. Accelerated vaccination regimen with double doses (40 μg) has been adopted at 0, 1 and 2 months with a follow-up vaccine at 6 months. Unfortunately, as with other immunosuppressed populations, the results of vaccination in these patients have been disappointing with response rates that barely reach 40%.[71] A second course of vaccination may slightly increase these results. (2) Anti-HBc determination of the donor with use of organs from anti-HBc-positive donors only in recipients already infected with HBV. In order to obtain a maximum benefit from these organs while at the same time reducing the risk of HBV transmission, these organs may be used in special circumstances in recipients not infected with HBV. The following criteria should then be applied.[72] As the risk of HBV transmission is low if the recipient is anti-HBs- and anti-HBcore-positive, selection of an anti-HBs-positive recipient may be sufficient without other interventions. However, there is concern

that vaccine-induced immunity may not be as effective as innate immunity in preventing acquisition of HBV from an infected donor. Livers from anti-HBc-positive donors can be directed next to recipients with isolated anti-HBc, although a low risk of HBV transmission appears to exist if no specific HBV prophylactic measures are taken. While initiating prophylaxis with HBIg and/or lamivudine to all patients will prevent transmission, this strategy has the potential for treating a high proportion of recipients who would have never developed infection. When no individuals with the above criteria exist in the waiting list, anti-HBc-positive donors can be offered to naïve recipients with critical clinical needs or with HCC although, in such cases, HBV prophylaxis with either lamivudine or HBIg or a combination of both agents is advisable given the high likelihood of HBV acquisition.

Treatment of *de novo* hepatitis B is similar to that described for recurrent hepatitis B. If started at early time-points, the results are generally better than those obtained with recurrent hepatitis B. Unfortunately, resistant mutants develop at the same rate, and adefovir or entecavir may prove to be preferred therapy for the primary management of this disease.

### Re-transplantation

The initial results on re-transplantation for patients with graft failure due to recurrent hepatitis B were discouraging due to high rates of HBV reinfection and even more aggressive disease in the second graft. Improved outcomes have been achieved with specific interventions, mainly with the use of aggressive immunoprophylaxis to prevent HBV reinfection in combination with lamivudine that is typically started prior to re-transplantation in order to suppress viral replication.[73–75] Fortunately, re-transplantation for recurrent HBV disease is rare, given the effective measures described above that prevent recurrent infection in the vast majority of those with pre-transplantation infection. If it is needed, three measures should be followed in order to improve the outcome: (1) avoid late re-transplantations when the hepatic failure is too advanced and renal insufficiency has developed; (2) use antiviral therapy to clear the virus prior to retransplantation; and (3) choose an aggressive prophylactic regimen to prevent reinfection.

### Living-related liver transplantation (LRLT)

There are no data regarding HBV recurrence following LRLT. Given the availability of excellent therapies to prevent and treat recurrence, it is likely that the results obtained with this technique will be similar to those obtained with cadaveric organs. In addition, adequate timing of pre-transplantation antiviral therapy is a potential advantage, as transplantation can be performed when HBV DNA has been cleared in serum but before the development of resistant mutants.[76]

### Transplantation in patients co-infected with HDV

Historically, patients with HBV and HDV infection were considered to be better candidates for liver transplantation than those with HBV infection alone, because of the lower HBV DNA levels and consequent lower risk of recurrent infection in the former than in the latter group.[9] Delta infection is an uncommon indication for liver transplantation. In the absence of HBIg, both HBV and delta virus can infect the graft, but HDV is not pathogenic until HBV replication also occurs. Interestingly though, HDV is detected early post-transplantation either in serum (HDV RNA) or liver (HDV RNA and/or delta antigen) in 80% of HBsAg-negative liver transplant recipients.[77,78] With prolonged follow-up and absence of HBV recurrence, these markers of HDV infection disappear. If HBV recurs, HDV is also detected leading to chronic hepatitis. HDV-HBV-related hepatitis is generally less severe than in patients with HBV alone. HBIg prophylaxis is effective at preventing recurrence in the majority of those with pre-transplantation co-infection.[77,78] The additional benefit of pre-transplantation treatment with lamivudine is largely unstudied but is commonly administered in clinical practice. Thus, current recommendations would be to pre-empt HBV and HDV infection of the graft as is undertaken for the prevention of recurrent HBV infection described above.

## Recurrent hepatitis C virus (HCV) infection

Once considered an excellent indication for liver transplantation, enthusiasm for liver transplantation in patients with end-stage HCV cirrhosis is waning, due to the growing evidence that recurrent HCV disease is an important cause of morbidity and even mortality in the post-transplantation period.[79] In contrast to HBV disease, there are no effective interventions to prevent post-transplantation HCV recurrence.[80]

HCV-related liver disease with or without alcohol and with or without HCC now represents the major indication for liver transplantation in the United States and Europe.[1,79] Historically, rates of HCV recurrence were modest (70%) and typically resulted in benign liver injury with no effect on survival. In contrast, more recent natural history studies based on strict histological follow-up, updated virological techniques and prolonged follow-up, have demonstrated that viral recurrence is universal, histological recurrence is very frequent, and advanced graft HCV disease occurs in a substantial

number of patients, leading to an adverse effect on graft and patient survival.[79,81,82] Due to the magnitude of the problem, with a preponderance of HCV as the primary indication for liver transplantation, the worsening patient and graft survival in HCV recipients,[81,83,84] and the growing demand for re-transplantation in recipients with recurrent HCV,[85] a Consensus Conference was recently held to overview the state of the art concerning liver transplantation and HCV disease. The conference participants examined the definition of recurrent HCV, the natural history of HCV after liver transplantation, the potential clinical predictors of adverse outcomes, treatment and management strategies, the contribution of different immunosuppressive regimens to outcome, and the role of re-transplantation for recurrent HCV in the face of an overall donor shortage.[86]

## Indications for liver transplantation

Cirrhosis due to chronic hepatitis C infection is associated with reduced survival, due to the development of hepatic complications, namely clinical decompensation and HCC. In the absence of decompensation, the 10-year survival approximates 80%, but survival decreases markedly once hepatic decompensation occurs (approximately 50% at 5 years).[87–89] The cumulative risk of clinical complications is 30% over a 10-year period. The risk of clinical decompensation unrelated to HCC has been estimated to be 15–20% after 4 years of follow-up, while the risk of developing HCC is 6–24% over the same time. Given the potential for an aggressive form of recurrent hepatitis C, timing of liver transplantation is a major challenge in transplant centres. Liver transplantation should only be offered when the risk-benefit balance clearly favours this option and not merely because the patient meets minimal listing criteria for transplantation. Thus, as the outcome of compensated HCV-cirrhotic patients is sufficiently good, liver transplantation should be reserved ideally for those with progressive liver disease that cannot be managed medically. Thus, while indications and contraindications for transplantation in these patients do not differ from those applied to other forms of liver diseases, decompensated patients should be aggressively managed with traditional medical therapy in an effort to avoid the premature transplantation of some of these patients. This is also true in the new era of living donor liver transplantation.

Criteria for selecting patients with HCC do not differ from those with HCC who are not HCV-infected.[89] However, because recurrent HCV will likely complicate the post-transplantation management of these patients, aggressive medical and surgical management of HCC including chemoembolization and hepatic resection should be undertaken before consideration of liver transplantation. Thus, resection may be considered the treatment of choice, particularly in those with compensated cirrhosis without relevant portal hypertension, with liver transplantation remaining as 'adjuvant' therapy.[89,90] The addition of antiviral therapy in these patients could potentially lead to viral eradication and improvement of hepatic fibrosis,[91] eliminating the future need for transplantation.

## Recurrence of HCV infection

While recurrence of HCV infection is based on virological parameters, the recurrence of HCV disease requires protocol and/or clinically indicated liver biopsies that

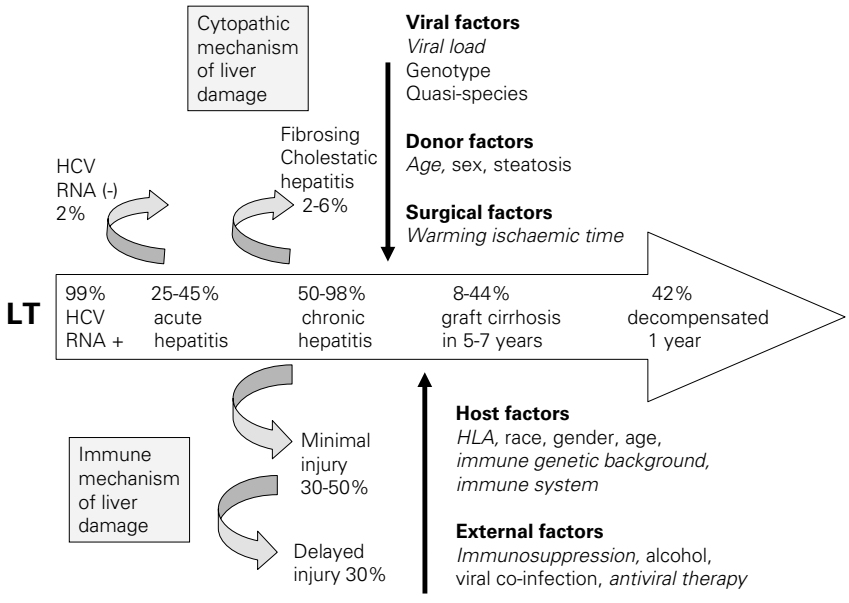

**Figure 22.1** Natural history of recurrent hepatitis C: mechanisms of liver lesion and factors that determine outcome. LT, liver transplantation.

report both grade and stage of disease. Indeed, recurrence of HCV infection is defined as the presence of virus in serum and liver. It occurs nearly universally following transplantation[92] and is characterized by a steep rise in levels of HCV RNA, that typically are 10–20-fold higher than before transplantation.[93] Recurrence of HCV disease, in contrast, occurs at various time points and exhibits a wide spectrum of histological findings from trivial inflammation in the absence of fibrosis to severe and progressive liver disease[94] (Fig. 22.1)

## Pathogenesis

A rapid and sharp decline in viral load occurs immediately after removal of the infected liver.[95] Following reperfusion, HCV RNA levels typically decrease further at a rate that exceeds the decrease observed during the previous anhepatic phase. HCV binding to and/or uptake by hepatocytes may contribute to this early post-transplant decrease in viraemia. Following this initial decline, HCV RNA levels either increase exponentially reaching pre-transplantation levels as soon as day 4, or continue a decline in the first post-transplant week to increase thereafter, peaking by the fourth postoperative month.[95] These differences in kinetics appear to be related to the use of corticosteroids, so that HCV RNA levels increase rapidly in patients receiving corticosteroids as part of the immunosuppressive regime, while they continue to decrease in those not receiving this drug. At 1 year post-transplantation, the levels are 10–20-fold higher than pre-transplantation.[93]

The mechanisms by which HCV leads to liver injury are incompletely understood. Several lines of indirect evidence support a role for the cellular immune response in shaping outcome following transplantation. It is likely that the increased levels of HCV replication typically observed – in conjunction with the altered host immune responsiveness – contribute to the pathogenesis of liver damage, particularly to the severe course of disease of the grafted liver. In addition, there is a spectrum of severity of recurrent HCV disease that may differ in pathogenesis and clearly differs in outcome.[94] Recurrent chronic hepatitis C disease, which can lead to cirrhosis, should be distinguished from recurrent cholestatic HCV disease. In the former, it is possible that the relative antiviral control by the immune response prevents cytopathic injury while perpetuating chronic liver injury.[96] In contrast, a direct cytopathic mechanism of liver injury appears to predominate in patients with severe cholestatic hepatitis.[97]

## Natural history of HCV recurrence

Early short-term survival is comparable to that obtained with other aetiologies. However, emerging data are demonstrating that the long-term outcome is not as benign as previously thought.[79,81–83]

Acute lobular hepatitis develops in approximately two-thirds of the patients within the first 6 months post-transplantation. By the fifth postoperative year, >80% of recipients will develop chronic recurrent HCV disease, characterized histologically by portal and periportal inflammation with or without the presence of portal and/or periportal fibrosis. Lobular hepatitis can also be part of the pathological picture.[98–102]

The natural history of this chronic hepatitis C is more aggressive than that observed in the immunocompetent population. Indeed, in the non-transplantation setting, it is estimated that approximately 20% of the infected patients will develop cirrhosis after a mean duration of infection of 30 years. In the transplant setting, this course is accelerated, and progression to cirrhosis occurs in a percentage of recipients that ranges, depending on the series, from 6% to 23% after a median of 3–4 years since transplantation.[81,83,84,98–104] The development of cirrhosis is associated with reduced graft and patient survival.[94] A recent study has estimated that the median time to develop cirrhosis after transplantation is approximately 9–12 years,[105] a duration significantly shorter than that described in the immunocompetent population. The progressive nature of liver disease in the transplant setting is also evident once the cirrhosis is established, with a higher likelihood of developing clinical decompensation and death compared with that observed in non-transplant patients with cirrhosis.[106] The 1-year actuarial risk of decompensation in patients with post-transplantation HCV cirrhosis is 42%, a percentage that is higher than the 28% at 10 years observed in HCV-infected non-transplant patients with cirrhosis.

In addition, in 5–10%, an accelerated course of liver injury leading to rapid development of liver failure has been observed,[107] reminiscent of that previously described in HBV-infected recipients with fibrosing cholestatic hepatitis. Recurrent cholestatic HCV disease can occur as the initial manifestation of recurrent HCV disease or can emerge in the setting of chronic HCV disease. The definition of fibrosing cholestatic hepatitis includes all of the following criteria: 1 month post-transplant, serum bilirubin >100 μmol/L, serum alkaline phosphatase and GGT more than five times the upper limits of normal, characteristic histology of central ballooning (not necrosis or fallout), a paucity of inflammation ± cholangiolar proliferation without bile duct loss, very high serum HCV RNA levels and absence of surgical biliary complications or hepatic artery thrombosis.[86]

Delayed hepatitis C-related severe liver damage may occur in recipients following initial benign recurrence. This acceleration in disease progression develops in

one-third of patients who have relatively slow fibrosis progression in the first 3–5 years of post-transplantation disease.[108]

Emerging data suggest that the rate of fibrosis progression, and thus the rate of development of graft cirrhosis due to recurrent hepatitis C, is accelerated in patients transplanted in recent years.[81,83,84,105]

Based on all these data, it is not surprising that in several centres a reduction in patient and graft survival among HCV-infected recipients has been observed, with a 5-year survival significantly lower among HCV-infected recipients than in those not infected with HCV (60–70% vs 76–77%).[81,82] In addition, the worse histological outcome seen in recent years is beginning to translate in some centres into a reduced survival among those transplanted recently.[81]

## Histological changes

Liver function tests are not correlated with either viraemia or with histological disease severity,[98–101,109,110] and protocol liver biopsies are generally needed to identify progression to severe forms of chronic hepatitis.

Early histological findings may be helpful in selecting the patients at high risk of disease progression.[98–101,109–113] In particular, the degree of activity and fibrosis staging observed in the first-year liver biopsy is associated with the subsequent risk of developing cirrhosis with only 3–10% of those with mild hepatitis developing cirrhosis compared with 30–60% in those with moderate to severe activity in their first-year liver biopsy.[98,99] Furthermore, not only the severity of initial histological findings, but also some specific histological features such as significant steatosis, ballooning degeneration, cholestasis and confluent necrosis observed on early biopsies may be helpful in predicting progression of disease.[98–101,111–113] Finally, the presence of some degree of fibrosis at baseline (i.e. F = 1 in the first-year liver biopsies) appears to predict the delayed onset of severe liver damage.[108]

## Pre- and post-liver transplant risk factors impacting on HCV recurrence

While some patients have an accelerated course to cirrhosis, there are others, approximately one-third, who remain stable with normal or near-normal histology during 5–10 years of follow-up. Identifying patients at risk of accelerated allograft loss is paramount to the decision about the timing of antiviral agents and/or need for re-transplantation. Factors which have been described as predictors of disease severity/progression and/or survival include those related to the host (demographics, genetic background, immune status, co-morbidities, hepatic function at transplantation), those related the virus (genotype, viral replication, viral quasi-species), those that are donor-related (age, degree of hepatic steatosis, weight, living vs cadaveric) and those related to the environment (surgical-related factors, immunosuppression, alcohol).[79,86]

### *The immune status*

Several indirect findings point towards the deleterious effect of the immunosuppressed status, a variable intrinsically related to the transplant setting (Table 22.3). It has even been suggested that the recent worsening in disease progression may be related to over-immunosuppression following the introduction of more potent immunosuppressive agents.[81,83,105] However, the true adverse effect of more potent immunosuppression on disease outcomes, immunosuppressive agents such as mycophenolate mofetil, lymphocyte-targeting immunoglobulins (e.g. daclizumab and basiliximab), as well as the newer agents with dose-dependent antiproliferative properties,[114–121] needs to be defined.

**Table 22.3** Indirect findings supporting the role of immunosuppression in the natural history of recurrent hepatitis C

| | |
|---|---|
| The course of hepatitis C is accelerated in liver transplant recipients as compared with that observed in immunocompetent patients: | Higher rate of fibrosis progression – 0.3/year (0.004–2.19/year) vs 0.2/year (0.09–0.8/year) – and higher risk of developing severe hepatitis<br>Shorter duration to cirrhosis from time of infection (median of 9–12 years vs 20–40 years)<br>Higher risk of clinical decompensation once HCV-related cirrhosis is established (50% in 1 year vs 20–25% in 10 years) |
| The course of hepatitis C is worse in recent years when significant changes have mainly occurred in the immunosuppressive therapy: | Use of newer and more potent first-line immunosuppressive drugs<br>Earlier and more abrupt discontinuation post-transplantation of second-line immunosuppressive drugs |
| The course of recurrent hepatitis C is worse in other immunosuppressed populations such as HIV-co-infected patients or those with hypogammaglobulinaemia | |

There is already ample evidence that severity of recurrence of HCV is linked in part to the degree of immunosuppression, with most studies showing a positive correlation between a high rate of cirrhosis development and potent immune suppression (high number of boluses of methyl-prednisolone, use of anti-lymphocytic preparations, high total cumulative doses of steroids).[122–125]

### *Immunogenetic background*

There is now strong evidence for the important role of genetics in host immune responses to infectious pathogens and in susceptibility to infection as well as in outcomes after exposure to microbial agents. Both the major histocompatibility complex (MHC) genes and non-MHC genes are increasingly identified as candidate genes with significant importance in outcome of infectious diseases. In HCV, specific HLA class II alleles, such as HLA B14 and HLA DRB1*04 have emerged as possible modulators of disease severity. Regulatory mechanisms that control cytokine production, including tumour necrosis factor (TNF)-α, operate in part at the gene level. It has been shown that cytokine genes are polymorphic at specific sites. These mutations may influence the production of cytokines encoded by the polymorphic gene. In one study, Rosen *et al*. evaluated the significance of polymorphisms at positions –238 and –308 of the TNF-α gene promoter (mutations associated with susceptibility to active hepatitis after HCV exposure in immunocompetent patients) in liver donors on the severity/outcome of recurrent HCV. They found that time to recurrence was shorter and the hepatic activity index greater in those who received an organ from donors with TNF-α –308 allele.[126] These data suggest that a specific donor TNF-α genotype, known to be associated with high TNF-α production, may contribute to the accelerated graft injury observed in liver transplant recipients with HCV infection.

