# Chapter 25
# Epidemiology

Josep Quer, Juan I Esteban Mur

The hepatitis C virus (HCV) is one of the leading known causes of chronic liver disease. It is responsible for more than 50% of liver transplantation among adults in Western countries.[1] The prevalence of HCV infection averages around 3% of the world population, resulting in about 210 million HCV-infected persons (Table 25.1), nearly five times more than human immunodeficiency virus (HIV)-infected individuals. The main route of HCV transmission in the past was blood transfusion. The virus has been spread since the early 1960s, and incidence increased until the early 1980s, then levelled off and declined sharply in the 1990s after cloning of HCV in 1989 and subsequent development of sensitive antibody tests that allowed the universal screening of blood donors.[2] With the current safety of the blood supply, nosocomial transmission has become the predominant mode of health-care-associated spread of HCV.

Although universal screening of blood donors in developed countries and improvements in infection control measures following Centers for Disease Control and Prevention (CDC) guidelines have significantly decreased exposure to the virus,[3] which in the younger generations is confined to high-risk groups such as drug addicts,[4] the large reservoir of chronically infected individuals, the high evolutionary potential of the virus,[5–7] the lack of routine screening of donated blood in countries with developing or transitional economies, the use of traditional medicine and tattooing in some cultures, and the global expansion of the human population with increasing fluxes of immigration from endemic areas to less prevalent regions strongly support the hypothesis that HCV is still spreading throughout the world. In western countries, although the incidence of HCV infection may be decreasing, the prevalence of liver disease caused by HCV is on the rise.

## Transmission mechanisms and groups at risk for HCV infection

The routes of HCV transmission include **percutaneous** exposure to infected products (red blood transfusion, injection of blood derivatives, sharing needles and equipment), **nosocomial** (patient-to-patient during haemodialysis or other situations, patient to health-care worker by accidental needle-stick, health-care worker to patient after surgery), **non-apparent percutaneous modes** (tattooing, circumcision, ear and body piercing using inadequately sterilized equipment), **preventive health campaigns** (vaccination, microtransfusions in underweight newborns,[8] therapy for schistosomiasis under suboptimal hygienic conditions), **sexual** (in case of vaginal mucosa damage, multiple sexual partners and commercial sex workers) and **vertical transmission** (infants born to high viraemic HCV-positive mothers and

**Table 25.1** Estimated prevalence and number infected according to world population (2003)

*Averaging data from Table 25.4 of prevalence among the general population.

co-infected with HIV). HCV is not spread by breastfeeding, sneezing, hugging, coughing, food or water, sharing eating utensils, or casual contact.[9]

The predominant modes of transmission have changed over time and differ between and even within countries. Before implementation of blood testing for HCV, blood transfusion and intravenous drug use were the predominant modes of transmission in Eastern[10] and Western hemispheres.[11,12] Groups dependent on human blood products (haemophiliacs, haemodialyzed and polytransfused patients) have the highest prevalences. Nowadays, in economically developed countries, new HCV infections are mainly due to drug use, while in developing countries with high prevalence of HCV with all age groups affected, unsafe injections, folk and traditional medical procedures and contaminated medical equipment appear to be the major risk factors for acquiring HCV infection. Besides these major routes of HCV transmission, there is still a percentage of anti-HCV-positive patients (30–70% depending on the area), with undefined epidemiological risk factor. These patients probably acquired HCV by one of the rare and low prevalence but potential routes of transmission such as inapparent parenteral or permucosal exposures to HCV (e.g. surgical and dental procedures, tattooing, acupuncture, intranasal cocaine, perinatal, sexual, accidental needlestick, and household transmission).

## Parenteral transmission

The parenteral route of HCV transmission is responsible for one-third to two-thirds of hepatitis C cases and constitutes the most commonly recognized and best characterized transmission mechanism of HCV. Anti-HCV testing has largely confirmed that HCV is responsible for the vast majority of hepatitis cases in which transfusion of blood or blood components or obvious percutaneous exposure to blood is involved.[13] The incidence of HCV in some risk groups directly depends on the baseline prevalence of HCV in the general population, so that recipients of blood products obtained from a low prevalence area have a low incidence of infection.

### *Percutaneous transmission*

#### *Transfusion recipients*

Before the implementation of mandatory anti-HCV screening in 1990, there was a wide range of transfusion-associated hepatitis C (TAH-C) incidences in different geographic areas, ranging from 0.5% in England,[14] 1.1% in Australia,[15] 3–4% in the United States,[16] 7.7% in Japan,[17] 11% in Spain,[18] 12.5% in Taiwan,[19] to 13% in Greece.[20] As expected, patients requiring multiple transfusions have a high prevalence of HCV infection. Among more than 1000 transfusion-dependent Italian thalassaemic patients, 80% had confirmed anti-HCV,[21] as well as 47% of Egyptian thalassaemic children and 75% of multitransfused patients in long-term remission from leukaemia with evidence of liver disease.[22,23]

Screening of blood donors for anti-HCV drastically reduced the risk of HCV transmission to very low levels that were associated with the window period. The recent implementation of investigational NAT (nucleic acid technology) in small pools of blood donations has improved the safety of the blood supply by reducing the window period and this has practically eradicated TAH-C, so that transfusion of screened blood should no longer be considered a primary risk factor for HCV infection (Table 25.2). The current risk of a blood recipient becoming infected with HCV is extremely low (1:1 935 900 in the United States[24]) and is predicted to be reduced to 1:425 714 in Spain,[25] 1:747 058 in Italy[26] and 1:8 300 000 in France.[27]

**Table 25.2** Estimated current risk of transfusion-transmitted hepatitis C virus infection associated with the use of routine antibody or antibody plus nucleic acid technology testing, as compared to those for hepatitis B virus (HBV), human immunodeficiency virus (HIV) and human T-lymphotropic virus (HTLV)

| Viral agent | Incidence (/100 000 person-years) | Window period (days) | Risk per unit | | | |
|---|---|---|---|---|---|---|
| | | | United States | France | Italy | Spain |
| HBV | 1.267 | 45 | 1:640 000 | 1:470 000 | | 1:74 000 |
| HCV (Aby) | 1.889 | 70 | 1:276 000 | 1:860 000 | 1:127 000 | 1:149 000 |
| HCV (+NAT) | 1.889 | 10 | 1:1 935 900 | 1:8 300 000* | 1:747 058* | 1:425 714* |

| HIV (+NAT) | 1.554 | 11 | 1:2 135 000 | 1:2 700 000* | 1:870 000* | 1:1 026 000* |
| HTLV | 0.239 | 51 | 1:2 993 000 | Nil | | |

Aby, antibody test only; +NAT, antibody plus nucleic acid technology, i.e. TMA (transcription-mediated amplification) or PCR (polymerase chain reaction); Aby+Ag, antibody plus p24 antigen.

*Predicted residual risk after implementation of NAT in 2001.

*Plasma product recipients*

The prevalence of HCV among haemophiliacs correlates with the amount and type of product transfused. Most of all haemophiliacs exposed to untreated commercial clotting factor concentrates have evidence of HCV infection,[28–32] whereas among those treated with cryoprecipitates, the rate was 66%.[31] In contrast, haemophiliacs who have exclusively received appropriately inactivated coagulation components or single-donor cryoprecipitate are generally anti-HCV-negative.[29–33] Screening of plasma pools used to manufacture concentrates should eliminate the risk of infection.

Transmission of HCV by transfusion of a platelet concentrate made from an anti-HCV and HCV-PCR-negative blood donation means that not only the routine screening of plasma donors used to manufacture concentrates but a careful selection, quarantine of plasma and virus inactivation of plasma and its derivatives, remain as necessary as they were before the nucleic acid amplification test came into use.[34]

Intravenous immune globulin (IVIG) has excellent safety records. However, two outbreaks of HCV infection have been described in women given intramuscular[35] or intravenous[36] contaminated anti-D immunoglobulins in the late 1970s and also two major and three minor outbreaks of hepatitis C in agammaglobulinaemic patients treated with different products manufactured by the Cohn fractionation method from unscreened donor plasma have been described.[37] Ironically, in 1993 a major outbreak of hepatitis C in agammaglobulinaemic patients was caused by a commercial immune globulin (Gammagard) prepared from enzyme immunoassay (EIA)-2 screened plasma. But this was not the last case, and in 1996, there was an outbreak of HCV infection in the United States linked with the administration of Gammagard.[38] Addition of an inactivation step to plasma screening and recombinant clotting factor use have solved the problem, and no further cases have been detected with the new preparations.[39]

*Haemodialysis patients*

Among patients on maintenance haemodialysis, prevalence of HCV infection averages 20%, although there are wide geographical variations (Fig. 25.1) ranging from <5% in northern Europe[40] to 30–50% in Japan,[41–43] Poland,[44] 30.25% Saudi Arabia,[45,46] Bosnia-Herzegovina 43.51%,[47] Brazil 39%,[48] Taiwan,[49,50] and Egypt.[51] Prevalence between 5% and 30%, has been reported from the United States,[52,53] 23.3% in New York (USA),[54] India,[55,56] Hong Kong,[57] Western Europe,[3,58–61] Thailand[62] and 5% Kenya.[63] The high prevalence of HCV infection in haemodialysis patients has been attributed not only to the frequency of blood transfusion among these patients, but also to increasing years on dialysis, suggesting that HCV may be transmitted among patients in the dialysis unit, probably as a result of poor infection control practices.[3,40,64,65] Comparison of HCV spread between two dialysis units in southern Sweden revealed that in one unit, there was no evidence of spread within the unit, and that the prevalence of HCV was dependent on the status of the patients entering for treatment. In the other unit, 36% of patients were infected during a 3-year period, including patients who had not received blood transfusions.[66] Outbreaks of HCV infection in dialysis units have also been attributed to poor infection control practices.[64] Finally, molecular epidemiology analysis of haemodialysis patients treated in an Italian unit with a high prevalence of HCV infection strongly suggested nosocomial spread of HCV genotype 4 within the unit.[67] In contrast, no seroconversions were found in a study in which anti-HCV-positive and anti-HCV-negative patients shared the same machines in a haemodialysis unit when universal precautions were rigorously applied.[68]

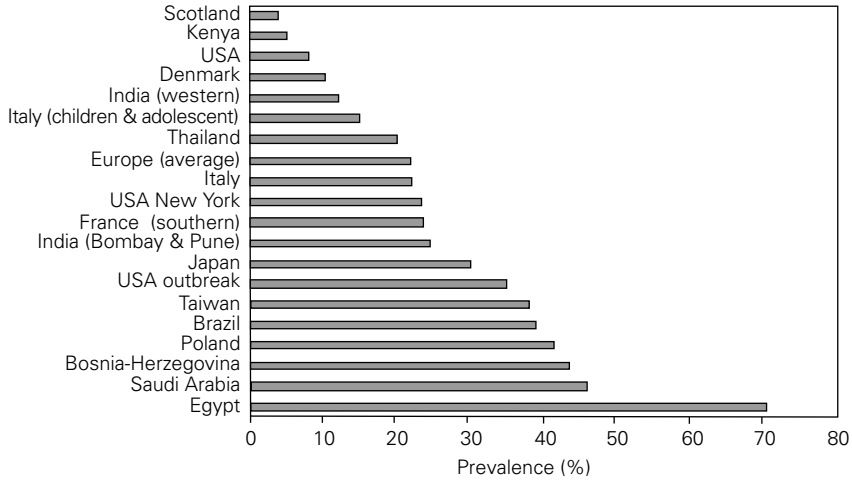

**Figure 25.1** Worldwide prevalence of HCV infection among haemodialysis patients

*Organ transplantation*

Organ transplant recipients are at high risk of acquiring HCV infection.[69] Infection in this setting can occur as a result of recurrence of HCV infection already present before transplantation, transfusion-associated transmission during transplantation, or the presence of HCV infection in the organ donor.[70,71] Antibody tests may underestimate the incidence of transmission and the prevalence of HCV infection among immunosuppressed organ recipients.[70] Hence, HCV RNA testing may be required to detect those patients who lose or do not develop HCV antibodies.[72–74]

The risk of transfusion-associated infection has dramatically decreased with the increased safety of the blood supply. In one study conducted between 1987 and 1991,[75] 14% of patients undergoing allogenic bone marrow transplantation developed HCV infection, but this rate fell to 1.6% after implementation of blood donor screening for anti-HCV.

The risk of transmission from an anti-HCV-positive organ donor to a seronegative recipient is very high. In some studies, 90–100% of recipients of kidneys, liver or heart from HCV-infected donors acquired HCV infection after transplantation.[69,70] In other studies,[76,77] infection rates have been reported to be much lower (approximately 50–60%). It is unknown whether differences in procurement or organ preservation techniques might account for these different transmission rates. Recurrence of HCV infection in the grafted organ after liver transplantation is the rule.[78–83]

### *Nosocomial transmission*

Previous hospitalization is an epidemiological risk factor in patients with HCV infection.[4,84] Because the prevalence of HCV infection among hospitalized patients is rather high (between 2% and 20% depending on the patient setting),[11] nosocomial transmission is likely if disinfection procedures are inadequate and contaminated equipment is shared between patients. In fact, nosocomial transmission may account for a substantial proportion of HCV infection among patients lacking a history of transfusion or other obvious parenteral exposure to HCV (see below). Patient-to-patient transmission has been implicated in outbreaks of HCV infection in a haematology ward[85] and in a paediatric oncology unit. Surgeon-to-patient transmission of HCV during cardiac surgery has been documented.[86] Transmission from a patient to an anaesthesiology assistant and from this to five patients has been reported recently.[87] The risk of transmission from an HCV-infected orthopaedic surgeon to patients is 0.48% (1/207),[88] but only 0.04% (1/2286) from gynaecologist to patient by caesarean.[89] It is likely that with the dramatic decrease of transfusion-associated hepatitis C, nosocomial transmission, albeit infrequent, will become the predominant mode of health-care-associated spread of HCV.

### *Intravenous drug use*

Intravenous drug addiction carries an extremely high risk of HCV infection. The prevalence of HCV among groups of intravenous drug users (IDUs) in all European Union countries ranged from 30% to 98%, with an incidence rate of 6.2–39.2 per 100 person-years.[90,91] Study data from the CDC showed that from 1986 to 1988, drug abuse was responsible for 42% of cases of acute hepatitis C acquired in the community,[92] and global studies have found anti-HCV in 70–90% of IDUs.[93] HCV infection occurs quickly after initiation of injecting illicit drugs, with higher risk for those injecting heroin than amphetamines. Infection during the first year of intravenous habit has been also reported in a study among prison inmates.[94] Recently, it has been reported that the shared use of drug injection paraphernalia other than syringes such as 'cookers' or cotton filters may be an important cause of HCV transmission between IDUs.[95]

## Non-apparent parenteral transmission

### *Tattooing*

Tattoos have been involved in HCV transmission.[96,97] In a Taiwanese study, 12.6% of 87 tattooed healthy young men without other risk factors were found to be anti-HCV-positive as compared with 2.4% of 126 matched control subjects. Tattooing has been epidemiologically linked to HCV infection in Australia.[98] Not exceptionally, tattoos are surrogate indicators of unconfessed intravenous drug abuse.

### *Acupuncture*

Acupuncture can be a potential risk factor when improperly sterilized needles are used by an inexperienced acupuncturist. Acupuncture has been associated with an increased risk of HCV infection among Korean adults with chronic liver disease.[99]

### *Health-care workers*

Transmission of HCV from infected patients to health-care workers has been documented,[100] and molecular evolutionary analysis has confirmed this mode of transmission.[101] Hollow-bore needle-stick exposures are the main cause of HCV transmission from patient to health-care worker.[39] In this sense, no seroconversions were detected after 105 accidental injuries caused by suture needles or sharp objects as compared with 1.2% after 331

needle-stick injuries involving hollow-bore needles.[102] Prospective studies have shown that the average risk of infection after a needle-stick injury involving HCV-positive blood may be as high as 3% with a range between 0.013% and 10% in different studies.[89,102–107] On the other hand, mucous membrane or skin contamination have not been associated with an increased risk of HCV infection.

Reported prevalence among general health-care workers in the UK has ranged between 0.3% and 0.7%,[108] 0.8% in Germany,[109] 1.8% in Spain,[110] 1.97–2% in Italy[105,111] and 2.7% in Hungary.[112] Hence, the prevalence of HCV infection among health-care workers appears to correlate with that of the general population or the specific high-risk group they serve, as well as the risk of accidental percutaneous injuries associated with a specific type of care.