Furthermore, some but not all authors have suggested that while HLA-B sharing between the donor and the recipient reduces the incidence of acute cellular rejection, it also promotes the recurrence of viral hepatitis.[127,128] Discrepancies may be explained by differences between studies in HLA typing methods, selection and ethnic backgrounds of patients as well as differences in immunosuppressive regimens used.

### *Donor-related variables*

The *age of the donor* was recently found to be independently associated with disease severity, disease progression and survival.[81,83,84,129] In one series, only 14% of the recipients who received an organ from a donor younger than 30 developed recurrent HCV-related cirrhosis. In contrast, 45% and 52% of those receiving the organ from donors aged 31–59 or older than 59 developed graft cirrhosis, respectively ($p$ <0.0001).[81] The changing organ donor profile with increasing age of the donors in recent years may explain the observed worsening in outcomes over the same time period. This observation has important implications for donor liver allocation, in that older donors might be more appropriate for HCV-negative recipients in whom the adverse effects of donor age appear to be less deleterious. In addition, the effect of donor age correlates with data from the immunocompetent population where age at the time of infection is an important and powerful determinant of fibrosis development. Age-related changes in liver response may be the key factor that determines the increased susceptibility of the older liver to HCV-related fibrosis.

The *anti-HCV status of the donor* may also influence the post-transplantation outcome. Superinfection has been described in this setting,[130] but it appears that histological outcome and survival do not differ from those observed in patients receiving organs from anti-HCV-negative donors.[131–133]

### *Viral-related variables*

*HCV RNA levels* prior to and/or soon after transplantation may predict survival and the rate/severity of hepatitis C of the graft.[105,134] These findings parallel those previously described for hepatitis B. In one study, patients with higher pre-transplantation HCV RNA levels (>log 1 mEq/mL) experienced mortality and graft loss rates 30% more frequently than those with lower levels.[134]

Studies evaluating the relationship between severity of liver disease post-transplantation and *HCV genotypes* are conflicting.[135–137] Some but not all studies have implicated genotype 1b in a more aggressive post-transplantation disease than non-1b genotype. It may possible that different strains belonging to genotype 1b may be implicated.[138,139]

*HCV heterogeneity* may be implicated in the pathogenesis of progressive HCV disease. However, results from the few studies published to date are inconclusive and somewhat discrepant,[94,140,141] and may be related to the small number of patients included, the different methodologies applied to assess HCV heterogeneity, the type of end-points chosen, the region of the genome evaluated, and the definition of disease severity.

### *Other host variables*

*Race* was recently found to influence outcome in patients with HCV recurrence, with non-Caucasians doing worse than Caucasians.[105,134]

In some studies, female *gender* has been associated with a severe course of recurrent hepatitis C and subse-

quent low survival.[82,83] Reasons that might explain this association are lacking.

In one study, a lack of association was observed between the rate of *fibrosis progression prior to transplantation* and that observed after transplantation,[105] suggesting that variables present at the time of transplantation and those related to post-transplantation management are more important in influencing disease progression than genetic or viral variables unique to the individual. The interpretation of these results is complicated, however, by difficulties in measuring accurately the duration of infection prior to liver transplantation.

In some studies, the presence of *HCC* was found to be a significant predictor of reduced patient and graft survival.[103] This may be explained by differences in patient and tumour selection criteria.[142]

Prolonged *re-warming time* during allograft implantation has been associated with severe recurrent disease.[143] If these data are confirmed, special emphasis should be placed on techniques to minimize re-warming time, such as vena cava preservation.

*Timing of recurrence* appears also to be related to the outcome, with early recurrence within the first 6 months associated with worse prognosis.[100]

Patients who develop *cytomegalovirus* (CMV) viraemia may be at increased risk of severe HCV recurrence.[84,144] The reasons for this association are unknown but probably relate to the degree of immune deficiency, the release of TNF by CMV and/or the existence of cross-reactive immunological responses.

Co-infection with other hepatotropic viruses such as *HBV* may influence histologic disease severity but results are conflicting. While no effect was found in an initial study,[145] co-infected patients appeared to have milder histological course than patients infected only with HCV.[103] Although viral interactions could explain this phenomenon, the passive transmission of antibodies against HCV in co-infected patients receiving HBIg during the pre-HCV era is a more likely explanation.[146]

In contrast, co-infection with other viruses such as *hepatitis G virus* (HGV) does not seem to influence the post-transplantation course of HCV disease.[147]

In summary, it is likely that the interaction between all these variables accounts for the differences in outcomes observed between different centres with cumulative rates of developing HCV-related graft cirrhosis that range from 10% to 50%.

## Prevention of HCV graft reinfection

Given the increasing number of patients progressing to HCV-related graft cirrhosis and the shortage of organ donors, development of strategies to improve the outcome of these recipients is mandatory. These strategies include an adequate timing of liver transplantation in patients with HCV-related end-stage liver disease (see above), antiviral therapy, and the use of specific immunosuppression regimens that may be less deleterious to HCV-infected patients than others.

### *Hepatitis C immunoglobulins (HCIg)*

In contrast to HBV, there is currently no available intervention to prevent universally HCV recurrence. In one study, polyclonal immunoglobulins containing anti-HCV were shown to decrease the incidence of recurrent HCV viraemia measured 1 year post-transplantation.[146] However, given the humoral immune failure in providing adequate and long-lasting neutralizing immunity against HCV, one would predict that additional approaches will be necessary. Indeed, a recent randomized controlled study of hepatitis C immunoglobulin found no benefit in terms of post-transplant clinical reinfection rate or HCV RNA levels.[148] Whether this negative study is a function of the dose of HCIg used, the timing of administration or the type of preparation used (non-neutralizing antibodies) is unknown. It is also possible if not likely, that diverse *quasi-species* nature of HCV makes this virus inherently more difficult to neutralize than the more stable HBV virus populations present in any individual.

### *Pre-transplantation antiviral therapy*

In theory, the rationale for treating patients with decompensated HCV-related cirrhosis is the same as for hepatitis B, i.e. (1) to slow down clinical disease progression and improve the hepatic synthetic function, and in doing so, to reverse the complications of liver disease and obviate/delay the need for liver transplantation; and (2) to achieve an improvement in post-transplantation outcome by clearing the virus prior to transplantation. While the first aim has become a reachable goal in patients with HBV-related decompensated cirrhosis, it remains to be proven in patients infected with HCV, at least with current antiviral agents. In contrast, clearance of HCV prior to transplantation may prevent viral recurrence, and reduction of HCV RNA levels could potentially improve post-transplantation disease progression. Patients waiting for liver transplantation due to HCV-related liver disease typically include two types of patients, those with compensated cirrhosis and HCC and those with decompensated cirrhosis. While in the former group it is likely that a complete course of antiviral therapy may be achieved with currently available drugs, it is less so in those with advanced hepatic insufficiency.

#### *Treatment of compensated cirrhosis (for HCC)*

Therapy of chronic hepatitis C has improved in recent

years with the addition of ribavirin and development of pegylated forms of IFN (PEG-IFNs). Sustained virological responses are achieved in 54–56% of patients compared with 44–47% of those treated with standard IFN and ribavirin. Response is strongly related to the infecting genotype, so that it may reach 78% in those infected with non-1 genotypes compared with 51% in those infected with genotype 1. Other factors that have been shown to influence virological response include viral load, body mass index, race and the degree of liver fibrosis. Although tolerance is adequate, the response rate to these therapies appears to be lower in patients with compensated cirrhosis or transition to cirrhosis than in patients with less advanced liver disease (43–50% vs 57–65% in non-cirrhotic patients).[149] In addition, histological analysis has shown that 49% of cirrhotic patients with a sustained virological response have an improvement in the fibrosis score, suggesting that advanced fibrosis can be reversed with therapy. It remains to be shown whether improvements in fibrosis can be reliably achieved in patients without a virological response who are treated with long-term, maintenance IFN therapy. Tolerability and side-effects are similar to those observed with standard IFN, with the exception of cytopenias, particularly neutropenia, that are more frequently seen with the PEG-IFNs. These side-effects may become a limitation when treating cirrhotic patients with marginal counts. The use of growth factors (i.e. erythropoietin and neutrophil stimulating factor) may be helpful in some cases and avoid the reduction and/or discontinuation of antiviral drugs. However, the potential benefit of these compounds needs to be tested in prospective randomized trials.

Thus, in summary, combination therapy with PEG-IFN and ribavirin should be recommended in patients with cirrhosis provided that no contraindications are present.[80] For patients infected with genotype 1, the optimal length of therapy and dose of ribavirin are probably 48 weeks and 1000–1200 mg. In contrast, for those infected with genotypes 2 and 3, 24 weeks and 800 mg of ribavirin are probably sufficient.

*Treatment of patients with decompensated cirrhosis (Table 22.4)*

The data available on treatment outcomes of antiviral therapy in patients with decompensated liver disease are limited to small uncontrolled case series.[150–152] However, it is clear from these studies that antiviral therapy should be administered with extreme caution in this population, as treatment may increase the risk of infectious complications and increase the likelihood of hepatic decompensation.

In two studies, therapy was started with low doses of IFN ± ribavirin, and doses were increased slowly as tolerated.[10,151] In contrast, complete doses of both drugs were used in a third study by Forns and colleagues.[152] These studies emphasize the advantages and disadvantages of this approach.

In the multicentre study by Crippin and colleagues,[150] HCV-infected patients at or near the top of their respective waiting lists were randomly assigned to one of three treatment arms, two involving therapy with IFN in monotherapy, and one in combination with ribavirin. Less than half the patients screened met entry criteria, with thrombocytopenia and leukopenia being the most common reasons for exclusion. Eventually, only 15 patients from five large transplant centres were treated. Nine patients received IFN monotherapy while six received combination therapy with ribavirin (400 mg twice daily). While on treatment, loss of detectable HCV RNA was seen in 33%. Unfortunately, recurrence of infection was not prevented in the single patient who underwent liver transplantation at the time when he was HCV RNA-negative (although he was negative by the relatively insensitive bDNA assay). In addition, a significant number of adverse effects occurred (n = 23), many of which were considered severe. While thrombocytopenia was the most frequent adverse event, infection was the most severe one. These side-effects, particularly life-threatening infections, ultimately led to the early termination of the study. There are several interesting conclusions from this study. (1) A large proportion of

**Table 22.4** Therapy of patients with HCV-related decompensated cirrhosis

| Author, year (number of patients)[ref] | Eligibility | Genotype 1 | Child A | VR* | Adverse events | Treatment DC | Prevention of recurrence of those HCV RNA-negative at transplantation |
|---|---|---|---|---|---|---|---|
| Crippin *et al.* 2002 (n = 15)[150] | 47% | 67% | 0% | 33% | 87% | 100% | No (n = 1) |

*HCV RNA clearance while on therapy.

patients awaiting transplantation will not benefit from this approach due to the presence of contraindications, particularly thrombocytopenia and neutropenia. (2) Awareness of the potential complications should be kept in mind when treating the small proportion of patients who meet initiation criteria.

The second reported study of treating patients awaiting liver transplantation comes from the University of Colorado in the United States. At the time of writing data have only been presented in abstract form.[151] In this study, Everson and colleagues treated 101 patients, 70% of whom were infected with HCV genotype 1, and approximately 50% of whom were Child's class A cirrhotics (i.e. they were relatively well compensated). Thus, most of the patients had a low Child Pugh score of <B7–8. Patients were treated with low doses of IFN (1.5 mU three times per week) and ribavirin (600 mg daily), with slow increases in dose of both drugs every 2 weeks as tolerated. Growth factors were administered as needed. Preliminary results of treating 91 patients were recently reported. On treatment, virological responses occurred in 38% and sustained virological response in 22% of patients. Sustained responses were more common in patients infected with genotypes other than 1. Interestingly, recurrent infection which was observed in all patients with detectable HCV RNA at the time of transplantation was prevented in the eight patients who were HCV RNA-negative at the time of transplantation. Although overall rates of severe adverse events were not reported, 28% of the patients had treatment discontinued because of the development of side-effects, and serious complications occurred in 8% of the patients. Results from this study are more optimistic than those of Crippin and colleagues. The main difference between the two studies lies in the severity of liver disease at initiation of therapy and the regimen used. While in the study by Crippin and colleagues, the mean Child Pugh score was 12, patients in the Everson study had significantly less advanced disease. In addition, lower doses were used at initiation in the latter study.

In the study by Forns and colleagues,[152] patients on the waiting list for liver transplantation were considered for antiviral therapy if the expected time on the waiting list was shorter than 4 months, if there was not evidence of renal failure and if patients met minimal blood count criteria. Of 50 patients evaluated, only 62% met entry criteria. The majority of these patients were infected with HCV genotype 1. At the time of inclusion, half of the patients were Child Pugh A while the other half were Child B/C. The regimen used consisted of IFN-α-2b 3 MU/daily and ribavirin 800 mg/day. A virological response was achieved in 30% of patients. Pretreatment viral load was significantly lower in responders than in non-responders ($3 \times 10^5$ vs $6.5 \times 10^5$ IU/mL). Of the nine patients who were HCV RNA-negative at the time of transplantation, six remained free of infection after a median follow-up of 46 weeks. Although side-effects and dose reductions were frequent, particularly due to cytopenias, no patients died while on therapy. However, treatment had to be discontinued in six patients due to thrombocytopenia (n = 4) and sepsis (n = 2). An interesting finding of this study was that of the relationship between viral load at 4 weeks of initiation of therapy and virological response. Indeed, the positive and negative predictive values of an early decrease in viral load (≥2 logs) were 82% and 100%, respectively.

## Post-transplantation antiviral therapy

Post-transplantation therapy may be started early following surgery or alternatively, at a later stage, when the disease is established. The major goal of pre-emptive post-transplantation therapy is to prevent reinfection of the graft, and in doing so, to reduce the rate and/or severity of recurrent disease. In contrast, the major goal of treatment of established disease is to eradicate viraemia, and in doing so, improve the histology.[80]

### *Post-transplantation pre-emptive therapy*

IFN alone or in combination with ribavirin has been attempted within the first 2 weeks after liver transplantation to prevent disease recurrence, or at least diminish the risk of aggressive histological progression. Two small but randomized trials have evaluated the role of IFN in this setting without observing an effect on survival.[153,154] In the first study, histological disease recurrence was observed less frequently in IFN-treated patients (eight of 30 evaluable at 1 year) than in those who were not treated (22 of 41; $p = 0.01$).[153] Interestingly, neither the rate of persistence of HCV RNA nor the level of HCV RNA was affected by treatment, suggesting that IFN may have beneficial effects other than decreasing viral replication. In a smaller controlled trial (n = 24), neither the incidence of histological recurrence nor its severity differed between groups.[154] However, IFN treatment delayed the development of HCV hepatitis, which occurred at a median of 408 days after transplantation in the treated group compared with 193 days in the untreated group. In a third placebo-controlled trial of pre-emptive therapy with IFN plus ribavirin, HCV RNA loss was observed in 3/21 (14%) of the treated group versus none of the placebo group. However, tolerability of therapy was problematic, with profound anaemias observed, requiring transfusion in many patients.[155] One small, uncontrolled series has evaluated the effect of pre-emptive combination therapy. In this case series, 36 recipients were treated with IFN-α2b and ribavirin starting the third post-transplant week and continued for 1 year.[156] After a median follow-up of 52 months, the actu-

arial 5-year survival was excellent (87.5%). At 36 months post-discontinuation of therapy, a sustained virological and biochemical response was achieved in 12 patients (33%), 20% in those infected with HCV genotype 1 and 100% in those with genotype 2. Liver biopsies were normal in these patients. In contrast, progression to severe hepatitis C was observed in four of the non-responders (11% of the overall series). Common side-effects included haemolytic anaemia and asthenia, which were well controlled with dose reduction. Well-designed controlled randomized studies are needed to confirm these findings.

Another recent study only published in the form of an abstract has emphasized the low applicability of this approach, as a substantial proportion of patients do not qualify to receive either IFN or ribavirin due to the presence of co-morbidities in the early post-transplant period, particularly leukopenia and thrombocytopenia.[157] In addition, the efficacy is low in those infected with HCV genotype 1, the group who constitute the vast majority of patients undergoing transplantation for HCV-related cirrhosis.

### *Treatment of patients with recurrent hepatitis C*

Monotherapy has resulted in extremely disappointing results with biochemical response achieved in a minority of IFN- or ribavirin-treated patients but in general, without virological and/or histological response.[80] Although combination therapy probably yields the greatest potential benefit, results are far from being acceptable. Studies on therapy of recurrent hepatitis C are scarce, non-randomized and generally based on small sample sizes.[158–168] The sustained virological response achieved in these studies ranges from 9% to 33%. In addition, both dose adjustments and drug discontinuations, mainly due to ribavirin toxicity, are frequent (30–40%). Although less common, severe adverse effects (particularly hepatic decompensation) may occur in treated patients (5% in previous studies). In a recent study, 6 vs 12 months of combination therapy were compared in 57 transplant patients. A sustained virological response was achieved in 6 of 27 patients treated for 6 months (22%) and in 5 of 30 patients treated for 12 months (17%) ($p = 0.4$). In addition, the response was found to be superior in those infected with HCV genotypes non-1 than in those infected with HCV genotype 1, after both 6 and 12 months of therapy (43% vs 15% and 43% vs 9%, respectively), thus suggesting that 6 months of therapy may be sufficient for recurrent hepatitis C even for genotype 1 cases.[167] However, the numbers of patients studied are too small to draw definitive conclusions. It appears from these preliminary findings that response to standard IFN and ribavirin is generally lower following liver transplantation than in immunocompetent patients. Reasons that may explain this low response rate probably include all of the following: (1) high levels of viraemia, (2) high frequency of HCV genotype 1 in these patients, (3) the low tolerability of IFN and ribavirin leading to frequent dose reductions, (4) lower responses to HCV therapy in immunocompromised patients, suggesting that an intact immune response facilitates treatment-associated viral clearance. In addition, the efficacy of therapy appears to be reduced in recipients with advanced recurrent hepatitis. Reversal of fibrosing cholestatic hepatitis is highly unusual. Many patients have renal insufficiency secondary to immunosuppressive agents, and because of impaired renal clearance of ribavirin, drug-associated haemolysis can be profound. Thus, if ribavirin is initiated as part of combination therapy, the dose should be 600–800 mg, depending on renal function and presence of anaemia. In small studies, early initiation of erythropoietin has been reported to increase the tolerability of ribavirin. In the early studies using IFN in monotherapy, there was concern regarding the induction of allograft rejection due to the potential for upregulating the expression of HLA class I and II. In the majority of studies, the bulk of evidence using combination therapy suggests that there is no increase in frequency or severity of rejection.

Data on post-treatment histology are generally lacking. In a recent randomized study, there were no major differences in the activity and fibrosis stage before treatment and at the end of follow-up.[168] In contrast, improvement in histology was observed in other small non-randomized studies. It is possible that an effect on histology will be seen with a longer follow-up.

There are still many aspects that need to be addressed, such as the optimal dose and duration of therapy, whether ribavirin maintenance is needed following IFN discontinuation, and/or the potential benefit of using growth factors.

In summary, each of the strategies has advantages and disadvantages. Prophylactic therapy while the patient is awaiting transplantation is the best theoretical approach. It is, however, limited by the low tolerability of antiviral agents in patients with advanced liver disease. In addition, it is unlikely that this approach will have a major impact on post-transplantation recurrence of HCV, as only a relatively small proportion of patients may qualify for therapy and the minority achieve viral clearance. In addition, treatment with IFN may theoretically result in the selection of more virulent or resistant viral strains, that ultimately lead to a more aggressive course of the disease or to a post-transplantation situation in which the limited antiviral agents that might have been available are no longer effective.

Pre-emptive post-transplantation therapy is another attractive approach. However, there are many unanswered questions remaining with this strategy. It is not

known whether this approach reduces the rate of recurrent hepatitis C or if it merely delays recurrence. In addition, if this strategy is to be used, it is not known whether all patients should be treated or if treatment should be focused on those at high risk of severe progression. Unfortunately, to date, no single factor or combination of factors is capable of accurately differentiating which patients will ultimately progress to cirrhosis from those with a more benign prognosis. Finally, tolerability of therapy is a major problem when HCV antiviral agents are administered early in the post-transplantation period, and adverse events are common and significant.

With the available drugs, treatment of the established disease is probably the most cost-effective option.[169] Although limited by a relatively low efficacy, tolerance appears to be better than when these drugs are given pre-emptively. Treatment should be offered preferentially to patients who develop progressive liver disease. In that sense, protocol liver biopsies may identify early histological changes that herald an aggressive course, and in such cases, therapy should be initiated at earlier stages when a response appears to occur more frequently.

## Alternative approaches

As the efficacy of antiviral therapy is limited in HCV-infected recipients, optimal management of long-term immunosuppression may be important in improving long-term outcomes. As excess immunosuppression has a deleterious effect on outcome of HCV infection, steroid doses should be minimized, anti-lymphocyte globulin avoided whenever possible, and other immunosuppressive agents should be kept to minimum levels. This is a trend already followed in many transplant centres, but its efficacy has yet to be proven. In fact, recent preliminary data suggest that a rapid steroid tapering may adversely impact HCV disease progression,[121] and it may be possible that the 'acceleration' in disease progression observed in recent years is in fact related to the recent changes in maintenance immunosuppression.[119] Potential hypotheses include the development of subclinical chronic rejection as a consequence of under-immunosuppression or liver damage due to the partial reconstitution of the immune system.

The choice of the appropriate immune suppression is currently under evaluation. Indeed, the effect of different immunosuppressive drugs on viral load and disease progression are unclear to date. Significant difficulties in assessing these associations have arisen recently as newer and more potent immunosuppressive agents are being used to prevent rejection of the graft. As a consequence, there has been an increase in drug combinations of varying potency. This, together with changes in immunosuppressive regimens in individual patients over time, limits our ability to assess accurately the role played by the immunosuppression in the progression of HCV-related liver disease. Our limited understanding as to how to optimize immune suppression underscores the importance of prospective studies comparing different types of immunosuppression-based regimens in HCV-infected recipients. These studies should focus not only on the induction phase but also on the maintenance phase, particularly the way in which steroids are tapered over time.

As a general rule, the optimal strategy should be to achieve a balance between prevention of acute and chronic rejection while minimizing the adverse effects of immunosuppression on recurrent hepatitis C. Based on the available information, the following recommendations were made at the recent Consensus Conference:[86] (1) induction immunosuppression should be performed with two drugs or reduced doses of one or more agents when using triple-drug therapy, and (2) when rejection is diagnosed histologically, the first approach should be to increase the dose(s) of the agents used for maintenance immunosuppression while avoiding bolus corticosteroids or T-cell depleting agents.

## Re-transplantation

Re-transplantation is the last option for patients with failing grafts due to recurrent disease. The number of patients infected with HCV in need of a second transplantation is expected to increase as primary transplant recipients survive long enough to develop graft failure from recurrent disease.[85,170] With the prospect of this increase, it has become imperative to determine whether all or indeed any patients with graft failure due to recurrent HCV disease are candidates for further transplantation. To date, there has been a certain reluctance to accept these patients for re-transplantation, particularly for those patients who have developed recurrent disease leading to graft failure over a short period of time. This fear with re-transplantation is related to four major concerns: (1) early reports suggesting a worse outcome following re-transplantation in HCV-infected recipients than in those uninfected;[170–173] (2) uncertainty regarding the natural history of recurrent hepatitis C in the second graft; (3) advanced age of the recipient, as most had their first transplant in their late fifties or early sixties; and (4) increased organ shortage.

More recent data have reported improved outcome, particularly when re-transplantation is performed before development of infectious and renal complications.[174] Given the poor natural history of compensated graft cirrhosis,[106] if re-transplantation is considered, it should ideally be performed before decompensation.[175] In that sense, serial liver biopsies may help in the diagnosis of clinically compensated HCV-related graft cirrhosis, fa-

cilitating an early referral for liver re-transplantation, at a stage where the probabilities of a favourable outcome are higher. However, under the current MELD organ allocation system,[176] patients have no realistic hope of receiving an organ until they have developed advanced graft failure with significant coagulopathy and frequent renal insufficiency. As a result, patients with hepatitis C-related graft failure will only receive an organ at a point when the chances of survival with re-transplantation are low. In order to improve the outcome, and in a similar way to what has been done with HCC, policies regarding the allocation of organs would have to be revised to offer re-transplantation to patients with recurrent hepatitis C for whom there is a reasonable expectation of long-term survival.

One aspect that remains debatable is whether the severity of recurrent HCV disease in the second graft is related to that observed in the first graft. In a recent case series based on annual protocol biopsies, HCV-related disease severity following re-transplantation was found to be related to that observed following the first transplant.[177] This study suggests that if re-transplantation is to be considered in these patients, it should only be done in the setting of some therapeutic strategy. Unfortunately, the frequent co-existence of co-morbidities and development of side-effects limit the potential utility of antiviral therapy in re-transplanted patients.[177]

Additional important aspects to be considered and that were recommended at the Consensus Conference[86] are: (1) the presence of cholestatic HCV disease should preclude re-transplantation other than in exceptional circumstances; (2) additional transplantation beyond the second graft for recurrent hepatitis should be discouraged; (3) there are minimal data concerning the role of re-transplantation in living donor recipients with recurrent HCV disease and no recommendations could be made.

In summary, as for HBV, three measures should be followed in order to improve the outcome: (1) avoid late re-transplantations when the hepatic failure is too advanced and renal insufficiency has developed, (2) use antiviral therapy at an early stage following re-transplantation, and (3) choose a mild anti-rejection regime so that infections and severe HCV recurrence may be decreased.

### Live donor liver transplantation for HCV-infected patients

Despite all the measures to improve the outcome of HCV-infected patients, the increased organ shortage has led to a dramatic increase in the number of patients on the waiting list and in those dying while waiting. The implementation of live donor liver transplantation (LDLT) was believed to be a potential solution to this problem.[178] The main unanswered question relates to the results obtained with this new technique. Are they the same as with standard liver transplantation in patients infected with HCV? To date, the question remains unanswered as results between centres are controversial.[179,180] While some studies have suggested that HCV recurs earlier and is associated with more severe hepatitis, other studies have not confirmed these data. Most of the evidence though, points towards a worse outcome than when using cadaveric donors. Recent unpublished data from the United Network for Organ Sharing (UNOS) show that the relative risk of graft loss and death are significantly higher with LDLT than with cadaveric liver transplantation (2.23 and 1.88, respectively).[179] In addition, and in a similar way to what has been described with standard transplantation, results in the LDLT group, although not reaching statistical significance, also appear to be worse in the HCV-positive group than in the HCV-negative group. However, the number of HCV-infected LDLT recipients to date is very small, the post-transplant follow-up interval is limited and the reports to date lack protocol liver biopsies. As a result, the data regarding the impact of LDLT on severity of HCV recurrence were deemed inconclusive by the Consensus group.[86]

## Conclusions

The management of HBV in the liver transplant setting has substantially improved in recent years,[8,181] and currently, the likelihood of serious disease due to HBV reinfection is unlikely. Indeed, with available combination therapy, survival is excellent, even in those with active pre-transplantation viral replication, and risk of recurrent disease of the allograft is low. The challenge now remains to identify the most cost-effective strategy to prevent recurrence. Benefits of treatment with nucleoside analogues prior to transplantation must be weighed against potential risks associated with the development of drug-resistant mutants, which in turn may impair the ability of HBIg to prevent HBV recurrence. Prolonged HBIg therapy is limited by costs and side-effects. If oral antiviral drugs are to be used in combination with HBIg, the type of antiviral agent and dose and duration of HBIg treatment remain uncertain.

In contrast to HBV, results in HCV-infected patients have not improved with time. HCV-related end-stage liver disease represents the predominant cause of transplantation in most transplant centres. Despite improvements in antiviral and immunosuppressive therapies in recent years, worsening of patient and graft survival has been observed in HCV recipients, with a resultant growth in demand for re-transplantation. As the severity of recurrence of HCV is linked to the degree of immunosuppression, better utilization of immunosuppressive drugs should lead to an improvement in outcome. In

contrast, if additional studies confirm that more severe recurrence of HCV results from the use of older or living donors, patient and graft survival may decline sharply as mean donor age increases inexorably and the frequency of LDLT increases substantially. Treatment of established recurrent hepatitis C is the only alternative currently available. There is a great need for improved antiviral drugs for use in this setting.

# Chapter 23
# Prevention

Jane N Zuckerman

## Introduction

Hepatitis B, which is a major public health problem throughout the world, is preventable by immunization. First-generation vaccines were prepared from the 22-nm hepatitis B surface antigen (HBsAg) particles purified and inactivated from plasma donations from chronic asymptomatic (healthy) carriers of hepatitis B virus. These preparations were safe and immunogenic but have been superseded largely by recombinant DNA vaccines produced by expression of HBsAg in yeast cells. The expression plasmid contains only the 3′ portion of the viral surface open reading frame (ORF) and only the major surface protein, without pre-S epitopes, is produced. Vaccines containing pre-S1 and pre-S2 as well as the major surface protein, so-called third-generation hepatitis B vaccines, have also been produced.

Before the availability of hepatitis B vaccines, passive immunization with hepatitis B immunoglobulin (HBIg) was used for prophylaxis under certain defined conditions.

## Passive immunization

HBIg is prepared specifically from pools of plasma with high titres of anti-HBs and may confer temporary passive immunity under certain defined conditions. The major indication for the administration of HBIg is a single acute exposure to HBV, such as occurs when blood containing HBsAg is inoculated, ingested or splashed onto mucous membranes and the conjunctiva. The optimal dose has not been established but doses in the range of 250–600 have been used effectively. HBIg should be administered as early as possible after exposure and preferably within 48 hours, usually 3 mL (containing 200 IU of ant-HBs per mL) in adults. It should not be administered 7 days or more after exposure. It is generally recommended that two doses of HBIg should be given 30 days apart.

Results following the use of HBIg for prophylaxis in babies born to carrier mothers indicate encouraging prevention of infection in the newborn if the immunoglobulin is given immediately, and certainly within 12 hours of birth. The dose of HBIg recommended in the newborn is 1–2 ml (200 IU of anti-HBs per mL). The risk of the baby developing the persistent carrier state is reduced by up to 70%. Combined passive and active immunization indicate an efficacy approaching 90%.

## Active immunization

See Figs 23.1 and 23.2. The discovery of variation in the epitopes presented on the surface of the virions and subviral particles identified several subtypes of HBV which differ in their geographical distribution. All isolates of the virus share a common epitope, a, which is a domain of the major surface protein that is believed to protrude as a double loop from the surface of the particle. Two other pairs of mutually exclusive antigenic determinants, d or y and w or r, are also present on the major surface protein. These variations have been correlated with single nucleotide changes in the surface ORF which lead to variation in single amino acids in the protein. Four principal subtypes of HBV are recognized: adw, adr, ayw and ayr. Subtype adw predominates in northern Europe, the Americas and Australasia and is also found in Africa and Asia. Subtype ayw is found in the Mediterranean region, eastern Europe, northern and western Africa, the Near East and the Indian subcontinent. In the Far East, adr predominates, but the rarer ayr occasionally may be found in Japan and Papua New Guinea. Based on the analysis of subdeterminants, nine subtypes of the virus have been proposed.

Hepatitis B virus (HBV) is now classified into seven genotypes, A–G, by sequence divergence >8% of the entire genome.[1,2] An eighth genotype, designated H, has been reported from Central America,[3] but has not been fully characterized yet. Although both genotypes and subtypes segregate geographically, the same subtype can be represented by several genotypes.

The major response of recipients of hepatitis B vaccines is to the common group determinant (epitope) a with consequent protection against all subtypes of the virus.

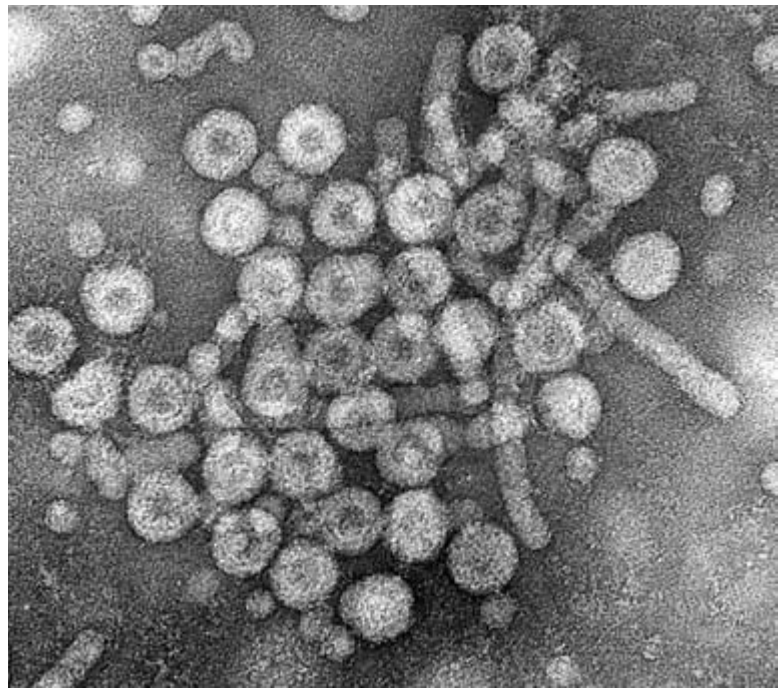

**Figure 23.1** Electron micrograph of plasma from a carrier of hepatitis B virus showing the 42-nm double spherical particles of the complete virus, tubular forms and small spherical particles measuring 22 nm in diameter (×200 000).

Immunization against hepatitis B is now recognized as a high priority in preventive medicine in all countries and strategies for immunization are being revised. Universal vaccination of infants and adolescents is recommended as a possible strategy to control the transmission of this infection. More than 150 countries now offer hepatitis B vaccine to all children, including the United States, Canada, Italy, France and most Western European countries.[4]

However, immunization against hepatitis B is at present recommended in a number of countries with a low prevalence of hepatitis B, mainly the UK and Scandinavian countries, only to groups which are at an increased risk of acquiring this infection. These groups include individuals requiring repeated transfusions of blood or blood products, prolonged inpatient treatment, patients who require frequent tissue penetration or need repeated circulatory access, patients with natural or acquired immune deficiency and patients with malignant diseases. Viral hepatitis is an occupational hazard among health-care personnel and the staff of institutions for people with mental disabilities and in some semi-closed institutions. High rates of infection with HBV occur in narcotic drug addicts and intravenous drug abusers, sexually active male homosexuals and prostitutes. Individuals working in high endemic areas are, however, at an increased risk of infection and should be immunized.

Young infants, children and susceptible persons (including travellers) living in certain tropical and subtropical areas where socio-economic conditions are poor and the prevalence of hepatitis B is high should also be immunized. It should be noted that in about 30% of patients with hepatitis B the mode of infection is not known and this is, therefore, a powerful argument for universal immunization.

## Site of injection for vaccination and antibody response

Hepatitis B vaccination should be given in the upper arm or the anterolateral aspect of the thigh and not in the buttock. There are over 100 reports of unexpectedly low antibody seroconversion rates after hepatitis B vaccine using injection into the buttock. In one centre in the United States a low antibody response was noted in 54% of healthy adult health-care personnel. Many studies have since shown that the antibody response rate was significantly higher in centres using deltoid injection than in centres using the buttock. On the basis of antibody tests after vaccination, the Advisory Committee on Immunization Practices of the Centres for Disease Control, USA recommended that the arm be used as the site for hepatitis B vaccination in adults, as has the Department of Health in the UK (reviewed in Zuckerman *et al*.[5]).