## Non-parenteral transmission

### *Maternal–infant transmission*

Vertical (mother-to-infant) transmission of HCV is uncommon. The prevalence of HCV-infected pregnant women is 0.1–2.4%, which is no different to that in the general age-matched population, although this value is higher in countries such as Cameroon (5.5–6.0%) and in DR Congo (4.3%) in which prevalence in blood donors is higher. From 60% to 70% of HCV-infected pregnant women have active infection with viraemia. Transmission of HCV occurs only when serum HCV RNA is above $10^6$ copies per mL. The global rate of vertical transmission is 4–7% per pregnancy. Co-infection with HIV increases the rate of transmission four- to fivefold. When or how mother-to-infant transmission of HCV occurs remains unknown, and there is the possibility of *in utero* infection and/or at the time of delivery. However, currently available data do not allow the recommendation of routine use of caesarean section for women with chronic hepatitis C unless there is HIV co-infection.[113] Breastfeeding carries no further risk of transmission.[73,113,114,115]

### *Sexual and household transmission*

Sexual transmission of HCV is still a controversial issue. However, evidence from studies of regular partners of HCV-infected patients[116] and direct evidence from particular cases[117,118] has shown that there is a small but definite risk of sexual transmission of HCV, and sexual transmission of HCV from a chronic patient to his sex partner after removal of an intrauterine device has recently been reported.[119] Sexual transmission of HCV has been shown to be extremely uncommon and it has been related to duration of the relationship, which implies that HCV transmission may be more likely to occur if the exposure is repetitive and extends over time. A possible reason for this low risk could be the presence of HCV RNA in semen at a very low level (<200 copies/mL).[120,121] It has been reported that the annual risk of inter-spousal transmission of HCV infection is extremely low (0.23% per year).[122] Damage of the vaginal mucosal might favour transmission, so in this case the use of barrier precautions is recommended despite the fact that the use of latex condoms is not currently recomended for stable monogamous sexual partners. Sexual partners of chronically infected individuals should not be accepted for blood donation. In this sense, it has been reported that lymphocytes from around 25% of seronegative spouses from HCV-infected patients proliferate in the presence of at least one HCV antigen.[123] This has raised the question as to how many spouses, despite being infected by a very small inoculum of virus, have been able to induce an effective lymphocyte immune response that generates a perdurable memory without any other sign of previous infection (anti-HCV- and HCV RNA-negative).

The pooled prevalence of anti-HCV among siblings and household contacts of patients with chronic liver disease was 4% compared with 0% among contacts of anti-HCV-negative controls. The pooled prevalence of anti-HCV among offspring of Japanese HCV-infected chronic liver disease patients was 17% compared with 10.4% of controls.[116] Hence, evidence exists that familiar, non-sexual and sexual transmission of HCV does occur.

### *Non-injecting drug users*

The prevalence of HCV among non-injecting drug users is higher than in the general population (4.7% in New York, USA). Recently, it has been suggested that sniffing or snorting heroin in combination with cocaine may increase the risk of HCV infection among non-injecting drug users.[124]

### *Sporadic hepatitis*

Acute hepatitis C with no apparent risk factor continues to occur. The mechanism of transmission of sporadic hepatitis C cases is possibly a combination of intravenous drug use, which is not revealed in the history, non-apparent or covert, nosocomial, percutaneous exposure, non-percutaneous mechanisms including sexual transmission, and perhaps as yet unidentified modes of virus dissemination. Recently, cocaine snorting has been suggested as a significant risk factor for HCV infection when it involves sharing of blood-contaminated straws.[125]

## Prevalence of HCV infection among blood donors and the general population

Global prevalence of HCV infection in blood donors is summarized in Plate 25.1 (found between p.786–7) and Table 25.3,[11,46,62,84,93,126–192] while prevalence in the general population is shown in Plate 25.2 (found between p.786–7) and Table 25.4. [28,43,126–128,130,135,138,155,161,167,174,178,184,190,193–269]

Low and moderate prevalence (0.3–2.5%) are predominant in the world map of blood donors cohort (Plate 25.1). Very low prevalence (<0.3%) has been reported in some areas of northern and central Europe, parts of the United States, Jamaica in Central America, New Zealand in Oceania, some countries in southern Africa such as Zambia, Zimbabwe and South Africa, and also in Asian countries such as Yemen, Iran and parts of Japan. High prevalence (2.5–5%) has been reported in some areas of Brazil (Rio de Janeiro), some countries in Central Africa such as Guinea, Togo, Chad, Rwanda, Burundi, parts of Nigeria, and in Asia in studies reported from the city of Jeddah in Saudi Arabia and in Harbin (China). Very high prevalence (5–10%) has been found particularly in countries in Africa, such as Nigeria, Cameroon, CAR and Tanzania, but also in some areas such as north-eastern Thailand, in the city of Beijing (China), Soqotran Island in Yemen and also in the Latina province in Italy. Extremely high prevalence (>10%) has been reported in Egypt (13.6–24.8%), Jakarta in Indonesia (24.3%), in the city of Ho Chi Minh in Vietnam (20.6%) and in Nigeria (12.3%), due to specific human interventions such as the parenteral therapy for schistosomiasis in Egypt,[270] or the poor sanitary conditions in Ho Chi Minh during and after the war, or the association between dental care and recombinant immunoblot assay (RIBA) positivity in Latina province in Italy.

gp, general population.

Confirmed anti-HCV-positive blood donors have a history of overt percutaneous exposure to blood (transfusion, intravenous drug abuse, tattooing, or occupational needle-stick exposure) in 30–75% of the cases, this antecedent being higher in areas with a lower prevalence of HCV infection..[93,99,136,271–273] Other factors significantly associated with HCV infection include a prior history of major surgery, the use of non-disposable needles, a history of tuberculosis or prolonged hospitalization before 1970 in older people, and the sharing of straws for cocaine snorting,[4,84,124,125] and certain folk remedies and customs in specific hyperendemic areas.[274–276] The use of paid instead of volunteer blood donations has been implicated as the cause of very high prevalences of HCV in some hyperendemic areas.[43,277,278] The lack of HCV infection, but not of hepatitis B, D or E virus infection, among Amerindian populations[209,279–281] traditionally excluded from any health-care system further supports the proposition that health-care-related covert parenteral exposures may have been an important mechanism of HCV spread in the developed world in the recent past. For instance, the indigenous tribe Parakana (Brazil) had no HCV infection during the first years in which they initiated outside contact in the 1970s and 1980s, but currently Parakana people have a prevalence of 1.4–1.6%.[281]

Because the selection of regular volunteer blood donors (and, to a lesser extent, first-time donors) generally excludes high-risk subjects for blood-borne infections or individuals with surrogate markers for such infections, the extent to which prevalence among blood donors can be extrapolated to the general population remains controversial, because: (1) prevalence among blood donors markedly increases with age and is slightly higher in men than in women;[84,136] (2) changes in blood donor recruitment policies may render data on first-time donors unreliable for extrapolation of prevalence to the general population; (3) prevalence studies in non-donor populations are scarce and usually limited to particular groups such as pregnant women or military recruits, which are biased by age and/or sex preselection or are restricted to small isolated peculiar populations; and (4) different geographical areas or specific populations within the same country may have widely different prevalence rates because of peculiar modes of covert percutaneous exposure. Despite these limitations, however, blood donors seem to have an overall prevalence 25–50% lower than the corresponding general population, which is represented in Plate 25.2 (found between p.786–7) and Table 25.4.

The overall prevalence of HCV among the general population (Table 25.4) reported for each continent gives medium values of 5.17% in Africa, 3.55% in Asia, 1.93% in America, 1.75% in Europe and 1.88% in Oceania. These data give a global prevalence of 2.856%, and this means that around 210 million people are infected by HCV.

## Summary

At least 210 million people are infected by HCV. New human practices together with global expansion of the human population have increased its spread over the world during the last decades. The most important routes of HCV transmission have been parenteral, including administration of therapeutic blood products (transfusion, plasma derivatives for haemophiliacs, immunoglobulin concentrates), intravenous drug use, and nosocomial transmission from patient to patient as in haemodialysis, patient to health-care worker after accidental needle-stick, and health-care worker to patient during surgery or other invasive procedures.

Screening of blood products has almost eradicated transfusion-associated hepatitis C, and transfusion of screened blood should no longer be considered a primary risk factor for HCV infection. In addition, the adoption of efficient inactivation steps in the manufacturing of plasma products has drastically reduced the risk of transmission to haemophiliacs or patients receiving immunoglobulin preparations.

Intravenous drug use continues to carry a high risk of HCV infection, and educational efforts to prevent sharing of drug paraphernalia along with appropriate rehabilitation programmes are the cornerstones of efforts to decrease or eliminate such transmission. Poor infection control practices are suggested as the major cause of transmission within haemodialysis units. With the current safety of the blood supply, nosocomial transmission has become the predominant mode of health-care-associated spread of HCV. Other parenteral routes of HCV transmission that deserve consideration are tattooing and acupuncture when improperly sterilized equipment is used.

The risk of perinatal transmission is very low, although concomitant HIV infection or high viral load in the mother appear to increase the risk. Household transmission may be related to covert percutaneous exposure during health care, folk medicine, exposure to non-disposable sharps and needles, and dental care. Sexual transmission remains controversial, but evidence exists from particular cases and, despite the fact that infection has been considered extremely uncommon, damage of the vaginal mucosa might favour transmission. Evidence of transmission to sexual partners of chronically infected individuals has also been reported, and this has opened the question as to how many spouses have been able to induce an effective lymphocyte immune response that generates durable memory without any other sign of previous infection.

Although the incidence of HCV infection may be decreasing, especially in Western countries, the prevalence of liver disease caused by HCV is on the rise due to the lag (20 years or longer) between onset of infection and clinical manifestation of liver diseases. Improvements in more effective and globally available treatments will help reduce or elongate the period of chronicity and the number of patients requiring liver transplants, which has increased significantly during the last decade. Although the incidence of HCV infection may be decreasing, the prevalence of liver disease caused by HCV is on the rise.[282]

# Chapter 26
# The immune response to hepatitis C virus in acute and chronic infection

Khadija Iken, Margaret J Koziel

Hepatitis C virus (HCV) infection has been increasingly recognized as a major cause of chronic hepatitis, liver cirrhosis and hepatocellular carcinoma (HCC) worldwide. In the United States, it is estimated that the virus infects approximately 1.8% of the population, and worldwide it may infect up to 177 million persons. Following infection, a majority (50–85%) of healthy adults will develop persistent infection. This high rate of persistent infection has hindered the ability to determine the correlates of protective immunity, although recent studies have demonstrated the importance of cellular immune responses in spontaneous clearance of HCV. In immunocompetent individuals, chronic active hepatitis, cirrhosis and HCC typically develop 10, 21 and 29 years after infection, respectively. It is estimated that the number of individuals who have been infected for more than 20 years, thus facing the highest risk of liver cancer, will triple by the year 2010.[1] In fact, a recent study predicted a dramatic rise in the death rate due to HCC in the next two to three decades.[2] However, the likelihood of progression of chronic disease is highly variable, and identification of the host and viral factors that are associated with slow compared to rapid progressors is another area of intense interest.

## Mechanisms of clearance

Determining the correlates of protective immunity in hepatitis C has been limited by several issues. First, the subclinical nature of acute hepatitis C renders prospective studies difficult, especially as studies of cellular immunity require either studies to be done with freshly isolated cells or on large numbers of cells, both of which are difficult to obtain in retrospective studies. Second, there is no small animal model for hepatitis C infection, and use of the chimpanzee model is limited because of the expense and limited availability of these animals (see Chapter 27). Finally, especially in chronic infection, responses are of low magnitude in the peripheral blood, which requires special techniques to identify the cells. Despite these obstacles, a number of recent studies have enhanced our understanding of the immune response that is associated with spontaneous recovery from hepatitis C.

### The role of humoral immunity

Unlike hepatitis B virus (HBV) infection, where antibody against hepatitis B surface antigen (anti-HBsAg) is necessary and sufficient for protection against infection, a role for antibodies in protection against natural HCV infection has been difficult to prove. The first detectable antibody responses against HCV antigens usually target non-structural (NS) protein 3 (NS3; anti-c33) and core (anti-22c) regions of the polyprotein. Later, responses against NS4 and envelope proteins (E1 and E2) develop.[3] Studies in infected humans have failed to identify an antibody reactivity pattern that clearly discriminates individuals with spontaneous recovery from those who go on to chronic infection.[4] An IgM antibody occurs in some individuals with acute hepatitis C but does not appear to predict outcome.[5]

Measurement of the ability of any given antibody to neutralize HCV infectivity is further compromised because of the lack of a robust tissue culture system. One surrogate for a true infectious tissue culture system is the use of pseudotyped viruses, which are chimeric viruses consisting of the replication machinery of one virus, such as human immunodeficiency virus (HIV) or vesicular stomatitis virus (VSV), with the envelope(s) of HCV. Using these chimeric viruses, several laboratories have demonstrated that neutralizing antibodies can be detected that prevent binding of envelope proteins to target cells.[6–9] Direct evidence for a protective role of HCV-specific antibodies derives from limited *in vivo* studies in which chimpanzees were protected against infection with an HCV inoculum that was first incubated with HCV-specific antibodies *in vitro*.[10] However, several investigators have also observed that circulating HCV-specific antibodies do not prevent reinfection of chimpanzees with either homologous or heterologous

isolates.[11,12] Furthermore, antibody responses to the envelope proteins develop slowly, achieve only modest titres and tend to be short-lived, suggesting that neutralizing antibodies may emerge too late or may not be strong enough to prevent chronic infection.[4] However, the chimpanzee model may be suboptimal for evaluation of the effect of antibody neutralization. While the humoral immune response to the non-structural HCV proteins appears to be similar in humans and chimpanzees, antibody responses to HCV structural proteins are observed less frequently in chimpanzees than in humans for reasons not understood.[13] As these proteins would be expected to serve as major targets of a neutralizing antibody response, failure of chimpanzees to develop such responses makes interpretation of preclinical studies of vaccine efficacy difficult in this model. Despite these limitations, a recent pilot study using recombinant anti-E1 antibody demonstrated improvement or stabilization of liver histology.[14]

## The role of cellular immunity

Effective clearance of an acute viral infection typically requires the coordinated function of multiple arms of the immune system, including the innate immune system – interferons (IFNs) and natural killer (NK) and natural killer T (NKT) cells – as well as the adaptive or acquired immune response specific to a given pathogen (CD4+ and CD8+ T cells) (Fig. 26.1). The exact importance of each arm of the immune response is typically dependent on the pathogen. The liver has a larger proportion of cells representative of components of innate immunity, such as NK, γδ T and NKT cells than the peripheral blood.[15,16] There is a relative paucity of literature on these cells in HCV despite their abundance within the hepatic lymphoid system. NK and NKT cells are the major components of innate immunity, and mount the first line of defence within minutes or hours against a number of pathogens by both direct cytolysis of infected cells and production of cytokines such as IFN-γ and interleukin (IL)-12, which have direct and indirect effects on viral replication. The early production of IFN-γ by these cells not only has antiviral effects but also mediates the intrahepatic recruitment of inflammatory cells.[17] These responses are activated within minutes to hours of infection, and so there is very limited information on the role of these responses in acutely infected persons. A single report in the chimpanzee model suggests that clearance of HCV is not dependent on the development of virus-specific CD4+ or CD8+ T cells, but rather upon the development of innate immunity, as measured by phenotypic markers of NK cells.[18] Similarly, although NKT cells have been demonstrated to be important in the clearance of HBV in animal models[19,20] there are no data for animal or human HCV infection.

## CD4+ T cells

CD4+ T cells recognize short antigenic peptides derived from proteolytic cleavage of exogenous antigen in the antigen-binding groove human leukocycle antigen (HLA) class II molecules, which are present on the surface of antigen-presenting cells such as dendritic cells, macrophages and B cells. HLA class II-restricted, antigen-specific CD4+ T cells orchestrate the effector immune response and are broadly divided into two main

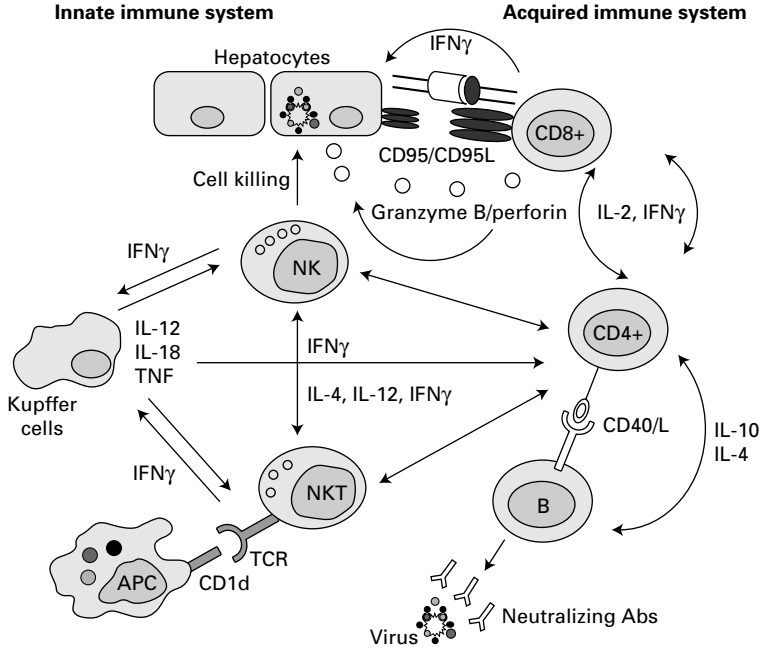

**Figure 26.1** The relationship of the innate and adaptive immune response to viral infection. Infection of hepatocytes by a viral infection leads to activation of natural killer (NK) cells, natural killer T (NKT)) and resident macrophages, which can act as antigen-presenting cells (APCs). Production of cytokines such as interferon-γ (IFN-γ) and interleukin (IL)-12 lead to activation of CD4+ T cells, which in turn direct CD8+ T cells. These CD8+ T cells play a critical role in controlling viral replication through both cytolysis of infected cells and production of cytokines.

categories called T-helper type 1 (Th1) and T-helper type 2 (Th2). Th1 cells produce IFN-γ and IL-2, and are essential for protection against a variety of intracellular infections by promoting cytotoxic T lymphocyte (CTL) activity, whereas Th2 cells produce IL-4, IL-5 and IL-10 and promote antibody responses. CD4+ responses are critical to both the generation and maintenance of antiviral immune responses, as they secrete cytokines that augment antibody production by B cells and prime CD8+ cells specific for virus-infected cells. Without CD4+ cells, induction of new immune responses is impaired and CTL memory cannot be maintained *in vivo*.[21,22]

In both experimental chimpanzee and natural human infection, clearance of hepatitis C is associated with a strong, polyclonal and sustained HCV-specific CD4+ T-cell response.[23–30] The appearance of these CD4+ T-cell responses is temporarily associated with a substantial decrease in viraemia in acute infection of the chimpanzee, and in this model the accumulation of HCV-specific $CD4^+$ T cells in the liver appears to be essential for clearance of HCV.[26,28,30] Individuals who mount a polyclonal HCV-specific CD4+ are more likely to clear HCV, whereas individuals who do not are more likely to become persistently infected.[25,29,31,32] Similarly, in infected persons who go on to resolve hepatitis spontaneously, the clearance of virus is associated with the development of a polyclonal CD4+ response.[24,25,33,34] In humans, CD4+ T-cell responses associated with viral clearance are targeted toward the non-structural proteins, although this may be a reflection of the technical limitations of expressing more highly variable proteins for use in *in vitro* assays.[24,25,33] Strong and multispecific responses of Th1 type directed to structural and non-structural HCV antigens were found to persist in most patients with spontaneous resolution of HCV infections, even when measured 8–17 years after the time of first exposure to the virus.[27] Loss of HCV-specific CD4+ during the initial months of infection is associated with relapse of viraemia,[34] whereas enhancement of CD4+ responses is associated with a higher likelihood of viral clearance after treatment.[35] The kinetics of this response appear to be important, as individuals who clear HCV infection have a more rapid and sustained induction of CD4+ responses than those who develop persistent disease.[36]

## CD8+ T cells

The function of CD8+ CTL requires the interaction of the polymorphic T-cell receptor (TCR) with MHC class I molecules displaying an endogenously synthesized peptide of 8–11 residues on the cell surface of infected cells. The effector function of CTLs consists both of cytolysis of infected cells and production of cytokines, such as tumour necrosis factor (TNF)-α and IFN-γ, that lead to viral clearance.[37,38] The importance of these non-cytolytic effector mechanisms has been shown for HIV and HBV,[39–41] although direct evidence in HCV is lacking. CTLs use two major pathways to eliminate infected cells, perforin Grangyme B and Fas:FasL. *In vitro*, HCV-specific CTLs appear to use both effector mechanisms,[42] although it is not known whether both pathways are operative *in vivo.*

As with the CD4+ response, polyclonal and multi-specific CD8+ CTL responses are also associated with spontaneous clearance in both chimpanzee[24,28,43,44] and human infection.[36,45,46] In the chimpanzee model, resolution of acute HCV was temporally associated with an early polyclonal and vigorous immune response in the liver.[43] Animals who recovered were found to have an early intrahepatic CTL response directed against multiple protein targets, whereas those who went on to chronic infection had a more narrowly focused response during acute infection. HCV-specific IFN-γ-secreting CD8+ T cells are abundant in recovered chimpanzees in comparison with those with chronic infection.[26,47] In animals that recover, protection from reinfection is maintained by the presence of memory CD8+ T cells, as depletion of these memory CD8+ prior to rechallenge resulted in reinfection in previously recovered animals.[44] The importance of the CD4+ memory response in maintaining an effective CD8+ response was demonstrated by Grakoui *et al*., who found that depletion of CD4+ T cells in light of existing memory CD8+ was associated with viral persistence and immune escape.[21]

Prospective studies of the CD8+ response in humans are limited by the low frequency of such responses in the peripheral blood, which requires that large amounts of blood be collected or that sophisticated techniques be applied in freshly collected blood. Therefore, studies to date have either been performed retrospectively, or if prospective, have studied only a few patients. These studies have shown that while CD8+ responses are generated in the majority of acutely infected persons, irrespective of outcome, the distinguishing feature of spontaneous recovery is the ability to maintain such responses over time.[27,46,48,49] The development of newer and more sensitive techniques, such as class I tetramers, which detect CD8+ T cells specific for a peptide epitope, and ELISpot assays, which can detect antigen-specific cells by virtue of their secreted cytokines in response to specific antigen, have provided further tools with which we can more efficiently measure the effectiveness of the early CTL responses.[50] Gruner *et al*. have demonstrated, using ELISpot techniques, a significant CD8+ T-cell response directed against multiple class I-restricted HCV epitopes of structural and non-structural regions of the HCV polyprotein, the appearance of which correlates with elimination of the virus.[45] The frequency reported by Gruner in the peripheral blood of individuals with acute HCV was 0.2% of total CD8+ T cells. Significant

proliferative responses of CD4+ T cells to NS3 and NS4 proteins accompanied the CTL responses and were maintained in those patients with resolving infection.[46] Lechner *et al*., using a combination of class I tetramer staining and ELISpot techniques, have also demonstrated that the successful eradication of HCV is associated with a peripheral blood CTL frequency of >7% at the peak of clinical illness, which is similar to that noted for infectious mononucleosis, and that this CTL response was simultaneously directed against eight different epitopes.[49] This frequency of CTLs contrasts with the low levels (0.07%) found in the peripheral blood of those individuals with chronic infection.[45,51] Taken together, these chimpanzee and human studies suggest that the presence of a broadly directed CTL response is associated with viral clearance.

## Mechanisms of chronicity in hepatitis C infection

Failure to eradicate HCV infection results in the development of chronic HCV infection with resultant chronic hepatitis, after which a significant proportion of individuals will develop cirrhosis and HCC. The mechanism by which chronic HCV infection develops and persists in the majority of infected persons remains unclear, but it does so despite the presence of HCV-specific CD4+ and CD8+ T-cell responses in the peripheral blood and the liver, suggesting that these responses are ineffective for the most part.[52–56] It is likely that HCV has developed a number of means to evade host defences, although most literature has focused on the role of quasi-species variability as a mechanism of immune escape. However, a number of other potential mechanisms have been reported, suggesting that there are multiple means by which this virus interferes with an effective immune response.

### Evasion of the immune response by quasi-species variation

The high degree of genetic variability of HCV probably is a major contributing factor to the development of chronicity. There are six major genotypes, multiple subtypes, and even in a single infected individual multiple strains can be isolated (see Chapter 24, Structure and molecular virology of HCV). The combination of a very high HCV replication rate, estimated at $10^{12}$ virions per day,[57] and the rapidity of viral replication and the lack of error proofing of the viral polymerase[58] probably account for the fact that the HCV RNA genome mutates frequently and appears to favour the selection of variant viruses, which escape recognition by humoral and cellular immune responses. The hypervariable region 1 (HVR1) of E2, in particular, appears to be a region which can mutate in response to immune pressure.[59] Although other B-cell epitopes exist,[60–62] most studies on escape from humoral immune responses have focused on the HVR1 region due to the highly variable nature of this region and its presumed role in binding to cellular receptors.[63] Whereas other regions of the genome develop both synonymous and non-synonymous mutations, the HVR region tends to have preferential accumulation of non-synonymous mutations.[64] In acute HCV infection, resolution of disease is associated with relative homogeneity of the envelope proteins, whereas progressive hepatitis was associated with genetic evolution of the quasi-species, which was temporally associated with the development of antibodies against the HVR1.[65] In patients with depressed humoral immunity, the rate of HVR1 evolution is less than in patients with normal humoral immunity.[66] Similarly, patients with severe recurrence of HCV after orthotopic liver transplantation tend to have a relatively homogeneous population compared with those with less severe recurrence of disease.[67]

### Mutations in CD4+ and CTL epitopes

Given the apparent critical importance of the cellular immune response to spontaneous recovery, several studies have focused on whether or not HCV can escape cellular immune responses. Mutations of MHC class I- or II- restricted epitopes could alter the outcome of infection by preventing, or delaying, clearance of infected hepatocytes by T cells. Mutations leading to abrogation of alteration of CD4+ and CD8+ function have been described. Sequence variants within NS3 have been reported to be associated with failure of clones specific for one viral sequence to proliferate and produce IL-2 upon stimulation with sequence variants.[68] Moreover, variants of the hypervariable region (HVR1) of the putative envelope 2 protein of HCV can act as powerful TCR antagonists for HVR1-specific CD4+ T cells isolated from HCV-infected individuals.[69] Naturally occurring variants can also significantly alter CD4+ function through alteration in cytokines produced upon recognition of variant sequences. In at least one report, sequence variants led to a Th1 to Th2 switch.[70,71] Amino acid substitutions that inhibit CD8+ CTL recognition have been observed in chimpanzees,[72,73] as well as in infected patients.[74–76] In acutely infected chimpanzees, comparison of the viral quasi-species in both epitopes and adjacent regions confirmed that mutations within epitopes recognized by virus-specific CTLs were more frequent than in adjacent regions, consistent with immune escape.[72] However, the frequency of this event has been called into question.[77] One argument against this mechanism as a sole explanation of persistence is the polyclonal nature of the immune response. With such a broadly directed response, it should be difficult for the virus to maintain sufficient

fitness to replicate when faced with the need to mutate at multiple sites.

## Genetic susceptibility to infection

In other diseases it has been possible to identify genetic markers of susceptibility or resistance to infection. Perhaps the best known example of this is the naturally occurring 32-base-pair deletion in the co-receptor for HIV, which results in resistance to HIV infection.[78] Given that the cellular receptor(s) for HCV have not been definitively identified, the search for genetic loci conferring resistance to chronic infection has focused on HLAs and other genes involved in regulation of the immune system. The HLAs are central to the host immune response and thus are ideal candidate genes to investigate for association with HCV outcomes. The HLA molecules are divided into two groups, class I and class II, and present foreign antigens to CD8+ T cells and to CD4+ T cells, respectively. Although a number of studies on the association of HLA antigens and the clinical outcome of HCV infection have been reported, to date there is no clear linkage between any given HLA type and outcome across multiple populations. For example, the study by Thursz and colleagues provides convincing evidence that the HLA class II alleles DRB1*1101 and DQB1*0301 are associated with spontaneous viral clearance,[79] whereas other studies showed that DRB1*01 was associated with clearance[80,81] and DRB1*0301 with persistence.[82] While HLA-B*57 was associated with viral clearance in both Caucasians and African-Americans, the association of HLA-C*w**0102 was present only in Caucasians, while HLA-Cw*04 and HLA-A*2301 were associated with viral persistence.[83,84] In addition to a lack of association across different populations, no study to date has linked functional defects in class I- or II-restricted responses with a given allele. Exploration of other polymorphisms in genes linked to immune responses, such as TNF-α or IL-10, similarly has failed to reveal a clear and consistent pattern, possibly on the basis of inadequate power of most of the studies.[85–88]

## HCV proteins as inhibitors of host immune responses

As the selection of escape mutants to antibodies and HCV-specific CTLs does not fully explain why HCV persists, several studies explored whether HCV proteins directly inhibit host immune responses. The IFN response is a major component of the early response against viral infections, and several studies have demonstrated that HCV proteins interfere with the IFN response (Fig. 26.2). A critical component of the endogenous RNA-dependent protein kinase (PKR) is induced by IFN and activated by double-stranded RNA. Activation of PKR by type I IFN requires its dimerization and autophosphorylation, which in turn phosphorylates the α-subunit of the eukaryotic translation initiation factor 2 α (eIF2 α) and inhibits viral protein synthesis. Although HCV is a strong inducer of type 1 IFN, it is relatively resistant to its antiviral effect. In fact, the glycoprotein E2 of HCV shares a high degree of sequence homology with the autophosphorylation sites of PKR and eIF2α.[89] E2 is able to inhibit PKR activation. This inhibition blocks the phosphorylation of eIF2α, and may contribute to development of resistance during IFN therapy. Other proteins of HCV have been shown to prevent endogenous response to viral infection. Similarly, one of the HCV non-structural proteins, NS5A, also binds to and inhibits PKR through a direct interaction between the C-terminal part of NS5A and the central part of PKR.[90] Recently, NS5A was also found to induce production of IL-8, which in turn partially inhibits the IFN-induced antiviral response *in vitro*.[91] The physiological relevance of this is supported by the finding that hepatitis C patients have shown an elevation of IL-8 in their serum in association with the resistance to IFN therapy,[92] suggesting that NS5A has several potential ways to interfere with the immune response. The HCV NS3/4A serine protease blocks the phosphorylation and effector action of IFN regulatory factor-3 (IRF-3), a key cellular antiviral signalling molecule.[93] Blockade of IRF-3 by NS3/4A results in a decreased transcription of IFN genes. Taken together, these results indicate that HCV has multiple means to inhibit the normal innate immune response to viral infection.

## Impairment of NK and NKT cell functions

Almost all literature to date has focused on the adaptive, antigen-specific response against HCV, despite the abundance of other cell types, such as NK, NKT and γδ T cells in the liver. Two recent reports indicate that HCV E2 protein may inhibit NK cell function and signalling *in vitro* through engagement of CD81, a tetraspanin molecule expressed on the surface of different cell lineage on NK cells.[94,95] Moreover, HCV core protein may impair NK cell activity via p53-dependent upregulation of TAP1 (transporter associated with antigen processing 1) and consequently MHC class I surface expression in liver cells.[96] The inefficient NK cell response could allow virus to evade and counteract a potential NK cell attack. However, studies in persistently infected humans have not consistently demonstrated defects in NK function,[97,98] so further exploration of the role of inhibition of NK function in persistence is needed.