Apart from the site of injection, there are several other factors which are associated with a poor or no antibody response to currently licensed vaccines. Indeed, all studies of antibody response to plasma-derived hepatitis B vaccines and hepatitis B vaccines prepared by recombinant DNA technology have shown that between 5%

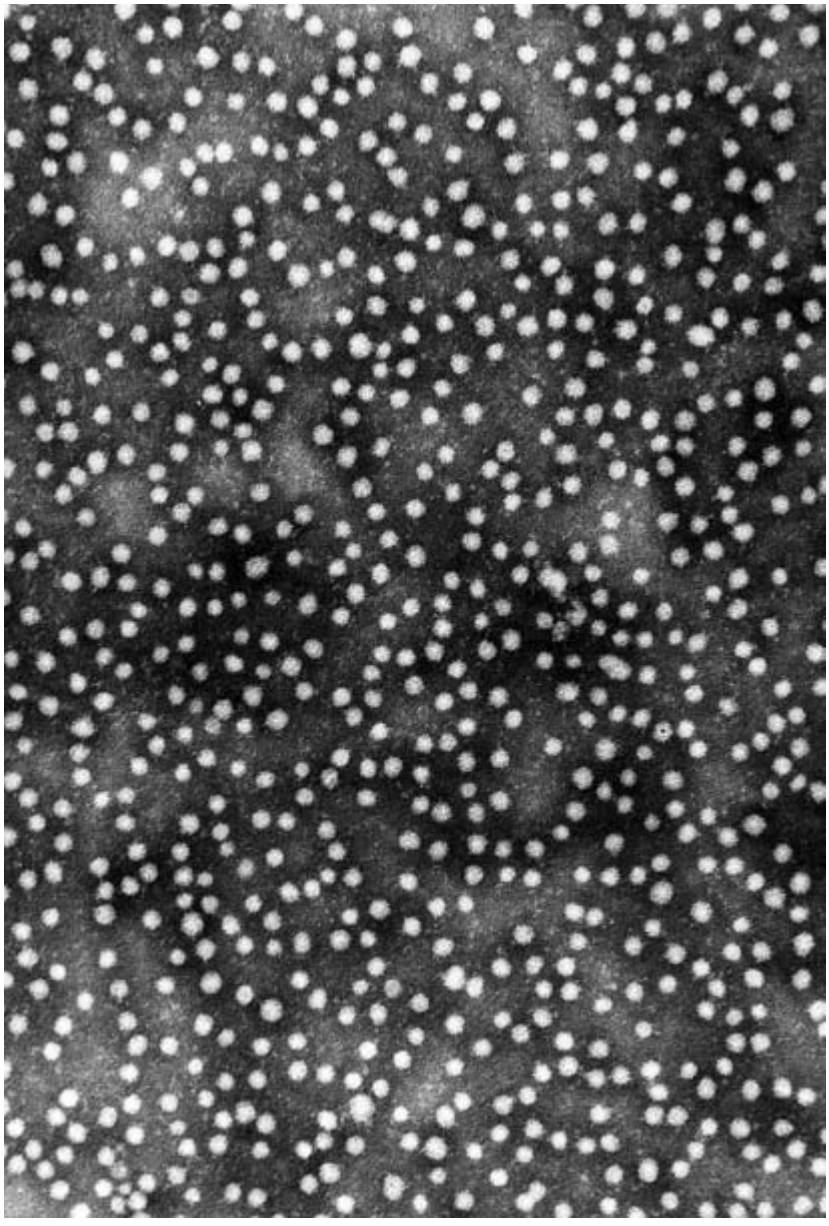

**Figure 23.2** Electron micrograph of plasma-derived hepatitis B vaccine showing the presence of purified 20–22-nm spherical particles of the excess protein coat (surface antigen, HBsAg) of the virus (×180 000).

and 10% or more of healthy immunocompetent subjects do not mount an antibody response (anti-HBs) to the surface antigen component (HBsAg) present in these preparations (non-responders), or that they respond poorly (hypo-responders). The exact proportion depends partly on the definition of non-responsiveness, generally less that 10 IU/L or 100 IU/L, respectively, against an international antibody standard (reviewed in Zuckerman *et al*.[5]).

## The kinetics of anti-HBs response to immunization and booster doses

The titre of vaccine-induced hepatitis B surface antibody (anti-HBs) declines, often rapidly, during the months and years following a complete course of primary immunization. The highest ant-HBs titres are generally observed 1 month after booster vaccination followed by a rapid decline during the next 12 months and thereafter more slowly. Mathematical models have been designed and an equation was derived consisting of several exponential terms with different half-life periods. It is considered by some researchers that the decline of anti-HBs concentration in an immunized subject can be predicted accurately by such antibody kinetics with preliminary recommendations on whether or not booster vaccination is necessary (see review by Zuckerman[6]).

If the minimum protection level is accepted at 10 IU/L, consideration should be given to the diversity of the individual immune response and the decrease in levels

of ant-HBs as well as to possible errors in quantitative ant-HBs determinations. It would then be reasonable to define a level of >10 IU/L and <100 IU/L as an indication for booster immunization. It has been demonstrated that a booster inoculation results in a rapid increase in anti-HBs titres within 4 days. However, it should be noted that even this time delay might permit infection of hepatocytes.

Several options can therefore be considered for maintaining protective immunity against hepatitis B infection.

- Relying upon immunological memory to protect against clinical infection and its complications, a view which is supported by *in vitro* studies showing immunological memory for HBsAg in B cells derived from vaccinated subjects who have lost their anti-HBs, but not in B cells from non-responders, and by post-vaccination surveys.
- Providing booster vaccination to all vaccinated subjects at regular intervals without determination of anti-HBs. This option is not supported by a number of investigators because non-responders must be detected.
- While an anti-HBs titre of about 10 IU/L may be protective, this level is not ideal from a laboratory point of view, as many serum samples may give non-specific reactions at this antibody level.
- Testing anti-HBs levels 1 month after the first booster and administering the next booster before the minimum protective level is reached.

No empirical data are available for the anti-HBs titre required for protection against particular routes of infection or the size of the infectious inoculum. The minimum protective level has been set at 10 IU/L against an international standard. However, the international standard is a preparation of immunoglobulin prepared from pooled plasma of individuals recovered from infection rather than immunized subjects and the antibody avidity is likely to be different. Furthermore, studies carried out in the 1980s indicated asymptomatic infection after immunization in subjects and health-care workers who had antibody titres below 50 IU/L.

There are studies showing that hepatitis B vaccines provide a high degree of protection against clinical symptomatic disease in immunocompetent persons despite declining levels of anti-HBs (reviewed by Zuckerman and Zuckerman[7]). These studies encouraged the Immunization Practices Advisory Committee of the United States, the National Advisory Committee on Immunization of Canada and the European Consensus Group[8] to recommend that routine booster immunization against hepatitis B is not required. Caution, however, dictates that those at high risk of exposure, such as cardiothoracic surgeons and gynaecologists, would be prudent to maintain a titre of 100 IU/L of anti-HBs by booster inoculations, more so in the absence of an appropriate international antibody reference preparation. Breakthrough infections have been reported and, whereas long-term follow-up of children and adults indicate that protection is attained for at least 9 years after immunization against chronic hepatitis B infection, even though anti-HBs levels may have become low or decline below detectable levels (reviewed by the European Consensus Group[9]), brief periods of viraemia may not have been detected because of infrequent testing. Longer follow-up studies of immunized subjects are required to guide policy, as is well illustrated by a study carried out in Gambian children.[10] It was found, by a cross-sectional study in the Gambia, that the efficacy of hepatitis B vaccination against chronic carriage of HBV 14 years after immunization was 94%, and the efficacy against infection was 80% and lower (65%) in those vaccinated at the age of 15–19 years. Further and longer follow-up studies of immunized subjects are therefore required to guide policy.

## Strategies for immunization against hepatitis B

The World Health Organization (WHO) has set a target for global control of hepatitis B, and recommended that all countries integrate hepatitis B vaccine into their national immunization programmes by 1997. Over 150 countries have introduced such programmes.

A number of strategic options are outlined below, including a proposal for immediate implementation of universal antenatal screening and immunization of infants born to carrier mothers as a minimum policy initiative.

There is strong support for the introduction of universal antenatal screening to identify hepatitis B carrier mothers and the vaccination of their babies. It is important that any other strategies do not interfere with the delivery of vaccine to this group. Immunization of this group will have the greatest impact in reducing the number of new hepatitis B carriers. For children outside this group, it is difficult to estimate the lifetime risk of acquiring a hepatitis infection, and four main approaches should be considered.

- To continue vaccination of 'high-risk' babies as defined above
- Universal infant immunization
- Universal adolescent immunization
- Vaccinate everybody.

### Vaccination of adolescents

This approach delivers immunization at a time close to the time when 'risk behaviour' would expose ado-

lescents to infection. Vaccination could be delivered as part of a wider package on health education in general, to include sex education, risk of AIDS, dangers of drug abuse, smoking, benefits of a healthy diet and lifestyle.

The problems with this approach are as follows.

- Persuading parents to accept vaccination of the children against sexually transmitted disease, a problem they may not wish to address at the time.
- Ensuring that a full course of three doses is given.
- There would be difficulty evaluating and monitoring vaccine cover. The systems for monitoring uptake of vaccine in this age group may not operate efficiently.

### Vaccination of infants

The advantages of this approach are as follows.

- It is known that vaccination can be delivered to babies.
- Parents would accept vaccination against hepatitis B along with other childhood vaccinations without reference to sexual behaviour.

The disadvantages of this approach are:

- Whether immunity would remain until exposure occurred in later life. This was thought to become less of a problem as more people were vaccinated as the chance of exposure to infection was reduced.
- That the introduction of further childhood vaccination would reduce the uptake of other childhood vaccinations. This problem would be avoided if hepatitis B could be delivered in a combined vaccine containing diptheria tetanus and pertussis (DPT), and such preparations are under evaluation.

Vaccination of infants is preferable to vaccination of adolescents as there are sufficient mechanisms to ensure, monitor and evaluate cover. A booster dose could be given in early adolescence combined with a health education package. A rolling programme could be introduced, giving priority to urban areas.

## Non-response to hepatitis B vaccines

All studies of the antibody response to currently licensed plasma-derived hepatitis B vaccines and hepatitis B vaccines prepared by recombinant DNA technology have shown that between 5% and 10% or more of healthy immunocompetent subjects do not mount an antibody response (anti-HBs) to the surface antigen component (HBsAg) present in these preparations (non-responders) or that they respond poorly (hypo-responders). The exact proportion depends partly on the definition of non-responsiveness or hypo-responsiveness, generally <10 IU/L or 100 IU/L of anti-HBs, respectively, against an international antibody standard (reviewed by Zuckerman[6]).

Non-responders remain susceptible to infection with HBV. While several factors are known to affect adversely the antibody response to HBsAg including the site and route of injection, gender, advancing age, body mass (overweight), immunosuppression and immunodeficiency, and mechanisms underlying non-responsiveness to the S component of HBsAg in humans remain largely unexplained, evidence is accumulating that there is an association between different HLA-DR alleles and specific low responsiveness in different ethnic populations. Considerable experimental evidence is available to suggest that the ability to produce antibody in response to specific protein antigens is controlled by dominant autosomal class II genes of the major histocompatibility complex (MHC) in the murine model.[11,12] Much effort has been devoted to overcoming class II-linked non-responsiveness to current hepatitis B vaccines.[13–16]

There is evidence that the pre-S1 and pre-S2 domains have an important immunogenic role in augmenting anti-HBs responses, preventing the attachment of the virus to hepatocytes and eliciting antibodies which are effective in viral clearance, stimulating cellular immune responses, and circumventing genetic non-responsiveness to the S antigen.[8,15] Thus, a number of studies indicated that the inclusion of pre-S components in recombinant or future synthetic vaccines should be developed. For example, the pre-S2 region is more immunogenic at the T- and B-cell levels than the S region in the mouse model,[15,17] as is the case with pre-S1 in the mouse[16] and in man and circumvents S region non-responsiveness at the level of antibody production.

Indeed, it was demonstrated in the murine model that the independence of MHC-linked gene regulation of immune responses to pre-S1, pre-S2 and S regions of hepatitis B surface antigen would assure fewer genetic non-responders to a vaccine containing all three antigenic regions.[16] Studies conducted in humans with experimental recombinant hepatitis B vaccines containing all three S components of the viral envelope polypeptides demonstrated the enhanced immunogenicity of such preparations when compared with conventional yeast-derived vaccines (as shown by Pay *et al*.[18] and others), although several earlier studies with vaccines containing the S, pre-S1 and pre-S2 components revealed significant differences from preparations containing only the S antigen.[19,20]

These observations led to the development of a new triple antigen hepatitis B vaccine, a third-generation recombinant DNA vaccine containing pre-S1, pre-S2 and S antigenic components of hepatitis B virus surface antigen of both subtypes adw and ayw. All three antigenic components are glycosylated, closely mimicking the surface protein of the virus itself, produced in a continuous mammalian cell line, the mouse c127 clonal cell line,

after transfection of the cells with recombinant HBsAg DNA.

Animal studies showed that the vaccine was well tolerated and a viral challenge study in chimpanzees demonstrated protective efficacy.

This vaccine was evaluated for reactogenicity in a number of clinical trials (reviewed by Zuckerman and Zuckerman[21]). The major conclusions from these studies were that the vaccine was safe and immunogenic and overcame the responsiveness to the single S antigen vaccines used widely in some 70% of non-responders, and that even a single dose of 20 μg of the triple antigen provided significant seroprotection levels of antibody. However, the anticipated high costs of the triple antigen vaccine will limit the use of the triple antigen vaccine initially to the following groups.

- Vaccination of non-responders to the current single antigen(s) vaccines, who are at risk of exposure to HBV infection.
- Subjects with inadequate humoral immune response to single antigen hepatitis B vaccines, e.g. those over the age of 40 years, males, obese individuals, smokers and other hypo-responders.
- Persons who require protection rapidly, e.g. healthcare employment involving potential exposure to parental procedures involving blood-to-blood contact (current schedules of immunization with single antigen hepatitis B vaccines involve three doses at 0, 1 and 6 months).

Studies are required to determine the efficacy of the triple antigen in patients who are immunocompromised and also to determine whether the inclusion of pre-S1 and pre-S2 antigenic components in this new vaccine will protect against the emergence of HBsAg mutants (see below.)

### Attempts to overcome non-responsiveness by the use of immunomodulators

Attempts have been made to enhance the anti-HBs response following immunization, particularly in patients treated by maintenance haemodialysis, but often with conflicting results or in limited studies, which have not been confirmed, including: α-interferon (IFN-α), interleukin (IL)-2 and thymopentin and other substances such as experimental oral adjuvants in mice and oestrogen.

## Hepatitis B surface antigen variants and immunization

There is evidence that amino acid substitutions within the *a* determinant of the surface antigen can allow replication of HBV in vaccinated persons, as antibodies induced by current vaccine do not recognize critical changes in the surface antigen domain. The emergence of variants of HBV, possibly due to selection pressure associated with extensive immunization in an endemic area, was suggested by the findings of HBV infection in individuals immunized successfully in Italy. These studies were extended subsequently by the finding of non-complexed HBsAg and anti-HBs and other markers of hepatitis B infection in 32 of 44 vaccinated subjects, and sequence analysis from one of these cases revealed a mutation in the nucleotide encoding that a determinant, the consequence of which was a substitution from glycine to arginine at amino acid position 145.[22]

Various mutations and variants of HBsAg have since been reported from many countries, including Italy, the UK, Holland, Germany, the USA, Brazil, Singapore, Taiwan, China, Japan, Thailand, India, and West and South Africa.[23,24] However, the most frequent and stable mutation was reported in the G145R variant. A large study in Singapore of 345 infants born to carrier mothers with HBsAg and HBeAg, who received HBIg at birth and plasma-derived hepatitis B vaccine within 24 hours of birth and then 1 month and 2 months later, revealed 41 breakthrough infections with HBV despite the presence of anti-HBs. There was no evidence of infection among 670 immunized children born to carrier mothers with HBsAg and anti-HBe, nor in any of 107 immunized infants born to mothers without HBsAg. The most frequent variant was a virus with the G145R mutation in the *a* determinant.[25] Another study in the USA of serum samples collected between 1981 and 1993 showed that 94 (8.6%) of 1092 infants born to carrier mothers became HBsAg-positive despite post-exposure prophylaxis with hepatitis B immunoglobulin and hepatitis B vaccine. Following amplification of HBV DNA, 22 children were found to have mutations of the surface antigen, most being in amino acids 142–145; five had a mixture of wild-type HBV and variants and 17 had only the 145 variant.[26]

In a more recent study in the USA[27] direct sequencing of amplified or cloned polymerase chain reaction (PCR) products, solid-phase detection of sequence-specific PCR products (SP-PCR) and limiting dilution cloning PCR (LDC-PCR) were compared to determine their sensitivity in detecting differing concentration of HBsAg variants in the same population of the infants studied in the 1981–1993 post-exposure prophylaxis of hepatitis B in infants born to carrier mothers. LDC-PCR had the greatest sensitivity and could detect HBsAg variants at a concentration of 0.1% of the total viral population. NBsAg variants were detected in 47 of 93 (51%) of infants with chronic HBV infection acquired after post-exposure prophylaxis, and more than half of the variants were detected only by the most sensitive methods. The G145R variant (glycine to arginine at aa 145) was identified most frequently.

A report from Taiwan[28] noted the increase in the prevalence of mutants of the a determinant of HBV over a period of 10 years in immunized children, from 8 of 103

(7.8%) in 1984 to 10 of 51 (19.6%) in 1989, and 9 of 32 (28.1%) in 1994. This is of particular concern. The prevalence of HBsAg mutants among those fully immunized was higher than among those not vaccinated (12/33 vs 15/153, $p = 0.0003$). In the 27 children with detectable mutants, the mean age of those vaccinated was lower than of those not vaccinated, and mutation occurred in a region with greatest hydrophilicity of the surface antigen (amino acids 140–149) and more frequently among those vaccinated than among those not vaccinated. More mutations to the neutralizing epitopes were found in the 1994 survey in Taiwan.

Another important aspect is the evidence that HBsAg mutants may not be detected by all of the blood donor screening tests and by existing diagnostic reagents. Such variants may therefore enter the blood supply or spread by other means. This is emphasized by the finding in Singapore, between 1990 and 1992, of 0.8% of carriers of HBV variants in a random population survey of 2001 people.[25,29] These findings add to the concern expressed in a study of mathematical models of HBV vaccination, which predict, on the assumption of no cross-immunity against the variant by current vaccines, that the variant will not become dominant over the wild-type virus for at least 50 years – but the G145R mutant may emerge as the common HBV in 100 (or more) years' time.[30]

It is important, therefore, to institute epidemiological monitoring of HBV surface mutants employing test reagents which have been validated for detection of the predominant mutations, and consideration should be given to incorporating into current hepatitis B vaccines antigenic components that will confer protection against infection by the predominant mutant(s).[31]

The current position can be summarized as follows.

- Variants of hepatitis B virus surface antigen proteins were identified over a decade ago and may have a potential impact on immunization against this important infection and on public health.[21]
- The G145R mutant is replication-competent and is stable. It appears to be the most common variant and may persist in the host for at least 14 years.
- There is evidence that sera of 10% (up to 40% in high-risk groups) of individuals with antibodies to hepatitis B core antigen (anti-HBc) as the only marker of HBV infection may contain HBV DNA. At least some of the chronic low level carriers of HBV, where surface antigen is not detected and anti-HBc is the only serological marker of HBV infection, are infected with surface mutants. Further studies are required.
- Epidemiological monitoring of HBV surface mutants is essential, employing test reagents that have been validated for detection of the predominant mutations.
- Urgent consideration should be given to the introduction of routine screening for hepatitis B by nucleic acid-based technology of blood donors and tissue and organ donors for transplantation.
- Consideration should be given to incorporation into the current hepatitis B vaccines of additional antigenic components that will confer protection against infection by the predominant *a* determinant mutation(s), if dictated by epidemiological findings.