NKT cells are a population that shares features of both classical T cells and NK cells, and are abundant within normal liver.[99] NKT cells actively cause liver destruction in certain models of hepatitis, both directly through their

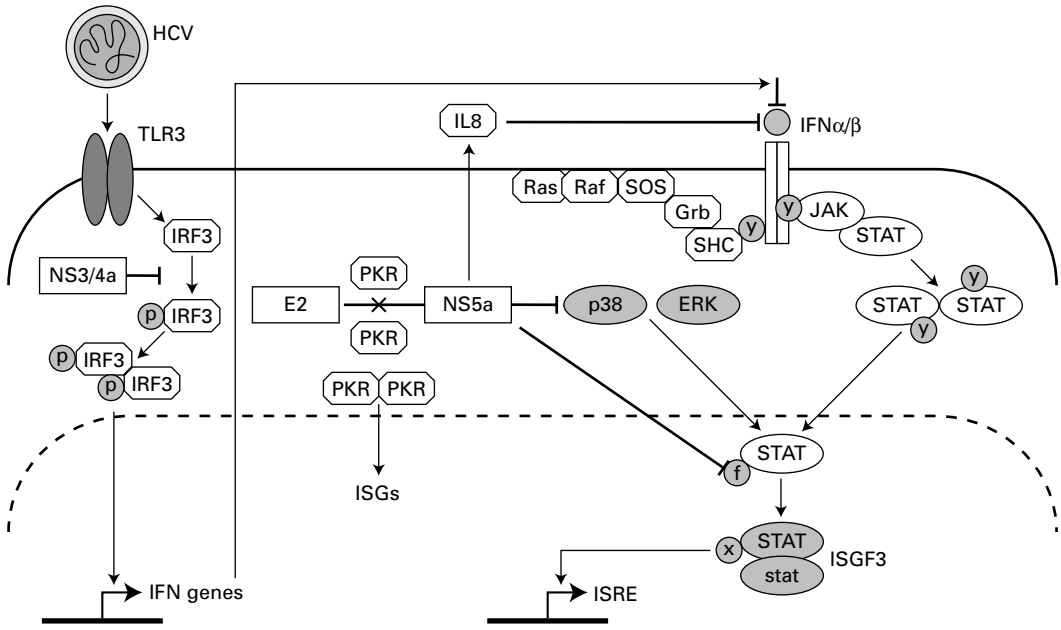

**Figure 26.2** Interference of HCV with the interferon (IFN) response system. Double-stranded RNA stimulates a multi-component complex that phosphorylates IR3, the critical factor required for virus-induced IFN production. Phosphorylated IRF3 dimerizes, moves to the nucleus and activates transcription of IFN genes. HCV NS3/4A results in blockade of IRF3 phosphorylation, and thus prevents IFN transcription. Signalling of IFN-α/β through its receptor is in part mediated by PKR, the active form of which is a dimer. Both HCV E2 and NS5a block dimerization of PKR. NS5a also can interfere with the phosphorylation of STAT proteins, which in turn decreases transcription of IFN responsive elements (ISRE) through interaction with the IFN gene factor 3 (ISGF3). In addition, NS5a stimulates the transcription of IL-8, which is a natural antagonist to IFN-α.

perforin and/or FasL-mediated CD1d-specific cytotoxic activity, and via the ability to activate other immune cells by release of both Th1 cytokines such as IFN-γ as well as Th2 IL-4.[100] As a consequence of their ability to lyse infected hepatocytes and produce cytokines, NKT cells within the liver may play a protective role in clearance of organisms such as *Salmonella* and HBV[20,101,102] as well as contributing to defence against tumours.[103] Conversely, NKT cells are implicated in models of liver injury, as depletion of NK1.1+ NKT ameliorates concanavalin A (ConA)-induced liver disease[104] and CD1d-deficient mice are highly resistant to ConA-induced hepatitis.[105]

There are two distinct populations of CD1d-reactive NKT cells. The first is the classically described 'invariant' TCR expressing Vα24-JαQ in man, paired to a limited set of Vβ chains. Using Vα24, it would appear that CD1d-reactive T cells within the liver are rare, as human liver contains low numbers of cells with this invariant NKT cell-like phenotype (≤1%).[15] In the peripheral circulation, Vα24+ NKT cells are more likely to be apoptotic in patients with chronic HCV than controls.[106] More recent studies using tetramers specific for Vα24+ NKT revealed a very low frequency of these cells in cirrhotic human liver.[107] However, recent results show that measuring only the invariant population may substantially underestimate the true numbers of CD1d-reactive T cells, as a second population expressing 'non-invariant' TCR has been recently been defined.[108] Using functional assays to identify CD1d-reactive T cells, Exley *et al*. have shown that large number of T cells within the human liver are in fact CD1d-reactive T cells.[109] These CD1d-reactive NKT are strongly pro-inflammatory Th1 polarized and are strikingly different from those in the peripheral blood (Th1/2-like) and bone marrow (Th2) of individuals. At present, it is unknown whether this strong Th1 bias is a result of HCV infection or a property of the normal liver, as a recent report found that a greater proportion of NKT intrahepatic-lymphocytes (IHL) in normal human liver produced IFN-γ rather than IL-4 in response to non-specific stimulation.[99]

## Impairment of dendritic cell functions

Dendritic cells (DCs) are important for the initiation of immune system responses to foreign antigens because of their ability to capture and present antigen to T cells. The ability of DCs to induce T-cell responses is also influenced by tissue localization, the antigen dose and the interaction with helper T cells. Recently, it has been shown that HCV may affect the functions of DCs. DCs

expressing HCV core and E1 proteins have an impaired ability to induce CD4+ and CD8+ T- cell responses both *in vitro* and *in vivo*.[110,111] Similarly, DCs from patients with chronic HCV infection showed an impaired ability to stimulate allogeneic T cells and to produce IFN.[112–114] Previous studies on myeloid DCs in HCV-infected patients reported impaired TNF-α-induced maturation that was associated with decreased expression of CD1a, HLA-DR and the co-stimulatory molecules CD83 and CD86.[112] Furthermore, core and NS3 increase production of TNF-α and IL-10 and inhibit DC differentiation in chronic HCV patients.[114] However, not all studies have confirmed that there is functional impairment of DCs.[115,116]

### Failure to generate HCV-specific T cells

In association with a failure of innate immunity or failure of DC function, many have speculated that chronic HCV is due to the failure to generate an HCV-specific T-cell response. For CD4+ responses, as discussed above, the kinetics and breadth of the initial response appears to be directly correlated with the likelihood of clearance. However, for the CTL response this relationship is less clear. While it is true that the magnitude of the response measured in the PBMCs (peripheral blood mononuclear cells) is lower in persons with chronic infection compared with those who have spontaneously resolved HCV, in chronic infection CD4+ and CD8+ T-cell responses appear to compartmentalize to the liver.[51–53,56,117–120] Therefore, persistent infection is not simply a failure to generate HCV-specific T cells, although the kinetics of the response may be different in those who spontaneously resolve compared with those who go on to develop chronic infection. In a recent study, subjects with acute HCV were examined for the kinetics of the immune response in the peripheral blood and liver. Responses were present in the periphery but declined over time whereas they were maintained in the liver tissue in all subjects with chronic infection.[121]

### Impairment of T-cell functions

Why some individuals can mount an effective T-cell response whereas others cannot remains unclear. Certainly, failure of DCs, as discussed above, could alter the kinetics of or the absolute magnitude of the T-cell response. Recent studies have explored whether, in addition to the specificity of the immune response and the kinetics, the function of HCV-specific cellular immune responses is different in those who go on to chronic infection compared with those with spontaneous recovery. For CD4 T cells, most studies have focused on whether there is a Th1 or IFN-γ dominant response, versus a Th2 dominant response. In acute HCV infection, viral clearance is more likely in patients displaying a Th1 profile.[29,31] It has therefore been speculated that an imbalance in Th1/Th2 cytokine production may impair the patient's ability to clear virus. However, examination of T cells *ex vivo* reveals a Th1 bias even in chronic infection.[52,54,56,122]

Other studies have examined whether or not HCV-specific CTLs are capable of effector function. As discussed above, the absolute number of tetramer-positive cells does not permit absolute discrimination of those with chronic evolution versus recovery. In some studies of acute HCV there appeared to be functional 'stunning' in that cells were less capable of producing cytokines thought to be important for the resolution of acute HCV.[46,123] Compared with subjects with acute HBV infection, T cells in acute HCV express significantly lower levels of perforin and decreased proliferation, lytic activity and IFN-γ.[124] However, Takaki *et al*. reported that CD8+ T cells from patients with resolved acute infection exhibit both cytotoxicity and IFN-γ production, but both responses are weak or absent in patients with chronic hepatitis C.[27] These data suggest that the abnormal functional status of virus-specific CD8+ T cells may well account for the failure of these patients to eradicate HCV infection.

What are the mechanisms for this dysfunction? Recent studies have shown that several viral proteins have potential effects on signalling pathways involved in immune response, cell proliferation or apoptosis. HCV core protein, the first protein produced during the early phase of viral infection, can suppress host immune response by inhibiting CTL activity in mice infected with recombinant vaccinia virus expressing core protein. In this model, it appeared that there was interaction between HCV core protein and complement (C1q) receptors on T cells, with resultant inhibition of proliferation and IFN-γ and IL-2 production.[125,126] Core protein increased the sensitivity of the cells to Fas-mediated apoptosis,[127] which may explain the increased Fas-mediated apoptosis observed in PBMCs from patients chronically infected with HCV.[128]

## The role of immune responses in chronic infection

The mechanisms responsible for tissue injury in acute and chronic infection are not well understood. HCV is not considered to be a cytopathic virus because of the absence of classic cytopathic features in liver biopsies, although HCV appears to have important interactions with host cell proteins that might adversely impact on hepatocyte survival or regeneration.[129] The classic understanding of the pathogenesis of liver injury is that it is due to the cellular immune response against the virus. However, there are fundamental problems with this simplistic understanding of the pathogenesis of liver

injury. Clinical experience with immunocompromised hosts indicates that patients with depressed cellular immunity, such as those with AIDS or following orthotopic liver transplantation, are more likely to have progression of liver disease (see Chapter 50). Studies of the role of immune responses in the progression of liver disease are difficult because the chimpanzee model does not develop liver fibrosis, at least in the short term. Moreover, the slow and highly variable rate of disease progression in infected persons limits our understanding of the role of immune responses in chronic infection.

Although it is often stated that immune responses fail to develop in the setting of chronic infection, this is not the case. Instead, responses in chronic infection appear to be preferentially localized to liver tissue. Both CD4+ and CD8+ responses are relatively enriched in liver tissue compared with those observed in peripheral blood.[51–53,56,117–120] Indeed, HCV-specific CTLs can be readily expanded from liver tissue without exogenous antigenic stimulation in both humans and chimpanzees,[52,53,118,130] and are detected at higher frequencies in liver than blood using tetramers.[51,117] Much less is known about the function of these T cells in the liver compared with their counterparts in the peripheral blood. Most studies on the HCV-specific CD8+ T cells in the liver have relied on T-cell lines or clones expanded by *in vitro* stimulation. Studies on these liver-derived CD8+ T-cell clones revealed that their specificity was diverse and comparable to those observed in individuals with acute spontaneous recovery, with some specificities found in the liver that were not identified in PBMCs.[52,53,118,131] This may indicate that the frequency of HCV-specific CD8+ T cells is higher in the liver than in the peripheral blood and/or that the specificity and other properties of the CTLs in the liver may differ from those in PBMCs. Therefore, in order to study the HCV-specific immune response in chronic infection, it is necessary to study responses in both peripheral blood and liver.

There is evidence both for and against a role of cellular immune responses in liver disease and fibrosis. The immune response may play a central role in liver injury, if the magnitude, specificity or effector function is such that viral replication cannot be completely controlled. The role of antigen-specific CTLs in liver cell damage is well established in murine models of viral hepatitis. HBV transgenic mice develop acute hepatitis upon adoptive transfer of syngeneic HBV-specific CD8+ T-cell clones.[132] Several recent studies have confirmed this model in HCV. Animals who only express HCV under the control of an inducible promoter develop inflammation of the liver, whereas those animals who are constitutively tolerant to HCV proteins do not develop inflammation.[133–135] It was recently shown that adoptive transfer of HCV-specific CTLs to transgenic animals bearing HCV structural proteins developed liver injury.[136] In infected persons, the role of cellular immune responses is more controversial, in part because of the difficulties of measuring low frequency responses in the blood and correlating these with progression of disease over time, which requires large numbers of patients to be followed for years. In a small study examining only CTL responses against HCV structural proteins, the presence of liver-derived CTL activity was associated with a higher hepatic necro-inflammatory score, as demonstrated by Nelson *et al*.[137] Reconstitution of the immune system after a period of depressed cellular immune responses, such as occurs after successful engraftment of bone marrow following transplantation, can be associated with dramatic increases in inflammatory activity in the liver, presumably on the basis of enhanced HCV-specific immune responses.[138] Additional supportive evidence for a role for CTLs in liver injury comes from a study where anti-CD8 monoclonal antibodies were administered to a patient with subsequent improvement in serum transaminases.[139] Finally, Nelson *et al*. have shown that recombinant IL-10 improves hepatic inflammation but also leads to increases in viral load via immune modulation.[140] These ineffectual CTLs are thought to exert most of their effect through cytotoxic effects on infected hepatocytes, although indirect effects on nearby, bystander uninfected cells cannot be excluded.[141] Activation of the Fas:FasL system on these activated CTLs may be responsible for a high level of lysis of bystander cells.[142] Production of cytokines by these CTLs may also lead to recruitment of inflammatory cells and activation of stellate cells, although direct evidence for this in HCV is currently lacking.

Alternatively, the cellular immune response may exert a protective effect against disease progression. As discussed above and elsewhere in this volume, patients with depressed cellular immunity have more rapid disease progression, suggesting that some aspects of the cellular immune response, while clearly ineffective at clearing virus, serve to limit liver damage in the presence of viral replication. For example, numerous studies have demonstrated that patients with HIV/AIDS have a higher fibrosis progression rate, particularly in those with CD4+ T-cell counts of <200/mm$^3$.[143–145] Prior to the advent of ART (antiretroviral therapy), several studies described a risk of progressive liver disease in persons with HIV that was in the order of a 3.6-fold increase in the risk of cirrhosis in persons with both infections[145] comparable to the risk of progression in persons with HCV who consume large amounts of alcohol. This rapid progression appeared to be most dramatic in persons with a CD4+ T-cell count <200/mm. Reconstitution of immunity leads to a decrease in the fibrosis progression rate and risk of clinical events due to liver disease.[146] Cross-sectional studies of a small number of subjects with HCV suggest that a more vigorous CD4+ response

is associated with less severe liver histology.[147] Two recent studies by Kamal and colleagues utilized the model of *Schistosoma mansoni* co-infection, in which there is rapid evolution to cirrhosis compared with those with HCV alone and a Th2 bias in co-infected persons. The rate of fibrosis progression was associated with the magnitude of the peripheral and intrahepatic immune response, although the former waned over time, in that subjects who had a vigorous type 1 response in the PBMCs and liver had slower fibrosis progression rates.[121,148] The role of CD8+ T cells is more controversial, with some studies suggesting a relationship between the presence of an HCV-specific CTL response being associated with a lower viral load,[137,149,150] whereas others have failed to find a relationship.[151] As viral load is a poor surrogate for liver damage and does not predict progression of disease in HCV, the clinical importance of the former studies is not clear. None of these cited studies demonstrated a relationship between any CD8+ responses and liver injury, and the number of subjects was relatively small. Therefore, this is another major gap in our understanding of the role of immune responses in liver disease pathogenesis.

# Chapter 27
# Natural history and experimental models

Patrizia Farci, Jens Bukh, Robert H Purcell

The development of animal model systems has provided an invaluable resource for the study of human viral hepatitis.[1] Although the first attempts to transmit this disease to non-human primates date back to the 1950s,[2] the potential value of a laboratory animal model was not clearly recognized until the early 1970s, when the first successful transmission of hepatitis B virus (HBV) infection to chimpanzees was reported.[3] In retrospect, it now appears that many of the failures in transmitting hepatitis to non-human primates occurred because many animals were already immune to the challenge virus. It was not until sensitive serological tests for identifying infections with hepatitis A virus (HAV) and HBV became available that consistent success could be achieved.

Non-human primates have played an important role in furthering our understanding of hepatitis A and B, but their use became widespread only after the discovery of the two causative agents, HAV and HBV.[1] In contrast, much of our understanding of non-A, non-B hepatitis (NANBH), as well as the discovery of its major causative agent, hepatitis C virus (HCV),[4] came from studies in chimpanzees. The first proof that NANBH was indeed an infectious disease caused by a transmissible agent came from almost simultaneous independent reports of successful transmission of human NANBH to chimpanzees,[5–7] and the demonstration of serial transmission to other chimpanzees.[8–10] Chimpanzees were essential to the demonstration that the transmissible agent was filterable[11] and had a lipid-containing envelope.[12] Moreover, chimpanzees also provided an *in vivo* system for the biological amplification of the putative virus to obtain sufficient material for attempts at identification. However, more than 15 years elapsed between the first rigorous description of the disease and the discovery of the aetiological agent.[4] The first specific serological assay for HCV infection was not developed until 1989.[13] This resulted from the partial cloning of the HCV genome after its recovery from plasma of an experimentally infected chimpanzee. In this chapter, we review the role that non-human primate models have played before and after the discovery of the aetiological agent of NANBH.

## The chimpanzee as a model for the study of NANBH in the pre-HCV era

Prospective studies of transfusion-associated hepatitis (TAH) conducted in the United States[14–16] and in Europe[17,18] in the 1960s and 1970s were instrumental in defining the natural history of NANBH. As a result of these studies, it became clear that NANBH was the most common and important complication of transfusion therapy, accounting for the majority of cases of TAH. More important, prospective studies demonstrated that NANBH had a remarkable propensity to progress to chronicity (reviewed by Dienstag[19] and Alter[20,21]). Moreover, besides the transfusion-associated form of NANBH, it was found that a significant proportion of cases, classified as sporadic, community-acquired NANBH, were not associated with identifiable percutaneous exposure.[22,23] Thus, like HBV, both a parenteral and a putative non-parenteral route were identified for the transmission of NANBH.

The discovery of NANBH led to a concerted effort to identify the causative agent. Numerous immunological and serological tests were developed, but none was sufficiently reliable, reproducible or specific to be accepted as a serological marker of NANBH.[24] In this setting, the development of a suitable animal model for NANBH represented an important breakthrough.[25] The animal model was crucial to defining the nature of the causative agent, evaluating suspected epidemiological risk factors and potential sources of infection, and reproducing the natural history of the disease. In addition, the chimpanzee was useful for evaluating the effectiveness of viral inactivation procedures.

Among the potential animal models, chimpanzees were identified as the most promising candidates because they were the only available non-human primates

reproducibly susceptible to both hepatitis A and hepatitis B.[26] The suitability of chimpanzees for hepatitis research stemmed from the close phylogenetic relationship between chimpanzees and humans, as indicated by their high degree of genetic relatedness and similarities in the immune responses and host–pathogen interactions to a variety of human agents.[1,27] The similarity between humans and chimpanzees also had practical applications, such as the ability to use the same reagents to detect proteins of the two species. Indeed, the chimpanzee has proven to be an excellent animal model for NANBH, as the course of primary infection, the acute phase of the disease, the development of the host immune response and the long-term sequelae of HCV infection in chimpanzees mimic well the clinical and immunological observations in humans. The host range of NANBH is remarkably limited.[28] Attempts to transmit the disease to other non-human primate species with inocula of proven infectivity yielded negative or equivocal results.

## Clinical features of NANBH in chimpanzees

Conclusive evidence that the different epidemiological forms of NANBH are associated with a transmissible agent(s) was provided by the successful transmission of NANBH to chimpanzees. Serum or plasma from different sources was used to inoculate the animals. Sources included patients with acute or chronic post-transfusion or community-acquired hepatitis or blood donors implicated in the transmission of hepatitis, as well as concentrates of coagulation factors VIII and IX and fibrinogen (reviewed by Dienstag[24]). After the first experiments in 1978, several laboratories around the world promptly reproduced the transmission of NANBH to chimpanzees. Between 1978 and 1980, using a variety of inocula, 152 animals were inoculated, 110 of which (70%) developed acute hepatitis. The success rate reached 100% in domestically raised chimpanzees that were inoculated with pedigreed infectious inocula.[29]

The clinical features of NANBH in chimpanzees closely reproduce those seen in humans.[24] The incubation period, defined as the time between inoculation and first increase in the alanine aminotransferase (ALT) levels, has ranged from 2 to 20 weeks, with a mean of approximately 7–8 weeks. The acute disease is relatively mild, with peak ALT levels ranging from 100 to 600 IU and, as seen in humans, both monophasic and biphasic ALT patterns can be observed. The incubation period and the severity of acute hepatitis are unrelated to the amount of the inoculum or to the route of administration. Moreover, there is no correlation between the severity of the disease and the number of passages in serial transmission studies. A question raised by the clinical studies of NANBH was the observation of discrete short and long incubation periods. The short incubation period, as brief as 4 days, was predominantly seen in haemophiliacs after therapy with factor VIII concentrates,[30–32] whereas the long incubation period (7–8 weeks) was a regular feature of classical TAH. Based on these observations, some authors hypothesized the existence of two distinct transmissible agents. These speculations, however, were not always supported by transmission studies of viruses from factor VIII concentrates to chimpanzees.[8,33] The incubation period and the clinical and histological characteristics of the disease in chimpanzees inoculated with serum from cases with a short incubation period were indistinguishable from those observed in animals developing NANBH after exposure to viruses associated with long-incubation-period hepatitis.

The development of chronic hepatitis, a hallmark of NANBH, is also a common sequela in chimpanzees. Long-term follow-up of experimentally infected animals demonstrated that NANBH progressed to chronicity in >50% of cases, a rate similar to that reported in humans. Several patterns of ALT elevations were seen in chronically infected chimpanzees. Interestingly, the fluctuating profile of the ALT levels, which is the most characteristic feature of chronic NANBH in humans, has also been observed in chimpanzees. Other patterns include persistent elevations of ALT or recrudescence of the disease several years after the first acute episode.[26,34,35]

## Infectivity studies in chimpanzees

In the absence of any reliable serological tests, the chimpanzee model was instrumental in establishing the duration of viraemia in NANBH virus infection. Successful transmission from sequential serum samples, obtained at various times during the course of acute NANBH, to additional chimpanzees demonstrated that the infectious agent was present in serum as early as 12 days before the first ALT elevation[6] and persisted at least until week 13 after inoculation (1 week after the peak ALT level).[10] Serological re-evaluation of serial subinoculation studies conducted in volunteers in 1969 documented that viraemia appeared within the first week after inoculation.[36] Although the persistence of elevated ALT levels after the acute episode suggested that the disease had progressed to chronicity, it was only through transmission studies in chimpanzees that conclusive proof of the persistence of the NANB agent in blood, in both humans and chimpanzees, could be obtained.[8–10] In addition, successful transmission of NANBH from blood donors or chimpanzees with normal ALT levels provided definitive evidence for the existence of asymptomatic chronic carriers.[37] Evidence was obtained in chimpanzees that a patient was continuously infectious for 6.5 years after the onset of acute hepatitis, even at times when the ALT levels were within normal limits.[37]

The availability of the chimpanzee model permitted the determination of infectivity titres of sera containing NANBH.[26,33] End-point titres of infectivity, defined as the greatest dilution of the inocula at which 50% of the animals became infected, were determined for several clinical samples implicated in the transmission of the disease. The results of these titration studies showed that the end-point infectivity titre of NANBH is generally very low, ranging from $10^0$ to $10^{2.5}$ 50% chimpanzee infectious doses ($CID_{50}$) per mL. Only two inocula among those reported to date had a high infectivity titre ($10^{6.5}$/mL each).[33,34] Thus, the infectivity of NANBH viruses in serum is markedly lower than that commonly observed in HBV ($10^8$)[26] and HDV infection ($10^{11}$).[38] This feature of NANBH may help to explain the difficulties initially encountered in transmission studies, before the introduction of pedigreed inocula, as well as the difficulty encountered in attempting to identify the causative agent.

## Physico-chemical properties of the NANB agent

Most of the physico-chemical properties of the putative agent of NANBH have been determined in experiments utilizing the chimpanzee. Both in humans and in experimentally infected chimpanzees, studies of serum and liver biopsies by electron microscopy (EM) failed to identify virus-like particles specific for NANBH. This failure most probably stemmed from the low infectivity titres of virus in clinical materials. The absence of any serological assays and the inability to grow the virus *in vitro* further hampered the characterization of the causative agent. Infectivity studies in chimpanzees demonstrated that the agent was stable at pH 8.0, but could be inactivated by formalin at a concentration of 1:1000 at 37 °C for 96 hours[39] or 1:2000 at 37 °C for 72 hours.[40] Infectivity could be abolished by heating at 100 °C for 5 minutes[40] or at 60 °C for 10 hours.[39] Complete inactivation of the agent was also achieved by heating at 60 °C for 30 hours after lyophilization,[41] a system that has been widely used for the treatment of pooled coagulation factors for transfusion. The agent is sensitive to a combination of β-propiolactone and ultraviolet light.[42,43] Inactivation by exposure to lipid solvents, such as chloroform, indicated that the agent contained essential lipids, presumably in an envelope.[12,44] Only an isolated report by Bradley *et al*.[44] demonstrated the existence of a chloroform-resistant agent of NANBH, in addition to the common chloroform-sensitive agent, but this could not be confirmed in subsequent tests of the same samples in chimpanzees (Purcell, unpublished data).

To determine the size of the NANBH agent, the virus was subjected to filtration through membranes of defined pore size. Infectivity was retained after filtration through 220-, 80- and 50-nm filters but was removed by a 30-nm filter.[45–47]

The results of the biochemical and physical analyses suggested that the NANBH agent was an enveloped virus with a diameter of 30–60 nm. These properties further suggested that the NANBH virus could belong to the togavirus-flavivirus group, the Hepadnaviridae family, the HDV-like agents, or a previously unrecognized category of virus. That the NANBH agent was not related to hepadnavirus or to HDV was subsequently suggested by nucleic acid hybridization studies.[48,49] Some authors had even proposed that the agent could be a retrovirus, based on the occasional detection of reverse transcriptase activity in the serum of infected patients.[50] However, in subsequent studies with pedigreed sera, these data were not reproduced in other laboratories.[51] Moreover, given the estimated size of the NANBH virus, the hypothesis that it was a retrovirus seemed highly unlikely.

## The role of the animal model in the discovery of hepatitis C virus

The pathway leading to the identification of the causative agent of NANBH was long and tortuous. In retrospect, the length of this process can be explained by the low levels of infectivity, and by the weak and delayed humoral immune response of the host.[52] For these reasons, attempts using conventional virological methods produced only deep frustration for many years. Instead, it was through an unconventional approach, taking advantage of the increasingly refined techniques of molecular biology, that success was eventually achieved. Again, the availability of the chimpanzee model was critical for the discovery of HCV, because it represented the only suitable source for the biological amplification of the putative agent. It was from a chronically infected chimpanzee that large amounts of pooled plasma with an unusually high titre of infectivity ($10^6$) were obtained for the molecular cloning of the viral genome.[4] Litres of plasma were pelleted to concentrate the virus particles, total RNA was extracted from the pellet and retrotranscribed into cDNA. More than 1 million colonies in a lambda gt11 expression system were screened with serum from a chronically infected patient, who served as a source of antiviral antibodies. A single positive clone, designated 5-1-1, which expressed a virus-specific immunogenic peptide was finally identified. As stated by Michael Houghton, the molecular identification of HCV was the culmination of a team effort spanning 7 years, during which 'hundreds of millions of bacterial cDNA clones were screened for a putative NANB hepatitis agent. Only one positive clone was the result of this strenuous effort. If we had missed or lost 5-1-1 from the library, we may still be looking for HCV'.[54] The 5-1-1 clone was then used to identify a larger clone (C100-

3) that was expressed in yeast as a fusion protein with superoxide dismutase. By using overlapping clones, the entire sequence of the HCV genome was subsequently obtained. Thus, HCV represents the first virus in the history of virology that has been characterized primarily by molecular means before it was visualized by EM or isolated in culture.

HCV is a small enveloped, single-stranded positive-sense RNA virus of about 9600 nucleotides in length, which has been classified in a separate genus, Hepacivirus, within the Flaviviridae family.[54] The chimpanzee model has been instrumental for the visualization of intracellular HCV particles, approximately 50 nm in diameter, by EM in liver tissue obtained during the acute phase of hepatitis C.[55] The HCV genome is organized in a manner similar to that of flaviviruses and pestiviruses, the other two genera of the family, and is more closely related to pestiviruses.[56] The viral genome contains a single open reading frame (ORF) with two non-coding regions of approximately 340 and 230 nucleotides at the 5′ end and 3′ end, respectively, and encodes a large polyprotein precursor, approximately 3000 amino acids in length, that is cleaved by cellular and viral proteases into structural proteins – core (c), envelope 1 (E1) and 2 (E2) – and non-structural proteins (designated as NS2–NS5).[57] It is not known whether p7, located between E2 and NS2, is structural or non-structural.[58]

The cloning and sequencing of the HCV genome and the development of serological assays for the detection of specific antibodies to HCV transformed the diagnosis of NANBH from one merely based on exclusion into that of a specific disease, hepatitis C. The application of this assay to clinical practice finally provided the best evidence that HCV is the major aetiological agent of post-transfusion NANBH,[21,59,60] as well as of community-acquired NANBH.[61] The diagnosis of hepatitis C is routinely based on a variety of diagnostic tests, which include indirect markers of HCV infection, such as the humoral response of the infected host, measured by solid-phase enzyme-linked immunoassay (EIA),[13] and the detection of direct markers such as HCV RNA in serum.[62] The development of a third-generation EIA 3, which has replaced the first- and second-generation EIAs, has significantly improved the specificity and sensitivity of detecting anti-HCV antibodies compared with their predecessors.[63] Other EIAs that measure antibodies directed to the E1 and E2 genes have been developed, but they are not yet commercially available, and their application has been limited to experimental studies. Currently, tests to measure HCV antigenaemia are limited to the detection of total HCV core antigen in peripheral blood by means of an ELISA assay.[64] However, the core antigen assay lacks the sensitivity to detect low-level replication (below 10 000–20 000 HCV RNA IU/mL). It has been recently reported that 1 core antigen picogram (pg) per mL is equivalent to approximately 8000 HCV RNA IU/mL and the limit of detection is 1–2 pg/mL.[62] Detection of nucleic acid sequences with the polymerase chain reaction (PCR) or other nucleic acid-based techniques is the most practical method to detect viraemia in the course of HCV infection.[62,65–67] In particular, a sensitive assay such as PCR is critical for evaluating the course of HCV infection, in which low levels of viraemia appear to be the rule, as demonstrated by experimental studies in chimpanzees. The animal model has been fundamental for evaluating the sensitivity of the PCR technique. By analyzing 10-fold serial dilutions of a reference plasma (strain H) whose infectivity was $10^{6.5}$ $CID_{50}$/mL; the PCR assay was capable of detecting HCV with a sensitivity approximately 10-fold greater than the infectivity titre in chimpanzees.[65,68,69]

## Genetic variability

Extensive molecular analysis has demonstrated that HCV is characterized by a high degree of genetic variability, a hallmark of RNA viruses.[70,71] Over the past few years, the study of the genetic variability of RNA viruses has received increasing attention because of the possibility of linking a better understanding of viral evolution to prospects for disease control and prevention.[72,73] The main factor contributing to the genetic variability of HCV is the error-prone nature of genome replication, because the RNA polymerase lacks a proofreading exonuclease activity, which is an important repair mechanism that removes misincorporated bases from newly synthesized RNA strands.[74] This leads to the generation of a high mutation rate during genome replication. Other properties, however, contribute to the extremely high genetic variability of HCV. These include the large population size, the high replication rate and the short generation time.[75]