Considerable progress has been made in the prevention of HBV infection by active immunization since the vaccine was first licensed in 1982. The global eradication of hepatitis B is attainable.

## The relationship between hepatitis C virus and the Flaviviridae family

Hepatitis C virus (HCV) is an enveloped positive-strand RNA virus of the genus Hepacivirus in the family Flaviviridae. The HCV genome is comprised of a positive-stranded RNA molecule of about 9500 nucleotides (nt)[1] containing a single long translational open reading frame (ORF) that encodes a large polypeptide of approximately 3000 amino acids (aa), beginning with the first in-frame methionine codon[2–4] bounded by 5′ and 3′ untranslated regions (UTRs) of approximately 341 and 230 nucleotides (Fig. 24.1). The 5′ UTR of the HCV genome has substantial primary sequence identity with the corresponding region of pestivirus genomes,[3,5,6] and a region of the encoded polypeptide exhibits significant sequence identity to nucleoside triphosphate (NTP)-binding helicases encoded by the pestiviruses and to a lesser extent, the flaviviruses.[3,7,8] Protease and replicase sequence motifs, conserved among the pestiviruses and flaviviruses are also present within the HCV-encoded polyprotein, which along with the more extensively conserved helicase sequence are all similarly colinear among the three types of viral polyproteins.[3] Although these are the only regions of HCV exhibiting significant primary sequence identity with pestiviruses and flaviviruses, the hydropathicity of the HCV-encoded polypeptide is remarkably similar to that of the flaviviruses and, to a lesser extent, to that of the pestiviruses, thus indicating similarities in their basic structures and functions.[3] Nucleotide and protein sequence analysis of GBV-A, GBV-B and GBV-C[9,10] show that these three viruses are more closely related to each other and HCV than to the other members of the Flaviviridae family. HCV, together with GBV-A, B and C form a new genus, Hepacivirus in the flavivirus family (Fig. 24.1)[11,12] of related viruses within the larger genus of *Flaviviridae*.[10] HCV causes chronic infection in >80% of cases,[13,14] which then predisposes patients to the sequential development of cirrhosis and primary hepatocellular carcinoma (HCC).[15]

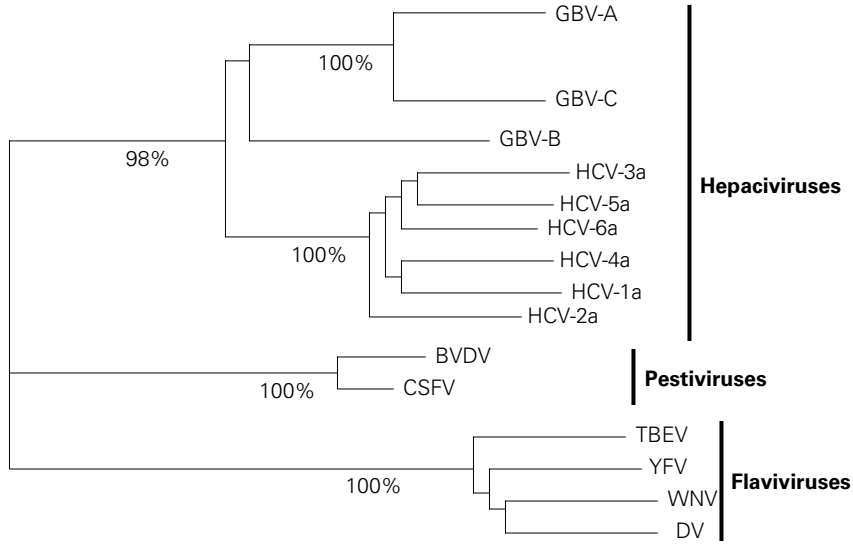

**Figure 24.1** Phylogenetic relationship between HCV and other members of the Flaviviridae. This figure shows a comparison of the predicted polymerase regions of HCV-1a, -2a, -3a, -4a, -5a and -6a, GBV-A, GBV-B, GVB-C, classical swine fever virus (CSFV), bovine viral diarrhoea virus (BVDV), tick-borne encephalitis virus (TBEV), yellow fever virus (YFV), West Nile virus (WNV) and dengue virus (DV). (Adapted from Simmonds.[11,12])

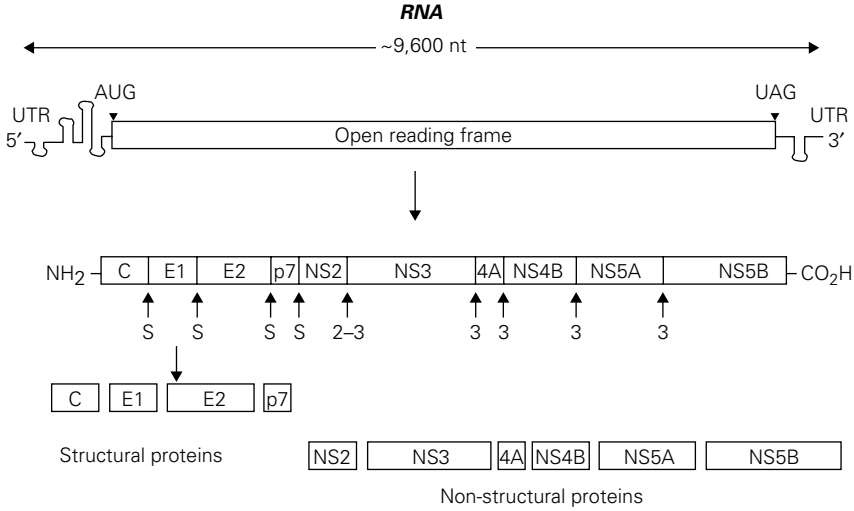

**Figure 24.2** Schematic organization of the HCV genome and the encoded proteins. The viral RNA consists of a single open reading frame (ORF), encoding about 3011 amino acids, bounded by 5′ and 3′ untranslated regions (UTRs). The polyprotein is cleaved post-translationally with signal peptidases (S) and the virus encoded NS2-3 (2-3) and NS3-4 (3) proteases to generate the mature structural and non-structural proteins.

## Structure of the virus

### The HCV virion

Analysis of the structure of HCV particles has been hampered by the low titre of virus in infectious sera and the difficulties of replicating the virus in culture systems. It is likely that HCV is an enveloped icosahedral virus, like other members of the Flaviviridae.[16,17] However, detailed structural analysis of HCV virions is still lacking. Particles with a diameter of 45–65 nm have been observed by electron microscopy in human plasma[18] and in chimpanzee and human liver chronically infected with HCV.[19,20] Non-enveloped nucleocapsids have also been detected in the plasma of infected chimpanzees.[21] HCV-like particles (HCV-LPs) have been detected in experimentally infected[19] or transfected cell lines.[22] HCV-LPs of 40–60 nm have also been produced by the expression of HCV structural proteins using: baculovirus vectors in insect cells;[23] Semliki Forest virus replicons[24] and VSV (vesicular stomatitis virus) vectors[25] in BHK 21 cells; and yeast expression vectors.[26] There is evidence that HCV particles are present in the circulation as immune complexes[27] or in association with serum lipoproteins.[28–31]

### Structural proteins

A large ORF extends throughout most of the HCV RNA genomic sequence and encodes a polypeptide of between 3010 and 3033 amino acids, depending on the source of the viral isolate.[2–3,32–36] As in the case for pestiviral and flaviviruses, the large HCV ORF encodes a polyprotein precursor that is processed co- and post-translationally to yield a variety of structural (virion) and non-structural (NS) proteins (Fig. 24.2 and Table 24.1). Structural proteins are processed from the N-terminal region of the HCV polyprotein precursor, beginning with an RNA-binding nucleocapsid polypeptide of basic charge (C; ca. 23 kDa) followed by two glycoproteins – E1 (33–35 kDa) and E2 (68–72 kDa) (Fig. 24.2). These proteins have been identified by *in vitro* translation of HCV RNA transcribed *in vitro* from cDNA clones[37,38] and also from mammalian cells[39–42] and insect cells[41] transfected with HCV cDNA. Additional proteins derived from core, 21 kDa and 17 kDa and a 7 kDa protein (p7) which lies between E2 and NS2 have also been found. The processing of the putative region of the HCV polyprotein is similar to that of flaviviruses and pestiviruses in being mediated at least in part by the host signal peptidases.[43–48]

### Core protein

The expression of the HCV structural protein coding region, by cell-free translation in the presence of microsomal membranes, or in tissue culture cells, produces a 23-kDa (previously identified as 21–22-kDa) core protein of 191 amino acids. This indicates that the cleavage of the core protein from the polyprotein is dependent on signal peptidases in the endoplasmic reticulum (ER).[27,49,50] HCV core protein has been identified in the sera of HCV-infected humans as a 21-kDa protein.[51] The core protein binds to membranes *in vitro* and in transfected cells, and has been shown to be associated with the cytoplasmic side of the ER. E1 was precipitated by anti-core antibodies in the presence of core protein, showing that core interacts with E1. In contrast, the E2 protein is not co-precipitated with anti-core antibodies in co-expression experiments. Following signalase cleavage, the E1 signal sequence may act, at least in part, to retain the upstream C protein in the ER in an analogous manner to that of the flaviviruses.[44–46] Little E1 is exposed on the cytosolic side of the ER, therefore the interaction between core and E1 probably takes place in the ER membrane

**Table 24.1** HCV proteins

| Protein | Molecular weight (kDa) | Main functions* |
|---|---|---|
| C | 21–23 | Nucleocapsid, |
| | | RNA binding |
| | 17 | F/AFRP protein? |
| E1 | 33–35 | Envelope protein |
| E2 | 70–72 | Envelope protein |
| p7 | 7 | Ion channel? |
| NS2 | 21–23 | NS2-3 protease component |
| NS3 | 70 | NS3/4 protease (protease domain) |
| | | NS2-3 protease (protease domain?) |
| | | NTPase |
| | | RNA helicase |
| | | DNA helicase? |
| | | RNA binding |
| NS4A | 8 | NS3/4 protease – co-factor |
| NS4B | 27 | Induction of ER 'membranous web' |
| | | NS5A phosphorylation |
| NS5A | 56–58 | Inhibition of IFN-α? |
| | | Inhibition of apoptosis? |
| NS5B | 65–68 | RNA-dependent RNA polymerase |

*See text for a discussion of the functions of the HCV proteins.

and deletion studies indicate that the C-terminal regions of both proteins are important for their interaction.[52]

The amino-terminal hydrophilic portion of the core protein contains a homotypic domain which allows the p21 core protein to interact with itself.[53] In contrast, core that was expressed as p23 did not interact with itself, indicating that the C-terminal domain may inhibit multimerization.[53] Both membrane-bound and membrane-free core exist in dimeric and multimeric forms. However, the processes involved in the assembly of the HCV capsid are not yet clear. Core proteins, which had the hydrophobic C-terminal domain deleted, also translocated to the nucleus. One of the three clusters of basic amino acids in the core protein, PRRGPR (aa 38–43) is similar to the nuclear localization signal found in human papilloma and human herpes viruses.[54] Intact core may therefore remain in the cytoplasm by being anchored to ER membranes and, if cleaved, it translocates to the nucleus. HCV core protein expressed *in vitro* has been shown to form nucleocapsid-like particles (NLPs).[55] The 75 N-terminal residues have been shown to be sufficient to assemble as NLPs *in vitro*.[56] NLPs have been detected in the nucleus when core was expressed in yeast[57] and in HCV-infected human liver.[58] Expression of core using a Semliki Forest virus replicon shows that core amino acid D111 is essential for the formation of NLPs.[58a]

Core protein has been shown to interact with lipid droplets via its central domain. Core proteins lacking part of the central domain (residues 125–144) were degraded by the proteosome.[59] Similar sequences in the core protein of GBV-B and in plant oleosin protein were shown to facilitate the association of these proteins with lipid droplets. It was shown that the HCV lipid binding domain could substitute for the equivalent domain in oleosin, allowing the hybrid protein to bind to lipid droplets.[60] After cleavage of the signal sequence between core and E1, the intramembrane cleaving protease, signal peptide peptidase (SPP), cleaves the signal sequence releasing core which can then associate with lipid droplets.[61] Core can be phosphorylated by both protein kinase A (PKA) and protein kinase C (PKC).[62] Serine residues ser-99 and ser-116 are the major phosphorylation sites for PKA and PKC, respectively, and the phosphorylation of ser-116 by both PKA and PKC may enhance the nuclear localization of core.[63] Ran/Gsp1p (a small GTPase) is required for the nuclear localization of core protein. However, the reduction in the nuclear localization of transcription factors, which normally use Ran/Gsp1p, in cells that express core suggests that core nuclear localization may disturb the transport of cellular proteins into the nucleus.[64] The proteosome activator PA28γ was shown to bind to core and the deletion of the PA28γ binding region from core led to its export from the nucleus to the cytoplasm.[65] HCV core can regulate the activity of cellular genes, including c-myc and c-fos, the long terminal repeats of Rous sarcoma virus and HIV-1 and SV40 early promoters.[66] Core activation of transcription from the interleukin-2 (IL-2) promoters via nuclear factor of activated T cells (NFAT), suggests that core expression may have consequences for IL-2-mediated T-cell development.[67]

Different reports have presented evidence that core can stimulate or inhibit apoptosis. Core can bind to the lymphotoxin β receptor (LTβR) and activate NF-κB ac-

tivity by increasing the degradation of Ikappa B kinase (IKKβ).[68,69] Consequently both Fas and tumour necrosis factor-α-(TNF-α)-mediated apoptosis are inhibited. Expression of core in HepG2 and HeLa cells activated the NF-κB signalling pathway in a dose-dependent manner. The use of dominant negative forms of TNF receptor-associated factor (TRAF2) showed significant blockage of the activation of this pathway by core. This suggests that core protein mimics pro-inflammatory cytokine activation of NF-κB through TRAF2.[70,71] Cells expressing HCV core were also shown to undergo apoptosis in response to stimulation with anti-Fas monoclonal antibodies[72] and core protein induced cell death via TNF signalling pathways[73] primarily by facilitating Fas-associated death domain (FADD) recruitment to TNFR1.[74] The expression of core was also shown to downregulate the expression of pRb and correspondingly upregulate the expression of E2F-1, which may sensitize cells to apoptosis.[75] Aggregation of Fas receptors by cytoplasmic core was shown to facilitate apoptosis in Jurkat cells.[76] By contrast, core expression has also been reported to inhibit TNF-α-induced apoptosis[77] and increase the level of bcl-x1 mRNA, which may inhibit apoptosis.[78] Core has also been implicated in cell transformation. Core has been shown to bind to p53 and enhance the expression of p21 (waf1/Cip1) indicating that this binding may lead to p53 activation.[79,80] Core inactivates a bZIP nuclear transcription protein, LZIP, by sequestering it in the cytoplasm and subsequently potentiating cellular transformation in NIH 3T3 cells.[81] Core expression is also able to immortalize primary human hepatocytes.[82] An increase in p53 and a reduction in c-myc were observed in core immortalized hepatocytes treated with an antisense core gene leading to cell death via apoptosis. This indicates that core is responsible for the regulation of the immortalized phenotype.[83] The expression of HCV core protein inhibits the replication of HBV.[84] The interaction of HCV core with the HBV X-protein suppresses HBV gene expression and the interaction of HCV core with HBV polymerase inhibited the formation of HBV virions.[85]

Members of the DEAD box family of RNA helicases, CAP-Rf,[86] DDX3[87] and DBX,[88] were shown to bind to core by the use of the yeast two-hybrid system, suggesting the possibility of core inhibiting host cell translation or other functions that involve RNA metabolism.

Recent evidence indicates that there may be a novel HCV protein produced by a –2/+1 ribosomal frameshift in the core reading frame and that this could give rise to the previously observed p17.[89] Peptides corresponding to this F (frameshift) protein or ARFP (alternative reading frame protein) have been shown to react with serum antibodies from chronically infected HCV patients, which suggests that p17 is produced during infection.[89–91] Cell-based expression systems have also shown that this protein is present in the cytoplasm, particularly in the perinuclear region.[92] The function of this protein is not clear.