The genetic variability of HCV is complex and has been classified in four hierarchical strata: genotypes, subgenotypes, isolates and quasi-species. Phylogenetic analysis of full-length or partial sequences of HCV strains collected worldwide led to the identification of six major genotypes and more than 100 subtypes, which differ in their global distribution.[70,76,77] In recent years, however, refined molecular techniques have provided the tools to demonstrate that, not only among different individuals but also within an infected individual, HCV circulates as a population of different, albeit closely related, genomes exhibiting a distribution that follows the model referred to as a 'quasi-species' [78] according to a concept that was first introduced by Eigen in 1971.[79] The quasi-species distribution is a highly dynamic process generating a continuously changing spectrum of mutant viruses, which favours adaptability in the event of environmental change.[80] Variation within an evolving quasi-species

is not only a direct reflection of the mutants generated during replication, but also the result of a competitive selection based on the viability and replicative efficiency of such mutants in a given environment (fitness).[80,81] The quasi-species as a whole, and not its individual components, is the true target of selection. The quasi-species behaves as an evolutionary unit and represents at any given moment the best fitting population that has established a status of equilibrium with the host.[82] The evolution of the viral quasi-species is strictly dependent on the population size of the virus that sustains the infection. Multiple factors act as selective forces, including the specific organ and cellular milieu and the neutralizing effects of both cellular and humoral immunity.[83] The degree of genetic heterogeneity of the HCV quasi-species can be studied at two different levels: the genetic complexity, defined as the total number of viral variants simultaneously present in a single sample, and the genetic diversity, defined as the average genetic distance among the different variants. By cloning and sequencing more than 100 molecular clones of HCV derived at a single time-point during the acute phase of hepatitis C from each of two patients, it was possible to obtain a detailed characterization of the HCV quasi-species.[84] Sequence analysis of the HVR1 demonstrated the simultaneous presence of 53 and 19 different viral variants in patients M and H, respectively. Within the 27 amino acids of the hypervariable region 1 (HVR1) of the E2 envelope glycoprotein of HCV, the genetic diversity among the mutant spectrum ranged from one to ten sites in HCV from patient M and from one to eight sites in HCV from patient H. The plasma source of HCV from patient H and the virus derived from it (H77) have been extensively studied both molecularly and in the chimpanzee model. For example, Ogata *et al*.[85] sequenced HCV isolates obtained from patient H during the acute hepatitis phase and after 13 years of follow-up. Their analysis, based on 50% of the HCV genome, showed a mutation rate of $1.92 \times 10^{-3}$ base substitutions per site per year. A similar study was conducted by Okamoto *et al*.[86] in a chimpanzee experimentally infected with HCV. Sequence analysis of the complete genome of two isolates obtained during the acute phase and 8.2 years later demonstrated a mutation rate of $1.44 \times 10^{-3}$ per site per year. The degree of variability is not homogeneously distributed within the entire viral genome. The 5′ non-coding region is among the most conserved,[87–89] and the E1 and E2 genes are the most variable.[90] The highest variability, both at the nucleotide level and at the amino acid level, has been detected at the amino-terminus of the E2 gene. This domain of 27 amino acids, the HVR1, may result from the continuous immune pressure of the host. [91,92] The HVR1, being the most variable region of the HCV genome, has been used as a fingerprint for identifying individual viral variants and for studying the genetic complexity and diversity of the viral quasi-species. Although the biological function of the HVR1 is only partially understood,[93] this region has attracted considerable interest because it has been shown to contain a neutralization epitope.[94,95] It is a target of antibodies that correlate with viral clearance[96] and it was postulated to serve as a decoy antigen[97] as well as, more recently, a receptor-binding domain.[98] A potential biological role of the HVR1 is suggested by the fact that, despite its extraordinarily high level of variation, there are important structural constraints in this region.[99] Penin and colleagues,[100] by analyzing more than 1300 HVR1 sequences derived from all the different genotypes, provided evidence of a striking similarity in both the hydrophobicity and antigenicity profiles. Moreover, they also documented a conservation of positively charged residues within the HVR1. These findings have been confirmed in other studies,[101] suggesting that the HVR1 contains conserved determinants that may play a critical role in the viral life-cycle, most likely at the level of viral entry.[102]

## The contribution of the animal model to the study of the natural history of HCV infection

Chimpanzees represent a valuable model for the study of the natural history of HCV infection because they reproduce, under carefully controlled experimental conditions, the disease observed in humans. The extensive clinical and experimental studies of NANBH conducted before the discovery of HCV had raised many questions that were difficult to address in the absence of specific diagnostic markers. After the discovery of HCV, antibody assays and sensitive assays for detecting the HCV genome, such as PCR, became available to investigators. These advances provided an opportunity to re-evaluate the early studies of experimental transmission in chimpanzees. Thus, chimpanzees have represented an optimal source of controlled clinical material for studying the kinetics of viral replication and the relationship between viraemia and the host immune response during the course of acute and chronic HCV infection. Moreover, the chimpanzee model has been fundamental for comparing the clinical and virological features of wild-type (polyclonal) HCV infection versus infection with molecularly cloned (monoclonal) HCV.

### Wild-type HCV infection in chimpanzees

Primary HCV infection in chimpanzees is characterized by the early appearance of HCV viraemia, which in most cases becomes detectable within 1 week after inoculation, long before other markers can be detected. [65,103–108] In two chimpanzees in which serum and liver specimens were obtained daily during the first week of

infection, newly synthesized HCV RNA in serum was detected as early as 3–4 days after inoculation.[107] During the acute phase, the peak viral titre ranges from $10^5$ to $10^7$ genome copies per mL. The detection of serum HCV RNA precedes the appearance of ultrastructural changes[107,109] and associated host-derived cytoplasmic antigens, as detected by monoclonal antibody 48-1, in hepatocytes.[107] By direct immunofluorescence, intrahepatic HCV antigens can be found in the cytoplasm of hepatocytes in the early phase of acute hepatitis, before the appearance of the antibody response. [110]

Evidence of hepatitis can be detected on average 7–10 weeks after inoculation, although low-level elevations of liver enzyme values often occur earlier, within the first 1–3 weeks after exposure to HCV.[5,33] This pattern of early ALT elevations resembles that observed in humans and is believed to result directly from HCV infection. The severity of hepatitis, as measured by the ALT levels, does not appear to correlate with the infectivity titre of the inoculum.[111,112] In self-limiting HCV infection of chimpanzees, the viraemia is transient and lasts for a variable period, ranging from 10 to 38 weeks[103,105,106] but occasionally can be longer.[113]

The humoral response to primary HCV infection is usually delayed with respect to the clinical onset of the disease and is highly variable. The biological reasons for the variable immune response observed in primary HCV infection in chimpanzees are unclear at present. Analysis of a large series of chimpanzees has shown that there is no correlation between the first appearance of HCV viraemia and the time of antibody seroconversion,[103,105,106] or between the infectivity titre and the time of seroconversion.[103,111] The time interval between inoculation and antibody seroconversion ranges from a few weeks to several months, and this interval is dependent on the antibody being measured. Antibodies directed to the nucleocapsid protein of HCV (anti-core) are usually the first to appear and can be detected immediately before or coincident with the major ALT peak, although there is an extreme variability among individual chimpanzees.[103,105] Antibodies to the NS3 appear coincidentally with or shortly after antibodies to core,[105] while antibodies to the NS4 are usually the last to appear, on average 10–15 weeks after the major ALT peak.[65,103–106, 114] The shortest interval from the onset of hepatitis to antibody seroconversion has been observed using the second-generation assay,[104–106] and more recently with the third-generation assay.[115,116]

Besides variations observed in the detection of antibodies directed to different HCV antigens, there are also intrinsic differences in the immune response of individual chimpanzees. This variability includes not only the time of seroconversion, but also the pattern of antibody response. In some animals, the antibody response was limited to anti-NS3 and anti-NS4,[104,106] while in others it was associated with the appearance of an isolated anti-core or anti-NS4 response.[103] The importance of individual variability is emphasized by the observation that the same inoculum induces different patterns of antibody response in different chimpanzees.[111] The introduction of the second-generation assay has diminished the variability in the humoral response observed with the single assays and has narrowed the length of the seronegative window (Figs 27.1–27.3) to an average of 5–8 weeks.[104–105] Moreover, it has considerably increased the sensitivity of the assay, as evidenced by the identification of cases that lacked antibodies detectable by first-generation assay (Fig. 27.4).[105,117] This notwithstanding, variability in the time of seroconversion has also been observed with the second-generation assay.

Data obtained both from the animal model and from humans during the early phase of acute hepatitis failed to identify any virological or serological markers that may be of value in predicting the outcome of HCV infec-

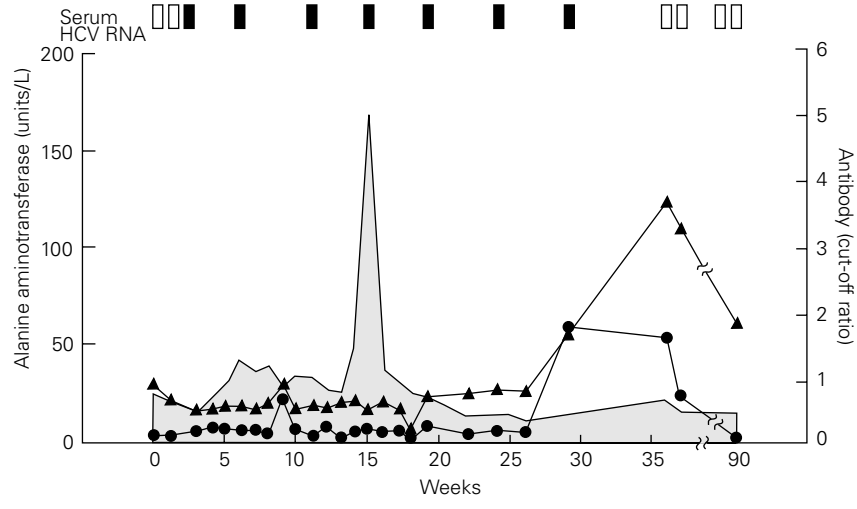

**Figure 27.1** Pattern of antibody response to hepatitis C virus (HCV) in chimpanzee 105 with transient HCV viraemia. Open bars indicate negative assays for serum HCV RNA by PCR, and solid bars positive assays. The grey area indicates the values of serum alanine aminotransferase. First-generation anti-HCV assay is indicated by circles, second-generation anti-HCV assay is indicated by triangles. The cut-off ratio represents the ratio between the absorbance value for the test sample and that for the assay cut-off; values above 1 were considered positive. (Modified from Farci *et al*.[105] with permission.)

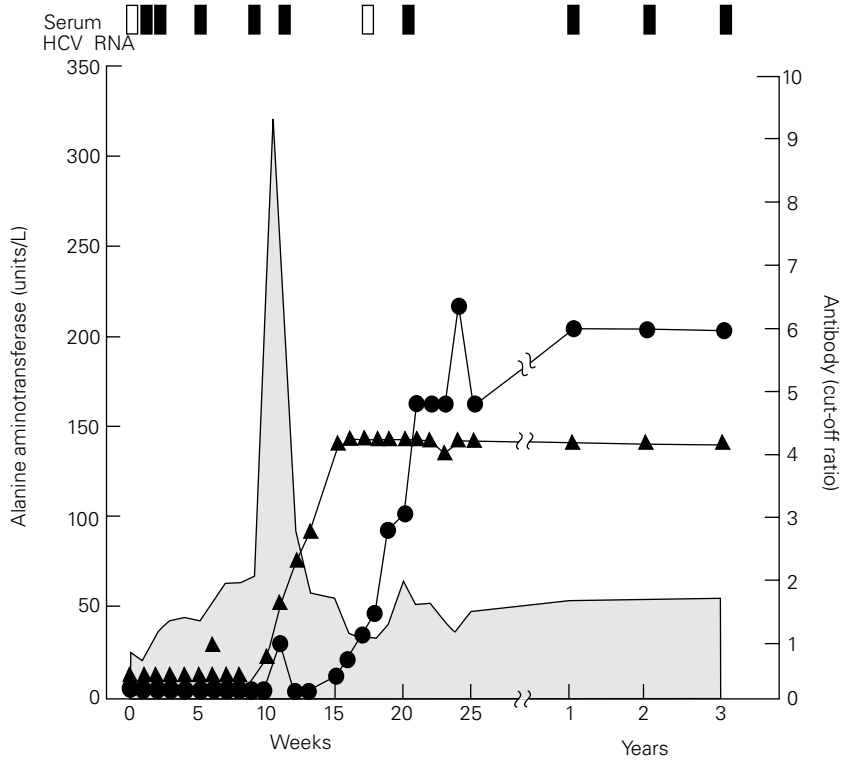

**Figure 27.2** Pattern of antibody response to hepatitis C virus (HCV) in chimpanzee 51 with chronic HCV infection and persistent HCV viraemia. The animal was inoculated with serum from a patient with chronic post-transfusion hepatitis (strain F), fifth passage in chimpanzees. Open bars indicate negative assays for serum HCV RNA by PCR, and solid bars positive assays. The grey area indicates the values of serum alanine aminotransferase. First-generation anti-HCV assay is indicated by circles, second-generation anti-HCV assay is indicated by triangles. The cut-off ratio represents the ratio between the absorbance value for the test sample and that for the assay cut-off; values above 1 were considered positive. (Modified from Farci *et al*.[105] with permission.)

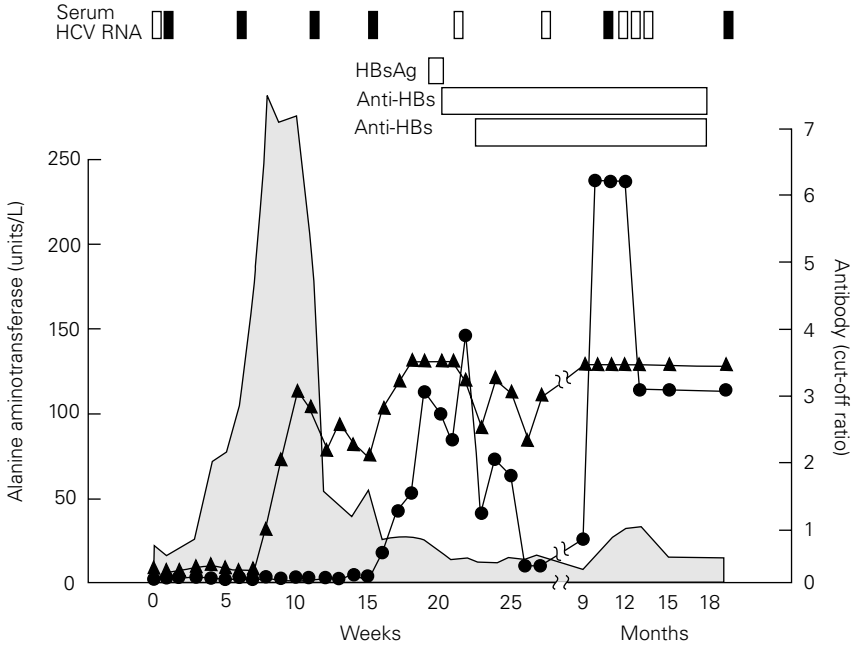

**Figure 27.3** Pattern of antibody response to hepatitis C virus (HCV) in chimpanzee 888 with chronic HCV infection and persistent HCV viraemia. Open bars indicate negative assays for serum HCV RNA by PCR, and solid bars positive assays. The grey area indicates the values of serum alanine aminotransferase. First-generation anti-HCV assay is indicated by circles, second-generation anti-HCV assay is indicated by triangles. The cut-off ratio represents the ratio between the absorbance value for the test sample and that for the assay cut-off; values above 1 were considered positive. Horizontal bars indicate the time during which serum was positive for hepatitis B surface antigen (HBsAg), for antibody to HBsAg (anti-HBs), and for antibody to hepatitis B core antigen (anti-HBc). (Modified from Farci *et al*.[105] with permission.)

tion. The initial antibody pattern was not significantly different between animals that developed chronic HCV infection and those that cleared the viraemia.[106] Thus, the detection of serum HCV RNA is the only currently available test that may provide prognostic information on the outcome of the disease. Sustained clearance of HCV RNA correlates with resolution of the disease, whereas persistence of detectable HCV RNA predicts progression to chronicity.[65] However, the lack of detectable HCV RNA by PCR does not necessarily exclude the presence of tiny amounts of infectious virus.[104] HCV RNA is also the crucial marker for establishing an early diagnosis of primary HCV infection. In fact, although the introduction of the second-generation antibody as-

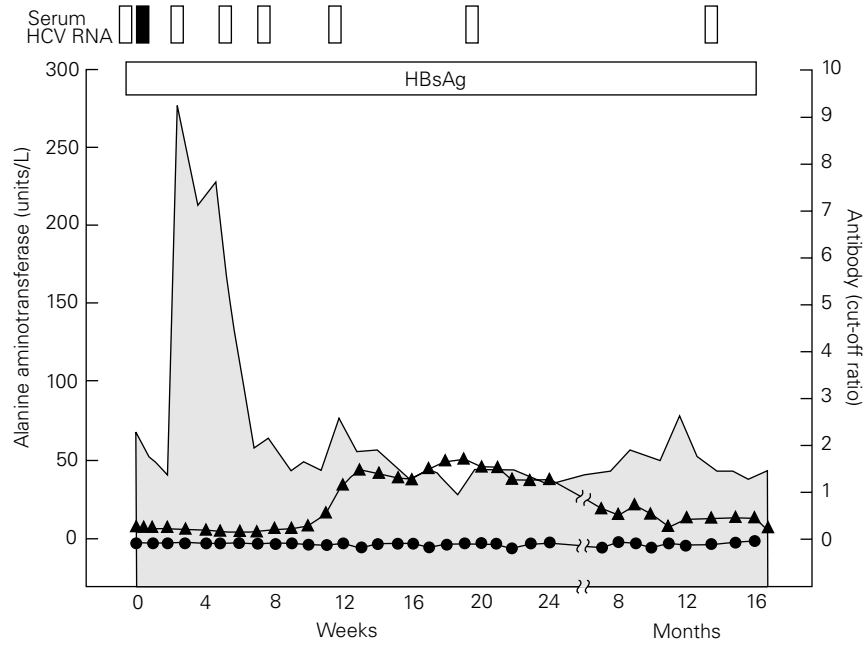

**Figure 27.4** Pattern of antibody response and HCV viraemia in chimpanzee 904, which was inoculated with serum from a patient with acute post-transfusion hepatitis (strain H). The animal was a chronic carrier of hepatitis B surface antigen (HBsAg) at the time of inoculation. Open bars indicate negative assays for serum HCV RNA by PCR, and solid bars positive assays. The grey area indicates the values of serum alanine aminotransferase. First-generation anti-HCV assay is indicated by circles, second-generation anti-HCV assay is indicated by triangles. The cut-off ratio represents the ratio between the absorbance value for the test sample and that for the assay cut-off; values above 1 were considered positive. The horizontal bar indicates the time during which serum was positive for hepatitis B surface antigen (HBsAg).

say has considerably narrowed the seronegative window and increased the sensitivity of the test, there is still a prolonged interval between the first detection of HCV RNA and antibody seroconversion.[105] This seronegative window has not been further narrowed by the introduction of tests for IgM class antibodies against different HCV antigens.[104] With the antibody assays so far available, there is still a serologically silent period, during which HCV RNA, as detected by PCR, is the only marker that permits early diagnosis of primary infection and identification of potentially infectious individuals who would be missed by conventional antibody testing.[65,103–106,109] However, the value of the PCR assay for predicting infectivity of donors of plasma or blood is not absolute, especially in view of the fact that the volumes of plasma tested by PCR are usually lower than those used for experimental inoculation in chimpanzees. In this respect, Beach *et al*.[104] reported successful transmission of HCV infection with 17-mL and 100-mL samples of two inocula that were negative for HCV RNA when 50-µL samples were tested by PCR.