## Envelope proteins

HCV has two envelope glycoproteins, E1 and E2, of molecular weights 33–35 kDa and 70–72 kDa. E1 and E2 are essential components of the HCV virion envelope and they are necessary for virion entry into host cells by direct receptor binding and possibly for membrane fusion. Internal signal sequences upstream of the E1 and E2 proteins direct the polyprotein precursor to the endoplasmic reticulum (ER), where they are translocated into the lumen, and after signal sequence cleavage[37,38,93] they remain anchored inside the lumen.[37,42] E1 and E2 are integral membrane proteins and are heavily glycosylated in the ER lumen with high-mannose carbohydrate chains, which contribute approximately one-half the mass of each of these glycoproteins.[37,38,42,93] The C-terminal region of E1 domain is very hydrophobic and terminates with the hydrophobic E2 signal sequence, which is cleaved by signal peptidase upon translocation into the ER lumen. Thus, the E2 signal sequence may serve, at least in part, as the E1 anchor in a manner reminiscent of the flaviviral envelope proteins.[44–46] Similarly, the signal peptidase cleavage between core and E1 results in the attachment of the hydrophobic E1 signal sequence to the C-terminus of the core protein.[37,38] Both E1 and E2 contain internal transmembrane domains (TMDs). Expression of E1 or E2 alone showed that they localized to the ER in a similar way to the E1E2 complex, and chimeric proteins which were constructed with E1 and E2 TMDs, e.g. with the ectodomains of CD4 or CD8, were also shown to localize to the ER. These TMDs are sufficient to localize E1 and E2 to the ER, to serve as membrane anchors and are involved in heterodimerization of E1 and E2.[94,95] The anchor domains of E1 and E2 are similar in structure to those of other members of the family *Flaviviridae*. They comprise two short stretches of hydrophobic residues separated by a short region which contains charged amino acids. Replacement of these charged amino acids in the HCV envelope glycoproteins led to alterations in the functions performed by the TMDs, i.e. protein anchoring, ER localization and assembly of glycoproteins, indicating that these functions are tightly linked together.[96] E1 and E2 proteins can be co-precipitated by antibodies against E1 or E2 when they are expressed together, indicating that these two proteins are associated in HCV-infected cells. However, little evidence for intermolecular disulfide bonding was observed between E1 and E2.[97,98] Furthermore, E1 in which cysteine residues have been replaced by other amino acids still forms aggregates with E2 by non-covalent (native) interactions. Analysis of the regions of E2 responsible for interaction with E1 shows that the TMD is critical for native com-

plex formation.[99] Before signal sequence cleavage the TMDs of E1 and E2 form a hairpin-like structure. After signal sequence cleavage of E1 and E2 in the ER, there is a dynamic change in the orientation of the C-terminal of these TMDs from luminal to cytosolic. Thus, by reorientating their C-terminals towards the cytosol, signal sequences at the C-terminal of E1 and E2 contribute to new functions, i.e. protein anchoring, E1E2 heterodimerization and ER retention.[100]

Immunostaining and electron microscopy showed that the E1 and E2 were predominantly located in the ER rather than at the cell surface, suggesting that there may be mechanisms for retention of these proteins in this compartment and that they are not translocated beyond the cis-Golgi.[101] Analysis of E2 expression by immunofluorescence and nocodazole treatment indicates that E2 does not cycle through the Golgi but is instead retained by the ER. Further evidence for the retention of HCV E2 by the ER is indicated by the absence of modifications to E2 glycans by Golgi enzymes. In addition, recombinant CD4, which contains the TMD of E2, is also retained in the ER without cycling through the Golgi.[102] E1 and E2-NS2 are rapidly released from the polyprotein by host cell signal peptidases and autocatalytic cleavage at the NS2/NS3 site. These primary cleavage products are core glycosylated and appear heterogeneous. In addition, the complex glycans that are usually acquired in the trans-Golgi do not appear in the E1 or E2.[103] The fact that the HCV glycoproteins do not appear to migrate further than the cis-Golgi may indicate that, like other Flaviviridae, the HCV buds from the endoplasmic reticulum and is released from cells via the endocytosis pathway. The absence of HCV glycoproteins in the plasma membrane should also reduce host immune responses and help to maintain chronic infections. However, immunofluorescence showed that 93% of chronically infected HCV patients had antibodies to E2 expressed in a Chinese hamster ovary cell line.[104] Most of these antibodies were against the hypervariable region 1 (HVR-1) of E2, which spans aa 384–414. Co-expression of the ER chaperones calnexin, calreticulin and BiP shows that they all interact with E1E2 heterodimers. Tunicamycin treatment indicates that these interactions are due to N-linked oligosaccharides on the HCV proteins interacting with the chaperones. Calnexin appears to play a role in the productive folding of the HCV glycoproteins, whereas calreticulin and BiP are involved in non-productive folding pathways.[105,106] Calnexin may therefore help to retain the E1E2 glycoproteins in the endoplasmic reticulum and thus prevent their migration to the plasma membrane and facilitate their interaction with the nucleocapsid.[103,107]

VSV pseudotyped with E2 showed that the HVR-1 binds to cell surface proteoglycans.[108] E2 glycoprotein was shown to bind to cell surface heparin sulfate proteoglycans (HSPG) and liver-derived highly sulfated heparin sulfate specifically inhibited cellular binding and entry of pseudotyped virions in a dose-dependent manner. Binding of E2 to HSPG may be the first step in the interaction between HCV and the cell surface, resulting in receptor-mediated entry and initiation of infection.[109] Analysis of antibodies to E1, E2 and HVR-1 in chronically infected chimpanzees indicates that there are low levels of detectable antibodies to E1 (22%) and E2 (15%) and HVR-1. Changes in the sequence of HVR-1 were analyzed by passaging HCV-infected human sera in chimpanzees. Subsequent analysis of the sequence complexity in the chimpanzees showed that there was much lower sequence diversity generated in chimpanzees than in humans and that very little change in sequence was shown during serial passage in chimpanzees. This indicates that the appearance of non-synonymous mutations is due to immune selection pressure rather than being an incidental result of HCV replication.[110,111] Sequence analysis of 460 HVR-1 clones, isolated at different times from six HCV-infected humans receiving interferon-α (IFN) therapy indicated that despite strong amino acid variability, the conformation of HVR-1 was highly conserved, with an overall basic stretch of amino acids located at specific sequence positions. This suggests that HVR-1 may be involved in interaction with negatively charged molecules, e.g. lipids, proteins or glycosaminoglycans (GAGs), and that the interaction with GAGs may have a role in host cell recognition and attachment.[112]

E2 protein binds to CD81, a tetraspanin which is present on the surface of B lymphocytes and hepatocytes. The binding region of E2 was mapped to the extracellular loop on CD81. Recombinant CD81 molecules which contain this loop were able to bind HCV and anti-HCV antibodies inhibited virus binding to CD81.[113] A truncated soluble form of E2 was shown to bind to CD81 but not other members of the tetraspanin family, e.g. CD9, CD63 and CD151. Binding of CD81 by soluble E2 induced the aggregation of lymphocytes and inhibited B-cell proliferation[114] and blocked natural killer (NK) cell activation, cytokine production and cytotoxic granular release and proliferation.[115,116] This suggests that E2 inhibition of cells of the immune system may be an evasion strategy by HCV to establish chronic infection. However, the interaction of E2 with CD81 showed that only 30% of CD81 molecules had become internalized after 12 hours, indicating that CD81 has a poor capacity to mediate virus entry[117] and the expression of human CD81 in transgenic mice did not confer susceptibility to HCV infection on them.[118] This indicates that CD81 is not the main/only receptor for HCV.

Infectious HCV pseudotyped retroviruses which displayed functional E1E2 glycoprotein complexes were shown to enter cells via a pH-dependent endocytosis

pathway. Expression of CD81 in non-permissive CD81-negative hepatocarcinoma cells restored susceptibility to the pseudotyped retrovirus infection. However, receptor competition assays show that scavenger receptor class B type 1 (SR-B1) is also required for the infection of CD81-expressing cells. Competition with soluble E2 could also prevent infection with the pseudotyped retrovirus. This suggests that CD81 and SR-B1 may both be important for the entry of HCV into hepatocytes.[119] E2 binds to dendritic cell-specific intracellular adhesion molecule 3-grabbing non-integrin (DC-SIGN) and liver endothelial L-SIGN via high-mannose glycans. Competition with mannan and carbohydrate recognition domain-specific antibodies interferes with this binding.[120,121] Soluble E2 and pseudotyped retroviruses that express both E1 and E2 bound efficiently to DC-SIGN and DC-SIGNR expressed on cell lines and primary human endothelial cells. However, no binding to other C-type lectins was observed. The interaction of E2 with DC-SIGN and related lectins may help to deliver HCV to the liver and possibly modulate the activity of dendritic cells.[122] The possible role of E1 and/or E2 in membrane fusion is unclear. However, computational analysis suggests that HCV E1 and pestivirus E2 glycoproteins are truncated class II fusion proteins.[123]

E2 contains a sequence identical to the phosphorylation sites of IFN-induced protein kinase R (PKR) and eIF2-α, a target for PKR. E2 expression blocked PKR kinase activity and its subsequent inhibitory effects on protein synthesis and cell growth.[124] E2 also binds to and inhibits PKR-like ER resident kinase (PERK) in a similar manner to its inhibition of PKR. By relieving the inhibition of translation caused by these kinases, E2 expression may also reduce ER stress, possibly promoting the persistence of HCV infection.[125]

### p7

Between E2 and NS2 there is an additional small polypeptide, p7, which is a 63 aa integral membrane polypeptide and comprises two transmembrane domains connected by a cytoplasmic loop and intraluminal amino- and carboxyl-terminal tails.[126,127] It is mainly located in intracellular membranes, but it is not yet clear whether these are primarily associated with the endoplasmic reticulum[126] or the mitochondria.[128] Studies *in vitro* have shown that p7 acts as a calcium ion channel[129,130] and can be inhibited by amantidine. HCV p7 has also been shown to be able to substitute for the influenza ion channel in a cell-based assay.[129] p7 appears to be essential for infection, as deletion or substitution mutations in the p7 region of an infectious HCV cDNA clone were not viable in chimpanzee infection studies.[127] Studies on genotype 1a and 2a chimeras of p7 also indicate that the intraluminal tails may interact with other HCV components in a genotype-specific manner.

## Replication of the virus

### Non-structural proteins

The organization of the non-structural (NS) protein-coding region of HCV (Fig 24.2) resembles those of flaviviruses and pestiviruses. Small amino acid sequence motifs conserved among proteases, helicases and replicases are colinear in all three types of viral-encoded polyproteins[3,8] and, despite the absence of extensive, overall primary sequence homologies in this region, the hydropathicity profiles of all three viral NS regions are similar, particularly for HCV and the flaviviruses.[3]

### NS3/NS4A protease

The NS3 protease domain contains a serine protease catalytic triad, his 1083, asp 1107 and ser 1165[131–133] (polyprotein numbering) and cleaves the HCV polyprotein at the junctions between NS3/NS4A, NS4A/NS4B, NS4B/NS5A and NS5A/NS5B. Protein sequence analysis localized the N-terminal residues (P1′) of NS4A (aa 1658), NS4B (aa 1712), NS5A (1773) and NS5B (2421)[131] and showed that small uncharged residues, e.g. ser or ala, appear to be preferred at P1′ and polar residues cys or thr are found at position P1 with a gly or asp found at position P5.[131,134,135]

NS4A was also shown to be important for NS3-mediated cleavage, particularly at the NS4B/NS5A site.[19,136–143] However, cleavage at the other non-structural protein junctions was variable in efficiency, with cleavage at the NS5A/NS5B junction being most efficient.[144–146] The N-terminal 181 residues of NS3 were found to be sufficient for the protease activity and it can cleave all of the non-structural protein sites in trans except the NS3/NS4A site.

Using a COS cell transfection system, it was shown that NS4A stabilizes NS3 and helps to localize it in the ER membrane.[147] The interaction of NS3 and NS4A requires the N-terminal 22 amino acids of the NS3 protein.[148] This was further demonstrated when a fusion protein, which contained the N-terminal 22 amino acids of NS3 fused to DHFR, also formed a stable complex with NS4A.[149] Co-expression and immunoprecipitation experiments showed that interactions between the NS4A and NS3 proteins could not be disrupted by non-ionic detergent treatment, showing that the interaction was relatively strong. Further studies showed that the central region of NS4A is important for the NS4A-dependent activation of NS3. Hydrophobic residues, in particular ile 29 and ile 25, were shown to be important for the NS4A activity. Peptides covering regions 21–34 of NS4A were able to substitute for intact NS4A in trans cleavage reactions, and mutants which destabilize the NS3–NS4A interaction abolish the NS4A-mediated stimulation of NS3.[150] Analysis of more than 250 HCV genomes showed that the threonine residue at aa 631 (T631) is strictly con-

served in the P1 position at the NS3–NS4A autoproteolysis junction. Wild-type T631 NS3-NS4A constructs require the central co-factor domain of NS4A to be present (aa 21–34). By contrast, T631C mutant protein underwent self-cleavage in the absence of the co-factor. Replicons derived from T631 mutants showed a reduced level of colony formation. T631 may slow processing at the NS4A cleavage site by ensuring proper interaction with the NS4A co-factor prior to cleavage with the polyprotein and prevent subsequent product inhibition by the NS3 C-terminus.[151]

Kinetic cleavage analysis of P6-P4′ peptides corresponding to all the intermolecular cleavage sites of the non-structural region of the HCV polyprotein had the following order of cleavage: NS5A/5B > NS4A/4B >> NS4B/5B. This indicates that the primary structure of the cleavage site is an important determinant for the efficiency with which each site is cleaved.[152] Purified NS3 protease domain (aa 1027–1281) efficiently cleaves a 17 mer peptide corresponding to the NS5A/5B junction. The addition of NS4A peptide amino acids 1673–1692 increases the Kcat from 2 to 15.8 minutes$^{-1}$ and decreases the Km from 250 to 99 μM.[153] Product inhibition of NS3 protease was observed with peptides corresponding to the NS4A/NS4B, NS4B/NS5A and NS5A/NS5B cleavage sites. No inhibition was observed with peptides corresponding to the NS2/NS3 cleavage site.[154] NMR spectroscopy data show that inhibitor peptides based on N-terminal cleavage products of NS3 peptide substrates bind to the protease in a well-defined and extended conformation,[155] and they appear to induce stabilization of the enzyme by causing tightening of the interdomain interaction in NS3[156] by an induced fit mechanism.[157]

Alignments of the NS3 protease of HCV, and GBV-A, B and C hepatitis viruses[9,10] with the 2A proteases of picornaviruses, showed the conservation of zinc binding domains in all of these proteases. Cys 97, cys 99, cys 145 and his 149 are likely to represent the zinc binding motif in the NS3 protease. Changes in the nuclear magnetoc resonance (NMR) signals of his 149 between pH 7 and 5 suggest that there may be structural changes at the metal binding site switching from a 'closed' to an 'open' conformation.[158] No similar zinc binding domain was found in NS3 of other members of the Flaviviridae family.[159] The presence of a zinc atom within this binding site appears to be necessary for structural integrity and activity of the enzyme, which is similar to the chymotrypsin-like 2A cysteine proteases of picornaviruses, indicating that NS3 is a member of a novel class of zinc binding chymotrypsin-like proteases.[159,160]

X-ray crystallography at 2.2–2.7 Å resolution was carried out with recombinant NS3 protease domains corresponding to the HCV BK[161,162] and H[163] strains. The catalytic triad of his 57, asp 81 and ser 139 of HCV is highly conserved and the protease domain folds in a chymotrypsin-like protease fashion, which includes two beta barrel domains and four short alpha helices with the catalytic site located in the crevice between the beta barrel domains. The substrate binding pocket is shallow, non-polar, with few features and is formed by the side chains of invariant residues phe 154, ala 157 and leu 135 and has a similar structure to the predicted S1 pocket.[135] The first 30 amino acids of the N-terminus of the NS3 protease extend away from the protein and contain β-strands that interact with neighbouring molecules. The interaction of NS3 with NS4A[161] leads to the ordering of the N-terminal 28 residues of the protease into a beta strand and an alpha helix and also causes local rearrangements which are important for the production of a catalytically favourable conformation of the active site.[162,163] A comparison of NS3 protease and NS3 protease–NS4A complex by NMR also indicates that there are large structural rearrangements of the strand loop regions formed by residues V51-D81 as a result of the NS4A binding.[164]

There have been many attempts to develop small molecule inhibitors against the NS3 protease, e.g. a hexapeptide inhibitor of NS3 protease was shown to have similar inhibitory properties to IFN-α in the treatment of replicon cells (see section on Replication models for HCV below). The half-life of HCV RNA was shown to be about 11 hours with this protease inhibitor and 14 hours with IFN-α treatment.[165] BILN 2061 is a small molecule that inhibits NS3 protease. It was shown to inhibit NS3 both *in vitro* and *in vivo*. Patients treated with BILN 2061 for 2 days had a large decrease in HCV RNA plasma levels.[166] However, the development of resistance variants to protease inhibitors can be problematic, e.g. replicon cell lines could be selected so that they became resistant to the presence of these inhibitors and sequence analysis revealed that point mutations in the protease were responsible for this resistance.[167] A comparison of two protease inhibitors, VX950 and BILN 2061, showed that point mutations led to resistance to both of these protease inhibitors. However, the major BILN 2061 resistance mutations, at asp168, are fully susceptible to VX950, whereas mutants resistant to VX950 at ala 156 remain sensitive to BILN 2061.[168] A number of approaches have also been used to try to develop novel inhibitors of NS3 proteases. A variable domain antibody fragment derived from a phage display library was a potent inhibitor of NS3 protease,[169,170] and the characterization of a mini-antibody inhibitor of NS3 protease led to the development of a cyclic peptide which inhibits NS3 protease.[171] Recently, a novel set of NS3 protease inhibitors was developed based on *Drosophila* serpin SP6 reactive site loop. These were shown to bind to NS3 via the induced fit behaviour of the catalytic site and inhibit NS3 protease.[172]

An NS3–NS4 complex was isolated from transfected COS cells and the effect of polynucleotides on the protease, and the NTPase and helicase (see below) was examined. The addition of poly(U) increased the activity of the protease fivefold, showing that there is interaction between the protease and NTPase/helicase domains, and that this interaction is likely to be important during virus infection. The apparent enhancement of the protease activated by poly(U) may also help to localize the processing of the NS5A/5B to the 3′-UTR where replicase assembly and minus-strand RNA synthesis are initiated.[173]

## NS3 NTPase/helicase

The C-terminal 442 aa of the HCV NS3 protein contains a DECH amino acid sequence motif,[3,174] which is characteristic of the DExH subfamily, of DEAD-box superfamily-2 NTPase/RNA helicases.[175,176] HCV NS3 NTPase activity can be stimulated by polynucleotides in a similar fashion to those of pestiviruses and flaviviruses. Comparisons of the binding of recombinant NS3 proteins showed that the helicase domain had to be present for poly(U) to bind to NS3. Recombinant NS3 helicase domains display RNA unwinding activity in the presence of divalent cations, $Mn^{2+}$ or $Mg^{2+}$ and adenosine triphosphate (ATP) in strand displacement assays. NS3 helicase can unwind RNA strands from substrates which contain 5′ and 3′ single-stranded regions (5′/3′) or substrates containing only 3′ single-stranded regions (3′/3′) but not substrates which contain 5′, single-stranded regions only (5′/5′) or on substrates lacking single-stranded region.[177] This indicates that the HCV helicase, like most RNA helicases, is unidirectional, in a 3′ to 5′ direction.[178] HCV NS3 helicase was also shown to efficiently unwind DNA/DNA and DNA/RNA substrates. The significance of DNA helicase activity is not clear, but it is possible that it can affect the unwinding of cellular nucleic acid, and this in turn could have some role in viral pathogenesis or persistence.[179] Full-length NS3, in an NS3–NS4A complex isolated from transfected COS cells, had a pH optimum of 7.5–8.5 for NTPase activity, compared with the previously observed optimum of pH 6.5 for the NTPase/helicase domain expressed on its own. The maximum activity of the NTPase was obtained when poly(U) was present. The concentration of poly(U) required for stimulation of the NTPase in the NS3–NS4A complex was up to 1000 times less than that required for recombinant proteins that contain only the NS3 NTPase/helicase domain. This indicates that the protease domain is important for efficient activity of the NTPase, indicating that there is interaction between the protease and helicase domains, and suggests that this interaction is likely to be important during virus replication.[180]

A 2.1 Å resolution of the structure of the HCV NS3 RNA helicase domain suggests that initial recognition involves interaction of the 3′ end of single-stranded substrate RNA with a conserved arginine-rich region on the RNA binding domain of NS3.[181] NS3 interacts efficiently and specifically with the 3′ ends of both positive- and negative-stranded RNA. Interaction with the 3′ negative-strand RNA appears to involve binding to a stem-loop structure (nucleotides 5–20 from the 3′ end). Deletion of this structure almost totally impaired NS3 binding. Binding to the 3′ positive-strand RNA involves the entire 3′ region.[182] In addition, RNA aptamers that were selected by their ability to bind to and inhibit HCV NS3 helicase were shown to have similar structures to the 3′ UTR of HCV genomic RNA.[183]

Mutational analysis of conserved regions in the helicase and NTPase domains of NS3 has shown that these residues are crucial for both NTPase and helicase activity,[184,185] indicating that these two activities are coupled. Mutational analysis also showed that some mutants that had lost NTPase activity, K1236A (in the GxGK motif) and D1316A (in the DExH motif) could still bind RNA efficiently. However, R1490A (in the QRxGRxGR motif) was defective in NTPase and could no longer bind dsRNA. This suggests that the conserved motifs cooperatively constitute a larger fuctional domain rather than acting as several independent domains.[186]

NS3 RNA helicase undergoes conformational changes, on binding of NTPs or ssRNA and after NTP hydrolysis, which drives helicase translocation along a nucleic acid. Binding of an NTP reduces the affinity of NS3 for ss nucleic acid but increases its affinity for ds nucleic acid. Therefore, the binding energy of NTP is used to bring NS3 out of a state in which it is tightly bound to ss nucleic acid, to facilitate translocation along the unwound duplex nucleic acid, whereas NTP hydrolysis and product release promotes tight binding to the ss nucleic acid.[187,188] Kinetic analysis suggests that NS3 helicase may function as a dimer,[189] and one study indicates that NS3 complexed with NS4A has a higher RNA helicase activity than NS3 alone.[179] HCV NS3 appears to be post-translationally methylated at R1488 in QRRGRTGR1493G motif IV. However, although methylation of specific arginine residues has been shown for a number of RNA binding proteins, the significance of this methylation for NS3 is unclear.[190] Adaptive mutations in the NS3 helicase (residue 470) have been shown to transform inactive replicon constructs into fully active RNA replicons. The mutations R470M for HCV BK and P470L for HCV 77 gave optimal activity.[191]

Monoclonal antibodies[192,193] and recombinant antibody fragments[194] specific for HCV NS3 protein abolished the helicase activity and an scFv, expressed in HCV-infected human hepatocytes by using adenovirus delivery of the

scFv coding sequence, resulted in a reduction in HCV genomic RNA.[195]

## NS3 interactions with the cell

NIH3T3 cells transfected with cDNA corresponding to the NS3 protease domain became transformed and these transformed cells were able to form tumours when injected into nude mice.[196] NIH3T3 cells which expressed the N-terminal region of NS3 were also shown to be resistant to actinomycin D-induced apoptosis. Induction of p53 during actinomycin D treatment was observed to be weaker in these cells than in untransformed cells. This suggests that the NS3 N-terminal domain has a suppressing effect on apoptosis by decreasing the amount of p53.[197] The N-terminus of NS3 (aa1055–1200) was shown to interact with the C-terminus of p53 (aa 301–306) and form a complex.[198] Full-length NS3 and a C-terminal truncated NS3 region (aa 1027–1459) were co-expressed in cells with p53. In the absence of expressed p53, full-length NS3 was found to be localized in the cytoplasm and truncated NS3 in the nucleus. In the presence of co-expressed p53, both proteins were co-localized in the nucleus. This indicates that p53 enhances the nuclear localization of NS3.[199] Staining of hepatocytes from HCV-infected patients with anti-NS3 antisera shows that while NS3 is mainly present in the cytoplasm, in a minority of infected cells NS3 was also present in the nucleus.[200] NS3 can bind Sm-D1, a small nuclear ribonucleoprotein (snRNP) complex component, associated with autoimmune disease and in cells overexpressing Sm-D1 there is an increase in the level NS3 in the nucleus.[201]

Examination of the NS3 aa sequence indicated a region of 14 amino acids (aa 1487–1500) which is similar to the inhibitory site of the heat-stable inhibitor of cAMP-dependent protein kinase (PKA). Synthetic peptides which corresponded to this region and a recombinant NS3 protein have been reported to be competitive inhibitors of PKA, and NS3 expression was shown to inhibit the translocation of the C subunit of PKA into the nucleus after stimulation with forskolin and reduce the level of histone phosphorylation.[202] The intracellular presence of HCV NS3 could block the normal function of PKA C subunits by directly binding to them.[203] However, one report suggests that the inhibition of PKA by NS3 is due to ATP hydrolysis.[204] NS3 has also been shown to bind to PKC and histones.[205] The significance of NS3 binding to host cell proteins is as yet unclear. Some reports have provided evidence for the internal cleavage of NS3 into two proteins of 49 kDa and 23 kDa when the NS3 region alone or the entire HCV ORF was expressed in mammalian or insect cells. Site-directed mutagenesis indicates that a cleavage position is within a highly conserved domain of the RNA helicase domain.[206,207] HCV NS3/4A serine protease was shown to block the phosphorylation and effector action of IFN regulatory factor 3 (IRF-3), which is a key molecule in the antiviral signalling pathway. The abolition of protease activity by mutation or protease inhibitor restored IRF-3 activity after challenge with another virus, showing that the effector of IRF-3 blockage was attributable to the protease activity of NS3.[208]

## NS5B

The NS5B protein coding sequence has primary sequence motifs, in particular 'GDD', which are conserved among all single-chain viral RNA-dependent RNA polymerases (RdRps)[3,7] and NS5B has been shown to have RdRp activity.[209] X-ray crystallography shows that most of the NS5B protein (the first 530 aa) forms a catalytic domain with 'fingers' and 'thumb' subdomains encircling the enzyme active site, in the 'palm' subdomain, typical of single chain polymerases.[210] X-ray crystallography also indicates that the fingers domain has a long binding groove which guides template RNA to the catalytic site[211] and an NTP binding region close to the active site.[212] The initiation of *in vitro* synthesis of RNA, using a template corresponding to the HCV 3' X region by NS5B, indicates that it is localized to the pyrimidine-rich region of stem I[213] and that *de novo* synthesis favours initiation from the +1 position to maintain the integrity of the template.[214,215] The C-terminal 21 amino acids of NS5B form an alpha-helical transmembrane domain that anchors it to the cytosolic face of the ER.[216] Mutational analysis showed that replicons lacking this transmembrane domain were unable to replicate, and the treatment of replicon cell lines with a synthetic peptide corresponding to the NS5B C-terminal domain prevented the membrane association of NS5B and reduced the level of replicon RNA, indicating that the association of NS5B with ER membranes facilitates RNA synthesis.[217]

Two non-nucleoside analogue inhibitors were shown to bind to the base of the thumb subdomain near its interface with the C-terminal extension of NS5B, suggesting that they interfere with a conformational change essential for the activity of the polymerase.[218] X-ray crystallographic analysis of the C-terminal region (aa 545–564), upstream from the membrane anchor, shows that it forms a hydrophobic pocket in the putative RNA binding cleft. However, deletion of this region enhanced the rate of RNA synthesis by up to 50-fold, indicating that it may have an important role in regulating RNA synthesis.[219] Two residues (glu 18 and his 502) that lie outside the catalytic site are critical for RdRp and are also necessary for the oligomerization of NS5B[220] which occurs in the presence of template RNA.[212,221] A ubiquitin-like protein, hPLIC1, appears to directly interact with NS5B, suggesting that it may be a regulator of HCV RNA replication.[222] Yeast two-hybrid system analysis has shown

that alpha actinin binds to NS5B, and this has been confirmed in RNA replicon cell lines. The use of RNA interference to ablate the synthesis of alpha actinin has also shown that it may be important for RNA replication.[223] The development of RdRp inhibitors is an important approach to the development of antivirals against HCV. Binding studies have shown that a heterocyclic agent ('compound 4') inhibitor of the polymerase, binds to NS5B but does not inhibit the binding of RNA, suggesting that it inhibits the initiation of RNA synthesis.[224] The addition of 2′ modified nucleoside analogues to RNA replicon cell lines inhibited HCV RNA replication. The analogues were incorporated into RNA but prevented the addition of the next nucleotide.[225]

## NS5A

NS5A occurs as a 56-kDa protein and as a 58-kDa hyperphosphorylated form of the 56-kDa protein.[226] The production of p58 is enhanced by the presence of NS4A[226] or NS4B,[227] which may modulate the activity of a cellular protein kinase. Peptide analysis of phosphorylated NS5A identified ser 2321 as the major phosphorylation site. The regions flanking ser 2321 are proline-rich, suggesting that a proline-directed protein kinase may be responsible for the majority of NS5A phosphorylation.[228] NS5A can be hyperphosphorylated when it forms part of a continuous NS3-NS5B polyprotein but not when the non-structural proteins are expressed separately in trans.[227] Deletion analysis has shown that the N-terminal 30 aa of NS5A form an amphipathic alpha helix which functions as a membrane anchor[229] and is conserved across different HCV isolates.[230] NS4A co-localizes with ApoA1 in the Golgi and with lipid droplets in the cytoplasm as well as the perinuclear membrane.[231] NS5A has been implicated as having a role in inhibiting host cell responses to IFN.[232] A region of genotype 1b NS5A termed the IFN sensitivity determining region (ISDR) together with an additional 26 aa carboxyl to the ISDR are required for NS5A to bind to the protein kinase R (PKR – which is induced by IFN-α) dimerization domain. This has the effect of disrupting kinase dimerization, thereby inhibiting its ability to phosphorylate eIF2-α and to shut off translation.[233] However, the role of NS5A in the inhibition of IFN-induced PKR remains controversial. For example, an analysis of mutations of NS5A in HCV-infected patients treated with INF-α did not show a statistically significant correlation of changes to the ISDR with the patients' responses to IFN-α therapy.[234] A cleaved form of NS5A that had lost both the N- and C-terminal portions (aa 155–389) was localized to the nucleus and showed transcriptional activity when fused to a Gal4A DNA binding domain, suggesting a role for NS5A in transcriptional regulation.[235] Binding studies and confocal microscopy indicate that NS5A can bind to p53[236] and suppress p53-mediated transcriptional transactivation and apoptosis.[237]

NS5A inhibits growth factor receptor bound protein 2 (Grb2) by the binding of NS5A polyproline motifs to Grb2 Scr homology 3 (SH3) domains[238] and inhibiting Grb2-mediated mitogenic signalling.[239] It also acts at the same time on the phosphatidylinositol 3-kinase–AKT protein kinase B (PI3K-AKT) cell survival pathway by interacting with the p85 subunit of PI3K. This increases the level of phosphorylation and activity of AKT, which in turn provides protection against the induction of apoptosis in cell lines that express NS5A.[240] This may be important in HCV pathogenesis and viral persistence.[239] NS5A inhibited the mitogenic and stress-activated transcription factor activating protein-1 (AP1) by binding via polyproline motifs, thereby perturbing mitogenic signalling pathways in HCV-infected hepatocytes.[241] NS5A also binds to the SH3 domains of a number of other members of the Src family of tyrosine kinases, e.g. Hck, Lck, Lyn and Fyn.[242] However, the significance of these interactions is not clear. NS5A blocked TNF-α-mediated apoptosis[243] but not Fas-induced apoptosis in cultured cells.[244] Similar results were obtained in NS5A transgenic mice, which were protected against hepatic apoptosis after injection by TNF-α but not when hepatic apoptosis was induced by injection with anti-Fas antibodies.[245] The binding of NS5A to TNF-α receptor associated death domain protein (TRADD) in these transgenic mice suggests that the protection against TNF-α may be by the inhibition of TRADD-mediated NF-κB activation.[245] However, this conflicts with other reports which show that expression of NS5A appears to activate NF-κB by tyrosine phosphorylation of IκB-α[246] and the translocation of NF-κB to the nucleus.[247]

## NS2

NS2 is a 21–23-kDa protein[248,249] forming part of the NS2-3 protease which is specific for the NS2/NS3 cleavage site.[249,250] Cleavage of the N-terminus of NS2 from the C-terminus of p7 is mediated by host signalase enzymes. Single amino acid changes of the NS2/NS3 cleavage site had little effect, and only mutations which altered the conformation of the region P5 to P3′, e.g. pro at P1 or P1′, had a major inhibitory effect on cleavage.[251] NS2 is a transmembrane protein in the ER,[252] and its association with the membrane may be required to assist in the proper folding of the nascent precursor for processing at the NS2/NS3 junction. Unlike most mammalian membrane or secretory proteins, the NS2 protein is translocated post-translationally, suggesting that changes occur in the folding of the protein, from an active autoprotease to a form that allows unfolding and translocation across the ER.[252] There are two internal signal sequences at aa 839–883 and aa 928–960 which target NS2 to the ER

where it appears to have multiple transmembrane domains, and it may have both the amino- and carboxyl-termini located in the lumen of the ER.[253] Different analyses of recombinant NS2-3 proteins indicate that it may be either a zinc-dependent enzyme, with a minimal protease catalytic region spanning aa 904–1206 that contains a zinc ion,[159,254] or alternatively, that it may be a cysteine protease with Cys993 and His 952 as a catalytic dyad.[255,256] NS2 may also have direct effects on host cells. It has been reported that NS2 binds to the death-inducing domain of the pro-apoptotic factor CIDE-B and inhibits the CIDE-B-induced release of cytochrome C from mitochondria and the subsequent caspase-mediated cell death mechanism.[257] In addition, the amino-terminal portion of NS2 has been shown to inhibit the expression of reporter genes controlled by liver and non-liver-specific promoter and enhancer elements, which indicates that it might have a role in altering host gene expression in chronic HCV infections.[258]

## NS4B

Confocal microscopy and proteinase protection assays indicate that NS4B is a cytoplasmically orientated integral membrane protein which is localized to the ER.[259] However, more recent data show that NS4B is a transmembrane protein with the carboxyl-terminus in the cytoplasm and the amino-terminus in the ER lumen.[260] The function of NS4B is not yet clear, however, the expression of NS4B can induce the formation of a 'membranous web' derived from the ER with which all of the HCV proteins[261] and genomic RNA are associated.[262] It is likely that this membranous web is the site of RNA replication in HCV-infected cells, as is the case for other *Flaviviridae*. There is also evidence that NS4B inhibits the traffic of proteins between the ER and the Golgi in infected cells,[263] that it inhibits protein synthesis[264,265] and that it modulates the hyperphosphorylation of NS5A.[227]

## The 5′ terminal UTR

The 5′ untranslated region (5′ UTR) of 341 nt length precedes the initiator methionine codon of the large ORF encoding the polyprotein precursor.[2–4,6,33–36] This is the only region of the HCV genome that shows substantial nucleotide sequence identity with other known viral genomes, exhibiting approximately 50% identity with the 5′ leaders of animal pestiviral RNA genomes[3,5,6] and up to 60% identity with the GBV-B 5′ UTR.[266] The 5′ UTR contains four domains (I–IV) which have extensive stem-loop structures (Fig. 24.3).[267,268] Domain IV extends beyond the 3′ UTR and contains the start codon of the polyprotein with a 3′ boundary between nucleotides +12 and +30,[269–271] and together with domains II and III forms the HCV internal ribosome entry site (IRES), which controls HCV protein translation. The HCV IRES differs, therefore, from the picornavirus model in having the authentic initiation codon located between upstream and downstream elements of the IRES.[270] Chimeric viruses in which the poliovirus IRES[272] or the BVDV 5′ UTR[273] was replaced by HCV 5′ UTR constructs have also confirmed that the HCV IRES functions *in vivo*, and that it will only function when the sequences downstream from the initiation codon are included. Electron microscopy of the IRES indicates that domains II, III and IV all form distinct regions within the molecule with a possible flexible hinge region between domains II and III. Pyrimidine tract binding (PTB) protein was also show to bind to domain III.[274]

The maintainance of the domain II stem-loop structure is necessary for the activity of the HCV IRES. However, this structure is relatively tolerant of sequence changes as long as the stem-loop is preserved.[268] NMR studies show that the free form of domain II is similar in shape to the 40S bound form.[275] Mutants that stabilize stem-loop IV reduce the translational efficiency of the IRES. Long-range interactions between nucleotides 24–38 and 428–442 in the stem-loop IV also reduce IRES-mediated translational efficiency.[276] Stem-loop IV may therefore regulate the translational efficiency of HCV, by interacting with viral proteins as part of a translational feedback mechanism similar to the translational control mechanisms found in bacteriophages. This would require stem-loop IV to melt before 40S ribosomal subunits could bind to the AUG and begin the process of translation.[277] In binding studies it was shown that core protein preferentially binds to oligonucleotides corresponding to the loop IIId domain of the 5′ UTR,[278] suggesting a possible site of interaction between the nucleocapsid and the genome. The La antigen has been shown to bind to the initiator AUG codon and to be a requirement for the initiation of translation, suggesting that La has a role in the selection of the AUG during the initiation of HCV polyprotein translation.[279]

40S ribosomal subunits form a stable pre-initiation complex with HCV IRES RNA without the requirement for initiation factors eIF3, eIF4A, eIF4B and eIF4F, which are required for cap mediated initiation in eukaryotes.[280] Chemical and enzymatic analysis of the structure of the IRES under physiological salt conditions shows that it folds into a unique three-dimensional structure in the absence of the translational apparatus and additional co-factors.[281] Analysis of the interaction of 40S ribosomal subunits with the HCV IRES by cryo-electron microscopy shows that domain IIId/e/f binds directly to 40S subunits; domain IIIb does not bind to to 40S subunits but is positioned such that it can bind eIF3; and domain II may be positioned in the E site of the 40S subunit such that it can facilitate the interaction of the 60S subunit with the 40S and initiate translation from the coding