The virological and serological profiles of chronic HCV infection differ from those seen in acute hepatitis. In chronic HCV infection, HCV viraemia usually follows two main patterns: persistent or intermittent (Figs 27.2 and 27.3).[103–106] In contrast to the variable, delayed, and weak antibody response seen in acute hepatitis, the serological pattern in chronic HCV infection is more sustained and consistent. Persistent viraemia is associated with the presence of antibodies against structural and non-structural proteins, both of which increase in parallel with the progression of the hepatitis and persist at high titres as the disease continues (Fig. 27.2).[105] The pattern of continuous viraemia documented for up to 10 years in one chimpanzee[109] and, more recently, for over 20 years in another (unpublished data) resembles the pattern seen in chronically infected humans. In chimpanzees with intermittent viraemia, the antibody profiles may differ from those observed in animals with continuous viraemia.

A correlation was not observed between the pattern of HCV viraemia and the ALT profile during long-term follow-up.[65,104,105] Persistent viraemia may be associated with the characteristic ALT fluctuations, or with mild, nearly normal ALT values. This disparity between HCV RNA and ALT levels indicates that HCV replication is not always associated with serious liver damage, for reasons that are not understood. In both humans and chimpanzees, the absence of ALT elevations for extended periods of time does not exclude the presence of circulating viral RNA and does not imply recovery from disease.[104,118] These clinical features complicate the definition of acute self-limiting hepatitis and suggest that caution should be used in the diagnosis of resolution of HCV infection.

## Monoclonal HCV infection in chimpanzees

The generation of infectious cDNA clones of HCV has represented an important advance in HCV research, providing new insights into the mechanisms of HCV pathogenesis, and permitting more detailed studies of the molecular biology of HCV.[119,120] Infectious cDNA clones of HCV have been generated for strains of genotypes 1a, 1b and 2a. As no reproducible cell culture systems

to grow HCV are currently available, demonstration of the infectivity of such clones would have been impossible without using chimpanzees. Chimpanzees became infected when genomic RNA transcripts synthesized *in vitro* from full-length HCV cDNA clones were inoculated directly into the liver, which can be done in a percutaneous procedure guided by ultrasound.[121] As the RNA inoculated was generated from a single HCV sequence, the animals became infected with a monoclonal virus. The mutation rate per nucleotide site per year ($1.48–1.57 \times 10^{-3}$)[122] was similar to that reported in chimpanzees infected with polyclonal virus ($1.44 \times 10^{-3}$).[86] Monoclonal infection of chimpanzees provides a simplified model for studies of HCV pathogenesis because the viral interaction with the host is not initially complicated by the quasi-species that is invariably present in a wild-type HCV inoculum.[113] Also, in pathogenesis studies, infection with a molecular clone eliminates the possibility that putative co-infecting agents may account for or modify the observed results. It furthermore permits true homologous challenge in studies of protective immunity[123,124] and in testing the efficacy of vaccine candidates.[125] Finally, this *in vivo* transfection system has made possible for the first time molecular analysis of HCV infectivity.[126,127]

The initial pattern of HCV infection after transfection of chimpanzees with monoclonal HCV RNA transcripts does not differ significantly from that observed in animals infected intravenously with the original uncloned virus.[115,119,120,123,128] The animals become viraemic at weeks 1–2 and the viral titres increase to reach a peak of $10^5$–$10^6$ genome equivalents per mL typically during weeks 8–12. The animals develop acute hepatitis, thus formally proving that HCV causes liver disease. A high rate of progression to chronicity was observed in animals with monoclonal HCV infection, indicating that, at least in chimpanzees, the presence of a quasi-species viral population during the early acute phase is not a requirement for viral persistence. Thus, monoclonal infection of chimpanzees provides a suitable model for studying the host factors that determine the outcome of acute HCV infection.[113,115] Major *et al*.[115] studied acute hepatitis C in 10 chimpanzees experimentally infected with the same monoclonal virus, representing the consensus sequence of the prototype HCV strain, H77. Irrespective of the outcome, the animals showed a significant decrease in virus titre after reaching peak levels. All 10 animals had similar levels of interferon (IFN)-γ induction in the liver, which coincided with the initial decrease in virus titre and with the development of hepatitis. As IFN-γ and IFN-induced genes in the liver are expressed as a result of the activation and liver-homing of immune cells, this result suggests the development of significant intrahepatic cellular immune responses in all animals. However, only four animals were able to clear the infection. These animals had 0.5–1 log lower peak titres of viraemia and their initial decrease in virus titres occurred 1–2 weeks earlier. Also, only the animals with resolving infection showed significant induction in the liver of mRNA specific for the epsilon chain of CD3, as well as for macrophage-inflammatory protein 1 (MIP-1) alpha, a chemokine involved in homing and activation of immune cells, which could indicate qualitative and/or quantitative differences in intrahepatic cellular immune responses. Such differences might simply reflect a higher level of immune cell activation, but are most likely related to the nature of the immune cells that are preferentially activated during an effective sterilizing immune response. The timing of these responses might also be crucial. As these animals were all infected with the same virus, the observed differences can with some certainty be associated with the host responses irrespective of the virus sequence.

## HCV and fulminant hepatitis

Before the discovery of HCV, the role of putative NANBH agents in fulminant hepatitis was difficult to establish, as diagnosis was merely based on exclusion criteria (reviewed by Dienstag[19]). In such studies, NANBH agents were thought to account for 30–40% of all cases of fulminant NANBH. However, these values probably overestimated the true incidence, because cases of drug toxicity or fulminant hepatitis B with undetectable HBsAg could have been included in this group. In contrast, prospective studies of post-transfusion NANBH suggest that fulminant NANBH is rare.[129–131]

The discovery of HCV permitted a more accurate investigation of the role of this virus in the aetiology of fulminant NANBH. The evidence thus far accumulated suggests that the association between HCV and fulminant hepatitis differs markedly according to the geographical area studied. In Japan and Taiwan, HCV infection, as determined by the presence of antibodies to HCV or serum HCV RNA, was documented in 40–60% of the patients, [132–138] whereas a number of studies conducted in Western countries failed to demonstrate conclusively an aetiological role of HCV in fulminant NANBH.[139–146] In these studies, the prevalence of HCV infection ranged from 0 to 12%. The only exception was a seroepidemiological survey conducted in California that reported a prevalence of 60%, associated with low socio-economic status and Hispanic ethnicity.[147] An aetiologic link between HCV and fulminant NANBH was established by longitudinal analysis of serum samples collected from a patient enrolled in the National Institutes of Health (NIH) prospective study of transfusion-associated NANBH.[148] Fulminant hepatitis C was associated with continuous HCV replication throughout the course of the disease, while antibody seroconversion

occurred after week 7, on the last few days before the patient's death. Therefore, as previously documented in acute hepatitis C, the detection of serum HCV RNA was the earliest and most valuable marker for the diagnosis of fulminant hepatitis C.

Interestingly, fulminant hepatitis C is characterized by high levels of viraemia associated with a highly homogeneous viral quasi-species population.[149] Although the pathogenic mechanism of virus-induced fulminant hepatic failure is not known, the extent of liver damage correlated with the magnitude of viral replication. In contrast, in patients with fulminant hepatitis B, HBV replication is barely detectable or even undetectable, while antibody titres are high.[150] This suggests that the mechanisms of fulminant liver injury in the two types of hepatitis differ. In fulminant hepatitis C, sequence analysis demonstrated a very low degree of diversity in the viral quasi-species, whereas considerable intra-patient variability has been detected in non-fulminant hepatitis C.[149] Whether this finding reflects the lack of selective immune pressure of the host, particularly the lack of specific antibodies, in this rapidly evolving syndrome remains to be established. Considering the persistence of viraemia observed in fulminant hepatitis C, it is very unlikely that HCV RNA-negative cases of fulminant NANBH could be related to HCV infection. Whether such cases are due to yet unidentified infectious agents or, as recently proposed,[151] represent a syndrome caused by non-infectious hepatotoxic agents is presently unknown. Animal models may be a valuable tool for addressing these questions.

Several attempts have been made to transmit hepatitis from plasma of patients with fulminant NANBH to animal models, but they have been unsuccessful.[33] Subsequently, however, by using a small amount of serum from a patient with fulminant hepatitis C (HC-TN, genotype 1a), HCV infection was successfully transmitted to a chimpanzee (Ch 1422).[152] The acute hepatitis developed by this animal was characterized by the highest serum ALT peak (744 U/L) and by the most severe pathological findings ever observed among more than 20 chimpanzees infected with different HCV strains. The animal developed antibodies to HCV and eventually cleared serum HCV RNA. Sequence analysis indicated that the virus recovered from the chimpanzee was the same as that isolated from the patient who served as the source of the virus. This represented the first experimental animal transmission of HCV from a patient with fulminant hepatitis and provided additional evidence for an aetiological role of HCV in the development of fulminant hepatitis.

Recently, a second animal (Ch 1581) was infected using plasma from chimpanzee 1422 and a third one (Ch 1579) was infected with RNA transcripts from a consensus cDNA clone of HC-TN (unpublished data). In contrast to Ch 1422, these two additional chimpanzees developed a typical acute hepatitis C with an ALT peak of 298 IU/L and 90 IU/L, respectively, and minimal activity grade in liver biopsy, as commonly seen in the chimpanzee model. Although the course of viraemia was similar, Ch 1579 resolved the infection whereas Ch 1581 became persistently infected. Thus, the unusual severity observed in chimpanzee 1422 did not breed true in the other two animals. Virulence depends upon a complex interplay between the virus and the host, and may be influenced by several factors including the dose of infecting virus, route of entry and virus sequence, as well as by the immune response of the host. With regard to the latter, Ch 1581 and Ch 1579 were previously exposed to HCV in attempts to transmit infection using sub-infectious doses of HCV or RNA transcripts from HCV molecular clones, which did not result in detectable infection, but may have primed some type of host immune responses, as previously demonstrated in chimpanzees.[126,153] By contrast, Ch 1422, which developed severe acute hepatitis, did not have such prior exposure. It is also unclear whether serial passage through chimpanzees may affect the biological properties of a particularly virulent strain of HCV. However, when the full-length consensus sequence obtained at the ALT peak from Ch 1422 was compared with those obtained at the ALT peak from the other two animals, only a single point mutation was detected in the sequence recovered from Ch 1581, which was already present at week 1 after infection, while no changes were detected in Ch 1579.

In conclusion, although the pathogenic mechanism of HCV-induced fulminant hepatic failure is not known, the evidence thus far accumulated suggests that HCV is an aetiological agent of fulminant hepatitis. Nevertheless, this is a rare event and in most cases of fulminant hepatitis the causative agents remain elusive. Although to date all attempts to transmit hepatitis from patients with non-A, non-B, non-C fulminant hepatitis to chimpanzees have failed (unpublished data), studies in animal models may be important in the search for yet unidentified factors implicated in the aetiology of this dramatic syndrome.

## Interactions among hepatitis viruses in chimpanzees

The chimpanzee animal model has been instrumental in documenting *in vivo* the phenomenon of viral interference between hepatotropic viruses. This notion has emerged from the observation that simultaneous or sequential infection of chimpanzees with more than one hepatitis virus could alter the course of infection. Several experimental studies have documented that, in chimpanzees with chronic NANBH, superinfection with HAV or HBV is associated with a significantly attenuated acute hepatitis.[154,155] Conversely, chronic HBV

infection does not appear to interfere with the clinical expression of acute hepatitis caused by superinfection with other hepatitis viruses. Instead, superinfection with other hepatitis viruses consistently causes a suppression of HBV replication.[154, 156–158] The most striking example of such an effect is superinfection of chronic HBV carriers with hepatitis delta virus, a unique RNA virus that requires the helper function of HBV for infection.[159] Similarly, superinfection of chronic HBV carriers with HAV results in the transient suppression of serum HBV DNA, usually not associated with variations in the titre of HBsAg. Likewise,[160] superinfection with NANBH virus does interfere with HBV synthesis, as evidenced by suppression of both HBV DNA and HBsAg serum levels.[154,156–158]

The effect of chronic HBV infection on the replication of HCV was unknown until recently. Using PCR, it has been possible to re-evaluate this aspect in sera from previous experimental studies in chimpanzees.[105] One chimpanzee, a chronic carrier of HBsAg, was inoculated with HCV-positive serum from a patient with post-transfusion NANBH. In this animal, serum HCV RNA was detected within 1 week after inoculation, preceding the clinical onset by 2 weeks (ALT peak of 280 U/L), and remained detectable for only 1 week (Fig. 27.4). This unusual pattern of HCV viraemia may be the consequence of an inhibitory effect of HBV infection on HCV replication. The animal developed a transient anti-HCV antibody response detected by the second-generation assay, but failed to develop antibodies to the NS4. It is likely that the short duration of HCV viraemia was responsible for the weak humoral immune response. The animal remained HBsAg-positive throughout the study. Replication of HBV was depressed during superinfection of this chimpanzee with HCV.[156] Thus, there may be a reciprocal inhibition of replication in dual infections by HBV and HCV. Although the short duration of HCV viraemia in this animal did not seem to influence the clinical picture of the acute episode, the acute disease occurred significantly earlier than usual (week 3 after inoculation). Another chimpanzee was inoculated with a commercial source of factor VIII containing both HBV and HCV (Fig. 27.3). This animal developed acute NANBH that progressed to chronicity. Serum HCV RNA appeared 1 week after inoculation, remained positive during the acute phase, and then fluctuated from positive to negative. Nineteen weeks after inoculation and approximately coincident with the disappearance of serum HCV RNA, the chimpanzee became transiently HBsAg-positive (for 1 week). One week later, anti-HBs and anti-HBc became detectable. Liver enzymes remained normal at the time of the appearance of these markers of HBV infection. The delay observed in the incubation period of hepatitis B may result from an inhibitory effect of HCV on HBV replication. This observation is consistent with other studies that documented that co-infection of chimpanzees with inocula containing both HBV and HCV may delay the onset of acute HBV infection.[161]

## HCV and hepatocellular carcinoma

Hepatocellular carcinoma (HCC) is the fifth most common cause of cancer.[162,163] It represents a major public health problem because its prevalence has increased worldwide, especially in Europe and the USA over the past decade. [164,165] In the USA, where the development of HCC is mainly related to HCV infection,[166] estimates of the burden of HCC suggest that its incidence will increase, within two decades, to values similar to those reported in Japan.[167] Cirrhosis represents the highest risk factor, as in 80% of the cases HCC develops in patients with cirrhosis.[168]

The aetiological role of HBV in the development of HCC has been well established by epidemiological studies, [169,170] as well as by studies of experimental carcinogenesis in the woodchuck animal model.[171] Virtually 100% of woodchucks chronically infected with woodchuck hepatitis virus (WHV), a member of the Hepadnaviridae family antigenically and structurally related to HBV,[172] develop liver cancer within approximately 4 years of infection.[173,174] The risk of HCC in chronic WHV infection is similar to that calculated by Beasley[175] for chronic HBV infection in humans: >40% of HBsAg carriers are predicted to die of HCC or some other form of liver disease.