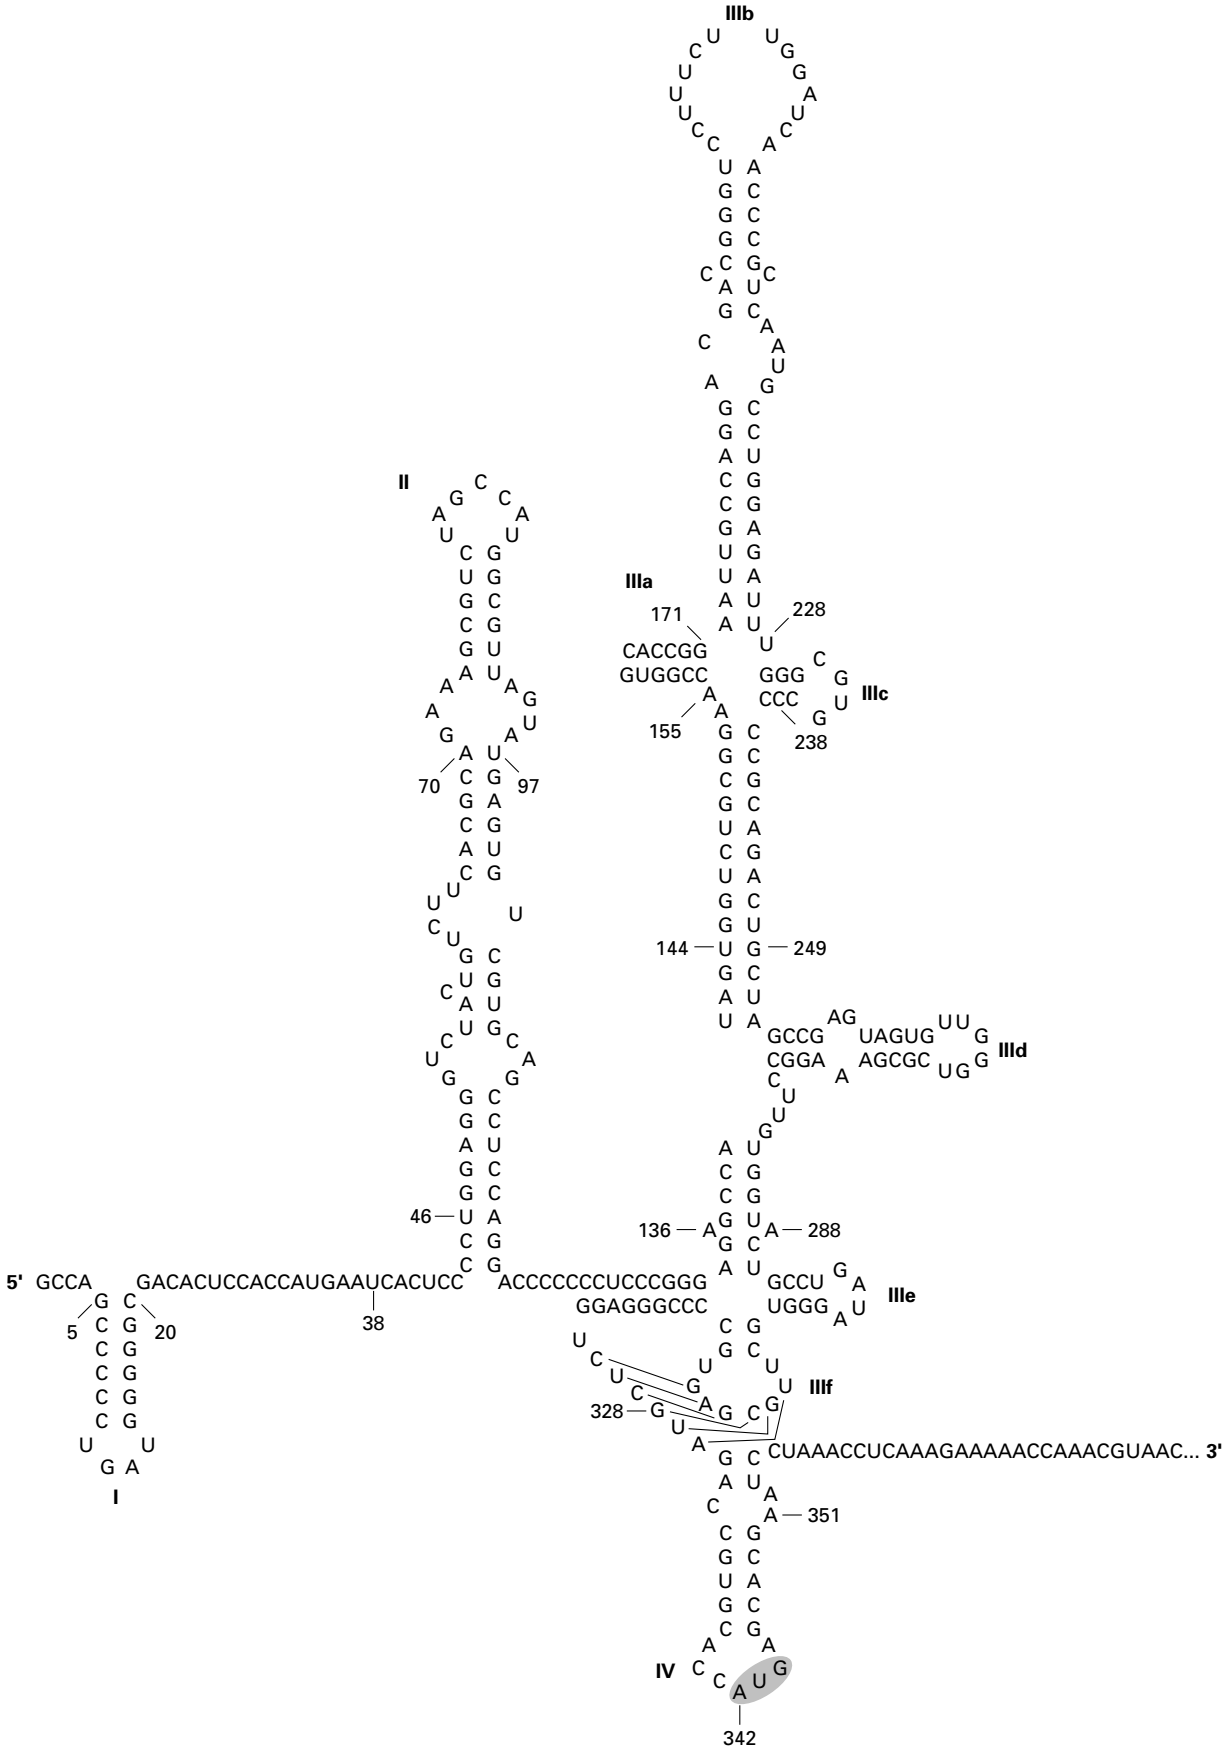

**Figure 24.3** Proposed secondary structure of the HCV RNA 5′ UTR. I–IV indicates the stem-loop domains. AUG (shaded) is the start codon of the polyprotein (after Honda *et al*.[268]). See text for a detailed discussion of the structure and function of the 5′ UTR.

sequence of the HCV genomic RNA.[282] Chemical and enzymatic modification analysis shows that domain IIIb and possibly domain IIIa binds to eIF3, and that domains IIIa/c/e/f all bind the 40S subunit with additional contacts between the 40S subunit and domains II and IV.[283] Cross-linking studies suggest that ribosomal proteins mediate the interaction of the 40S subunit with the IRES. In a UV cross-linking study ribosomal protein S5 could be linked to the IRES.[284] However, 4-thiouridine-mediated cross-linking linked several ribosomal proteins to the IRES, though not S5.[285]

Cultured lymphoblastoid cells inoculated with H77 serum led to the appearance of three substitutions, G107A, C204A and G243A, in the 5′ UTR,[286] all of which showed 2–2.5-fold greater translational activity in human lymphoblastoid cell lines compared with monocyte, granulocyte or hepatocyte cell lines or cell-free translation. The different translational efficiencies of quasi-species variants in different cell types from the same patient could help to explain why they are selected for in these different cells.[287,288] In RNA replicons, the first 125 nucleotides of the 5′ UTR are sufficient for RNA replication, but at a much lower level than when the intact 5′ UTR is present. Deletion of the 40 nucleotide sequence upstream of the IRES abolishes RNA replication, showing that sequences required for RNA replication also lie outside the IRES.[289] 5′ UTR sequences that had mutations in the first 43 nucleotides, and which also had compensatory mutations which preserved the stem-loop structure, were still functional in RNA replication.[290]

## The 3′ terminal UTR

The 3′ terminal untranslated region (3′ UTR) is located downstream of the stop codon terminating the large ORF encoding the viral polyprotein. The 3′ UTR comprises three structurally distinct RNA domains. From 5′ to 3′ these are: (1) an upstream variable region (VR) of about 40 nucleotides which varies considerably between different genotypes, (2) a long poly(U)-poly(U/UC) tract and (3) a 98 nucleotide (3′X) sequence which forms three stem-loop structures (SL1, SL2 and SL3) and terminates in a U residue and which is highly conserved between all HCV genotypes.[291–295] The 98 nucleotide 3′X sequence appears to be the authentic 3′ end of the genome and has been found in genomic RNA in serum and its complement has been found in anti-genomic RNA extracted from HCV-infected liver. Comparisons between the HCV 3′ UTR and those of flaviviruses and pestiviruses show little sequence homology. However, the 3′ UTRs of HCV and the GBV-B[9,292] appear to be similarly organized. The function of the 3′ UTR is not yet clear. It may play an important role in minus- and plus-strand RNA synthesis, in the packaging of viral RNAs or even in the regulation of protein translation. The highly conserved 3′X sequence may interact with viral or cellular proteins or RNA elements to initiate these processes. Mutational analysis and UV cross-linking showed that PTB binds to the pyrimidine-rich region of the 3′ UTR[296] and possibly to 3′X stem-loops 2 and 3.[295] A 35-kDa protein corresponding to heterogeneous nuclear ribonuclearprotein C (hnRNPC) was also shown to bind to this region.[296] In one study, the presence of a 3′X region which is capable of binding PTB has been shown to enhance the efficiency of translation from the HCV IRES three- to fivefold.[297] However, other studies have reported little effect of the 3′ UTR on IRES-mediated translation.[298,299] Infectivity studies in chimpanzees show that the 3′X sequence[300,301] and the poly(U/UC) sequences are essential. However, levels of virus replication similar to wild-type HCV were observed with a genome that had a 24 nucleotide deletion in the variable region.[300] RNA replicons that had the variable region deleted were able to replicate but at a much lower level. However, deletion of either the poly(U/UC) or the 3′X were not viable.[302,303] Full-length NS3 and the helicase domain of NS3 both bind specifically to the 3′ UTR, possibly as part of a replication complex. These proteins also bind to the 3′ UTR of negative-strand HCV RNA.[182]

## Replication models for HCV

PBMCs (peripheral blood mononuclear cells) from healthy donors were experimentally infected with HCV-positive sera, and using reverse transcriptase polymerase chain reaction (RT-PCR) it was reported that HCV negative-strand RNA was present in cells but not in cell culture supernatant.[304] However, highly stringent strand-specific RT-PCR, using a thermostable reverse transcriptase (rTth), detected negative-strand RNA in liver but not in PBMCs or other extrahepatic sites in HCV-infected chimpanzees and humans, indicating that HCV does replicate in liver but not in non-hepatic cells.[305] Similarly, there is uncertainty about many of the reports of HCV replicating in cell culture systems, e.g. HPBMa102-2, a human lymphocytic cell line,[286,306] Daudi cells, a human B-cell line[286] and the human T-cell leukaemia virus type 1-infected cell clone MT-2C,[307] as this very stringent rTth RT-PCR procedure for the detection of HCV negative-strand RNA was not used.

Primary chimpanzee hepatocytes were maintained in culture and it was shown that they could be infected with HCV *in vitro*.[308] Subsequently, RNA transcripts from full-length clones of HCV genotype 1a were found to be infectious after direct intrahepatic inoculation of chimpanzees.[309–312] An analysis of the sequences of HCV following the infection of chimpanzees by transcribed RNA from infectious cDNA clones indicates that the establishment of persistent infections is not due to changes in the HVR-1 region.[313] Serum from a chimpanzee infect-

ed after transfection with RNA from an infectious HCV cDNA clone was shown to be infectious when injected into a second naïve chimpanzee.[314] Similarly, virions derived from HepG2 cells transfected with full-length HCV RNA were also shown to be infectious in chimpanzees.[315]

The difficulties with chimpanzee-based models for HCV replication models mean that there is considerable interest in the development of alternative small animal models. Athymic nude mice which were implanted with human HCC from HCV-infected patients showed that HCV RNA was detectable in tumour cells as well as mouse liver and serum up to 42 days after the implant.[316] SCID mice carrying a plasminogen activator transgene (Alb-uPA) were engrafted with human hepatocytes which resulted in chimeric mouse-human livers. Following the inoculation of these mice with HCV-infected human sera, negative-strand HCV RNA and proteins could be detected in the chimeric liver nodules. Virus from these mice was shown to be capable of being serially passaged through three subsequent generations of mice with chimeric livers.[317] HCV-infected mice with chimeric human livers were infected with an adenovirus vector containing the gene for the BH3 interacting domain death agonist (BID), which had been modified to contain an NS3 cleavage site and consequently could be activated by the NS3-NS4A protease, thus triggering apoptosis. Mice with chimeric livers exhibited HCV-dependent apoptosis and showed a considerable decline in serum HCV titres after infection with the BID-expressing adenovirus.[318] A transgenic mouse which expresses the human poliovirus (PV) receptor was infected by chimeric PV/HCV in which the PV IRES was replaced by the HCV IRES. Chimeric PV/HCV virus replicates well in the liver but not in the brain, in contrast to control PV virus, which replicates in both of these tissues. This suggests that the tissue tropism of HCV may be partly determined by the activity of the IRES.[319] One report also suggests that tree shrews (*Tupia belangeri chinensis*) can be infected with HCV.[320]

Given its similarities to HCV, GBV-B may provide a surrogate model for HCV replication. Intrahepatic transfection of transcripts from a full-length GBV-B cDNA clone has also resulted in the development of severe hepatitis in tamarins. High viral titres were detected in these animals, indicating that GBV-B is a true hepatitis virus[321,322] and virions derived from the transfected animals could be transmitted to naïve tamarins.[322] Hepatocytes obtained from GBV-B-infected tamarins secreted virions and had high levels of cell associate RNA for up to 42 days in culture. NS3 protein could also be detected by immunofluorescence.[323] Infection of a tamarin has also resulted in a chronic infection.[324] GBV-B has been transmitted in marmosets and has also been shown to infect isolated marmoset primary hepatocytes.[325]

Subgenomic replicating HCV RNAs (RNA replicons) have become important cell-based models for HCV RNA replication. These were developed from full-length HCV genomes in which the sequence coding for core to p7 or from core to NS2 was replaced by a gene cassette which consisted of neomycin phosphotransferase (i.e. a 'neo' selectable marker and a downstream encephalocardiomyocarditis virus [EMCV] IRES). In this construct the neogene is translated under the control of the HCV IRES and the HCV NS proteins are translated under the control of the EMCV IRES. Huh7 cells transfected with RNA replicons are grown in culture medium which contains G418, which only allows the growth of cells lines that contain the replicating HCV RNA replicons.[326,327] It was originally thought that only Huh7 cells were able to allow the propagation of HCV RNA replicons, possibly indicating a requirement for essential human liver-specific 'factors'. However, more recently, subgenomic replicons have been shown to replicate in mouse hepatoma and non-hepatic human epithelial cells. This indicates that translation and RNA-directed RNA replication of HCV RNA do not depend on hepatocyte- or human-specific factors.[328,329] Fractionation and EM of NS proteins from RNA replicon cell lines showed that they were all associated with the ER. Morphological alterations of the ER in these cell lines, e.g. convoluted cisternae and paracrystalline structures, resemble alterations previously observed in liver biopsies of HCV-infected individuals and in flavivirus-infected cells (i.e. the membranous web).[330] Ribonuclear complexes (RCs) purified from these cell lines were shown to synthesize HCV replicon RNA *in vitro*. Replicative forms (RFs) and replicative intermediates (RIs) were synthesized from endogenous RNA templates and were shown to contain both minus- and plus-strand RNAs.[331] Pulse chase analysis showed that incorporation into ssRNA was chased into dsRNA, indicating that newly synthesized RNA could serve as a template for further rounds of RNA synthesis.[332] The activity of HCV synthesis was analyzed in digitonin-permeabilized replicon cells. It was shown that replication complexes were protected from access from nuclease and protease by membrane compartmentalization. It was also shown that only a small part of the NS proteins were resistant to protease action, suggesting that the majority of NS proteins do not form part of the compartmentalized replication complexes in replicon cells.[333]

## Heterogeneity of the HCV genome

There is substantial sequence variation in the HCV genome resulting from the lack of proofreading of NS5B RdRp and the subsequent accumulation of errors in replicating HCV genomic RNA. This means that, even in a single infected individual, the HCV genome does not exist as a homogeneous species. Rather, it exists as

a quasi-species of closely related but nevertheless heterogeneous genomes.[334] In addition, the process of host selection and adaptation of a rapidly mutating genome has led to the evolution of many distinct HCV genotypes. A large number of studies have been conducted on the phylogeny of HCV. Analyses of the 5′ terminal RNA sequence upstream of the large ORF indicated the existence of three main HCV types – 1, 2 and 3.[335] When the more variable NS3 and NS5 sequences of the ORF itself were included, HCV types 1 and 2 could be divided into subtypes a and b.[335] Comparison of the sequences of NS5 from around the world showed evidence of six major genotypes. These could be redivided into 11 different populations or subtypes.[336] In a different study, comparison of the E1 gene in 51 isolates from around the world showed that they could be divided into at least 12 genotypes.[337] To standardize the various systems that had developed in different laboratories, a new system for the nomenclature of HCV genotypes was proposed. Sequence comparisons were made between the NS5 region of HCV variants from a worldwide panel. The sequence similarities between members of different genotypes were 55–72%. Similarities between those within related subgroups ranged from 75% to 86% and individual isolates from each of the clusters showed 88% sequence similarity.[338,339] Six genotypes or clades (1, 2, 3, 4, 5, 6) with a variable number of subtypes (designated a, b, … etc.) for each of these genotypes were suggested, and this has now become the standard system for the nomenclature of HCV genotypes.[339] The core and E1 regions show similar ranges of sequence similarity, corresponding to those previously described for NS5. This indicates that there is little evidence for variants which are due to recombination between more than one genotype.[336] Sequence and genotyping studies indicate that the quite closely related subtypes, HCV-1a and HCV-1b, predominate in the USA and Japan, respectively, although less common types also occur in both countries.[335,340–348] In Europe, genotypes 1a, 1b, 2 and 3 and have been commonly observed.[334, 335,345–352] Type 4 HCV appears to predominate in Egypt and Zaire,[336] 1b, 2b and 2a in the Far East, 5a is the main genotype in South Africa, but was rarely seen elsewhere in the world.[358] While the average rate of change of the HCV genome within a single persistently infected individual has been estimated to be $1–2 \times 10^{-3}$ nt changes per site per year,[353–355] there is a much higher rate of change at the 5′ end of the E2 coding sequence.[353–356] This E2 hypervariable region (HVR-1) is the most variable region of the HCV polyprotein and is different in virtually every isolate studied so far.[350,357] The emergence of HVR-1 variants suggests that escape mutants in the HVR-1 region may play an important role in the development of chronicity.[358,359] Heteroduplex gel shift analysis was used to compare the quasi-species nature of sera from different patients. Analysis of the HVR-1 sequence obtained by PCR amplification showed that there were two kinds of quasi-species, simple quasi-species that had a homogenoeous gel shift profile and complex quasi-species that gave rise to multiple bands on gel shift analysis.[360] However, despite the high level of variability of the HVR-1, there are strong constraints which maintain similar physicochemical characteristics of HVR-1 from different genotypes.[112] The lack of patient response to IFN therapy has also been correlated with heterogeneity of the E2 HVR region,[361] which is consistent with the hypothesis that persistence of HCV is attributable to E2 HVR-1 escape mutants.[358] The HCV populations in chronically infected patients were shown to be composed of quasi-species of heterogeneous viruses with variations in the E2 HVR region. During IFN treatment some quasi-species disappeared and at the end of treatment reappeared, and a number of quasi-species which had originally been present as a minor fraction were selected.[362,363] Major changes in HVR-1 were also observed during treatment with IFN-α.[364] This indicates that there are differences in the sensitivity of different variants to IFN.