The high rate of progression to chronicity of HCV infection, leading to cirrhosis in 20–35% of the cases, [16,118,161,176–180] makes HCV a major cause of HCC worldwide.[162,163] Before the discovery of HCV, several studies supported the epidemiological, clinical and histological evidence of an association between chronic NANBH and liver cancer.[181–183] With the advent of HCV serology and PCR, the evidence that HCV may be aetiologically associated with HCC has grown,[164,165,184–196] although in some HCC patients occult HBV infection has been recently documented in liver tissue. [197] The mechanism of carcinogenesis by HCV is still poorly understood.[198] Unlike other human oncogenic viruses, HCV is not involved in tumorigenesis by integrating into the host genome, as its life-cycle does not involve DNA intermediates. The study of HCV as a causative agent of HCC is hampered by the lack of an efficient *in vitro* system for the propagation of the virus. Moreover, at present, there are no useful animal models for the study of HCV-associated hepatocarcinogenesis.

Chimpanzees can be readily infected with HCV, resulting in either acute or chronic infection, but HCC has been thus far reported only in one chimpanzee experimentally infected with serum obtained from a patient with chronic NANBH.[199] The animal had developed

acute NANBH that progressed to chronicity. HCC was diagnosed 7 years after the initial inoculation. A homogenate of liver obtained from this animal at autopsy transmitted NANBH to another chimpanzee. HCC, however, was independently found in two other chimpanzees in the same facility, and no evidence of HCV infection could be found in these animals, thus weakening the association between HCV infection and HCC in the first animal.[200] Indeed, many chimpanzees chronically infected with HBV or HCV have been followed for more than 18 and 12 years, respectively, without detecting HCC.[201] This is not surprising, however, as the lifespan of chimpanzees is only slightly less than that of humans. Therefore, if HCV is carcinogenic for chimpanzees, the incubation period must be longer, as seen in humans. The long-term observation of chimpanzees following experimental hepatitis C may eventually help to clarify the issue of the putative role of HCV in the aetiology of HCC.

## Immunity to HCV

Shortly after NANBH was identified, clinical and experimental data suggesting the existence of more than one NANBH agent accumulated.[202] The clinical evidence was based on the sequential occurrence of multiple, distinct episodes of acute NANBH in individuals, such as haemophiliacs,[32,203] drug addicts,[122,204,205] or haemodialyzed patients, [206,207] who were repeatedly exposed to blood or its derivatives. Another clinical finding that lent more credence to this hypothesis was the observation, as noted previously, of two distinct forms of NANBH: one characterized by a short (1–3 weeks) and one by a long (7–9 weeks) incubation period. The former occurred more frequently in haemophiliacs.[30–32] Additional evidence for the existence of more than one NANBH virus came from cross-challenge studies in chimpanzees. These studies documented a clinical pattern similar to that seen in humans and characterized by multiple bouts of acute hepatitis in single animals infected with different inocula.[8,208–212]

Despite multiple lines of evidence suggesting the existence of at least two agents of NANBH, other observations in experimentally infected chimpanzees argued against this hypothesis. The availability of an animal model permitting the repetition of experiments under carefully controlled conditions generated data that generally failed to confirm the existence of multiple NANBH agents. The short incubation period seen in haemophiliacs did not always breed true in chimpanzees infected with factor VIII concentrate preparations and previously implicated in the transmission of such forms of NANBH.[8,33] Similarly, most cross-challenge studies in chimpanzees failed to induce a second episode of acute hepatitis.[33,213,214] To further complicate the picture, recurrent episodes of hepatitis were also seen in chimpanzees that were not rechallenged,[213] as well as in animals rechallenged with the same inoculum.[215,216] Thus, explanations other than the existence of multiple NANBH agents could account for these observations.

After the discovery of HCV, extensive seroepidemiological studies have conclusively shown that this virus is the major cause of both post-transfusion and community-acquired NANBH,[13,118,177]and that other hepatitis agents, if they exist, account for only a minority of such cases. Therefore, other explanations had to be found for the episodes of recurrent NANBH seen both in humans and in experimental models, such as the emergence of neutralization-escape mutants or the failure of the host to mount an effective immune response, leading to reactivation or reinfection with the same virus.

### Lack of protective immunity against re-infection and superinfection with HCV

The degree of protection afforded by primary infection against subsequent re-exposure to the virus is a measure of the maximum protection that can be expected from a vaccine against that virus. To examine the question of protective immunity against HCV, experimental cross-challenge studies in chimpanzees, with both homologous and heterologous HCV strains, were re-evaluated.[217] The patterns of viraemia and antibody response were studied in five chimpanzees sequentially inoculated at intervals of 6 months to 2 years with different HCV strains of proven infectivity, obtained from individual patients included in the NIH prospective study of post-transfusion NANBH. Three chimpanzees were challenged twice and two were challenged four times. All were followed for a mean period of 32 months (range 12–51 months). One chimpanzee was rechallenged with the homologous inoculum, and the remaining four were rechallenged with heterologous inocula. After the first virus challenge, all animals developed acute hepatitis C. Viraemia was transient in four animals, but became chronic in one. All chimpanzees seroconverted to HCV, as measured by first- or second-generation antibody assays. In contrast, none of the animals developed detectable antibodies directed to the E2 glycoprotein, and only two had detectable antibodies to the NS5 gene product (anti-NS5). Each rechallenge of a convalescent chimpanzee resulted in the reappearance, within 1–3 weeks, of serum HCV RNA, although the duration of viraemia during rechallenge was shorter (range 1–10 weeks) than that seen during primary infection (range 11–17 weeks). The recurrence of viraemia was always associated with reappearance of antibodies against the non-structural proteins C100-3 or NS5, an indication that viral replication had recurred (Fig. 27.5). Although there was less biochemical evidence of hepatitis after

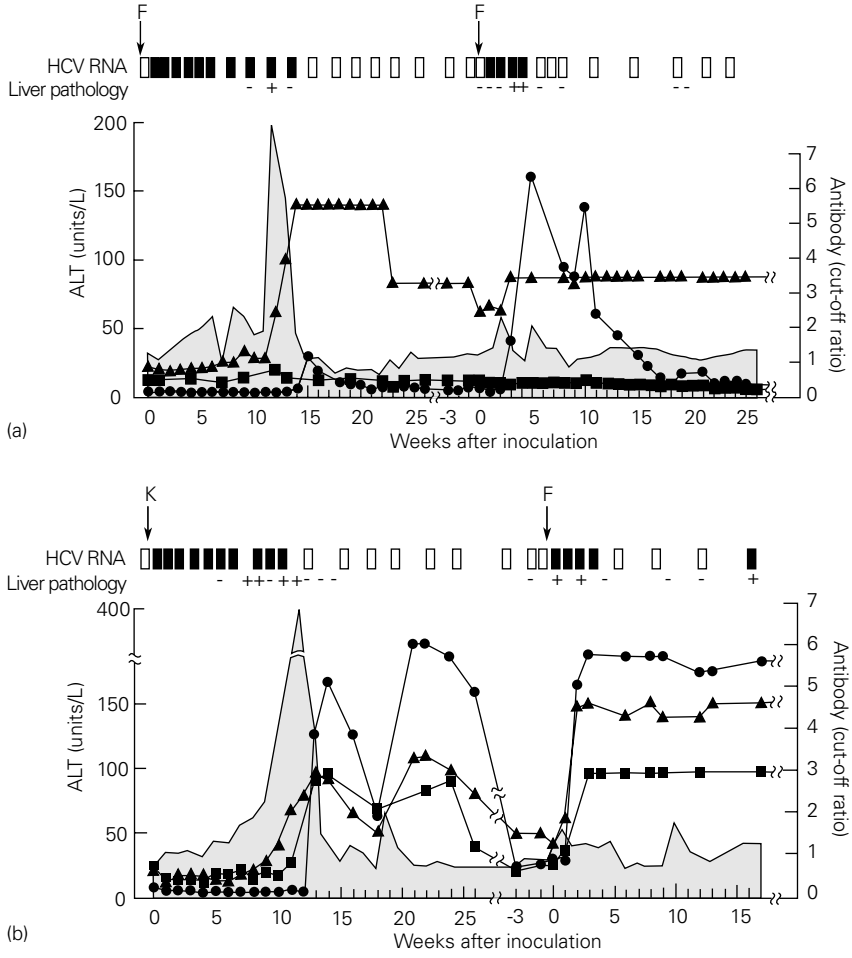

**Figure 27.5** Course of HCV infection in chimpanzee 963 rechallenged with the homologous HCV strain (a) and in chimpanzee 793 with a heterologous HCV strain (b). The grey areas indicate the values of serum ALT. The arrows indicate the time of challenge and the strain used for inoculation. Open bars indicate negative assays for serum HCV RNA by PCR, and solid bars positive assays. Liver pathology indicates necroinflammatory changes rated as negative or positive. First-generation anti-HCV assay is indicated by circles, second-generation anti-HCV assay is indicated by triangles, and squares indicate anti-NS5. The cut-off ratio represents the ratio between the absorbance value for the test sample and that for the assay cut-off; values above 1 were considered positive. (Modified from Farci *et al*.[217] with permission.)

subsequent challenges, the degree of histopathological changes was similar in each bout of hepatitis and the risk of developing a chronic infection was similar to that observed after primary infection. Genetic analysis of the HVR1 demonstrated that the recurrence of viraemia was not due to reactivation of the original challenge strain, but to infection with the HCV strain used for rechallenge (Fig. 27.5). Reinfection occurred several times in a chimpanzee challenged with four different HCV strains and also occurred in a chimpanzee rechallenged with the homologous inoculum. Similar data were reported by Prince *et al*.,[218] who documented the reappearance of HCV viraemia in chimpanzees rechallenged with either homologous or heterologous strains of HCV. Several other studies subsequently confirmed that chimpanzees that had resolved a first episode of acute experimental HCV infection again develop viraemia when rechallenged with either the homologous or heterologous viruses of the same major genotype.[123,124,217–220] As previously observed, however, the duration of viraemia is in most cases significantly shortened following reinfection and biochemical evidence of hepatitis can be observed in only a few cases. Transient infection was also documented following heterologous rechallenge with a different major genotype.[221] The availability of monoclonal virus made possible *bona fide* homologous rechallenge studies, which demonstrated that reinfection is not the result of the emergence of immune escape variants.[123,124] Strikingly, even in this 'best-case scenario' for the host, reinfection can result in persistent infection, as illustrated by studies in two chimpanzees rechallenged with homologous monoclonal virus after resolution of primary infection by monoclonal genotype 1a virus (unpublished data). In one animal, rechallenge resulted in transient viraemia lasting 2 weeks, but in a second animal HCV persisted despite vigorous anamnestic intrahepatic T-cell responses.

Inoculation of both HCV antibody-positive and -negative human immunoglobulin preparations failed to prevent HCV infection in chimpanzees, when administered intravenously 1 hour after virus challenge.[222] Serum HCV RNA was detected in each chimpanzee within a few days after inoculation, regardless of the type of immunoglobulin infused. However, the liver enzyme peak was delayed in the animal that received hepatitis C immune globulin. These data suggest that post-expo-

sure administration of hepatitis C immune globulin can markedly prolong the incubation period of acute hepatitis C, but not prevent or delay HCV infection.

The data obtained in the animal model, that HCV does not induce a protective immune response against reinfection with either homologous or heterologous viral strains, suggested that this mechanism could be the cause of the multiple episodes of NANBH occurring in individual patients, such as polytransfused individuals and intravenous drug users. Evidence that HCV may cause more than one episode of acute hepatitis was obtained in polytransfused thalassaemic children.[223] Three thalassaemic children from Sardinia, Italy, selected among those who experienced more than one episode of acute NANBH, were studied. In each case, the first episode of hepatitis was a classic acute hepatitis C, associated with the appearance of serum HCV RNA and antibody seroconversion. Interestingly, in each case the second hepatitis was as severe as the primary hepatitis and, as previously seen in the chimpanzee model, viraemia persisted in parallel with the development of chronic hepatitis. Sequence analysis of the HVR1 region demonstrated that in two children the reappearance of viraemia was due to reinfection with a different viral strain. Thus, reinfection with HCV may account for the multiple, distinct episodes of acute NANBH documented in thalassaemic children undergoing long-term transfusion therapy. Another important observation related to the ability of HCV to induce a protective immune response in the host is the occurrence of superinfection with heterologous HCV strains, both in humans and in chimpanzees chronically infected with HCV.[224] The first evidence of superinfection was obtained by Kao *et al*.,[225] who documented a second episode of post-transfusion acute hepatitis C in a chronic HCV carrier. By sequence analysis, they demonstrated that the superinfection event was transient and that the new virus was subsequently cleared and replaced by the original strain. Superinfection with HCV has been observed also in the setting of liver transplantation. [152] The superinfection event was again transient, lasting only for 2 weeks. Similar evidence has been obtained in the animal model.[226,227] Okamoto *et al*. demonstrated that chimpanzees chronically infected with HCV genotype 1b can be superinfected with genotype la and subsequently 2a.[226] The superinfecting strain may either replace the original virus or transiently co-exist and eventually replace it. However, the most important observation was that each rechallenge of a chronically infected animal was associated with a new episode of liver damage. These findings have important implications for both the pathogenesis and the differential diagnosis of an acute exacerbation of chronic hepatitis C.

Patients undergoing liver transplantation for HCV-related chronic liver disease have an almost universal recurrence of HCV infection after surgery.[228] The evidence obtained both in humans and chimpanzees strongly suggests that these patients may not be protected against superinfection with different HCV strains. Prospective studies will be important for determining the impact of these events on the natural history of the disease in transplanted patients.

## Neutralizing antibody response against HCV

One of the most important issues related to the immune responses elicited by HCV is the fact that the majority of infected individuals fail to clear the infection despite a competent immune system that produces large amounts of anti-HCV antibodies.[176,229] Only a minority of the patients is able to eradicate the virus. This small subset of individuals might develop an earlier and/or more effective protective immune response. A critical question raised by these observations is whether HCV infection induces in the host the production of neutralizing antibodies (NAbs) and whether such antibodies are involved in the resolution of acute self-limited hepatitis C. It is well established that NAbs play an important role in the prevention of, and recovery from, viral infections and provide the best correlate of protection against several viral infections in vaccinated individuals.

The lack of efficient and reproducible *in vitro* systems for the propagation of HCV in cell culture has severely hampered the study of the host immune response to HCV, in particular the identification and characterization of NAbs. Although some degree of HCV replication has been demonstrated in selected continuous cell lines,[230] none of these *in vitro* systems reproducibly permits the growth of complete, replication-competent HCV. Thus, until recently, the chimpanzee *in vivo* model has remained the only system for the study of antibody-mediated HCV neutralization, although there are obvious limitations related to their routine use, primarily because they are a costly and endangered species. Over the past few years, new systems for testing NAbs to HCV have become available with the development of *in vitro* neutralization assays based on molecular approaches, such as pseudoparticles and virus-like particles. Although the physiological relevance of these systems is currently under investigation, their use has significantly expanded our possibilities to investigate the protective role of humoral immunity to HCV.

## *In vivo* neutralization of HCV in the chimpanzee model

The most conclusive evidence that infection with HCV does elicit NAbs in the host has been obtained in a study performed by *ex vivo* neutralization followed by testing of residual infectivity in the chimpanzee model.[231] How-

ever, the same study clearly demonstrated that the effectiveness of NAbs in resolving HCV infection is limited by a severely restricted spectrum of activity. Plasma from a chronically HCV-infected individual (patient H) was tested for its ability to neutralize HCV obtained from the same patient during the acute phase of post-transfusion NANBH (H77).[232] The infectivity of the inoculum had been previously titrated in chimpanzees.[112] The plasma tested as a putative source of NAbs was collected from patient H at two time-points, 2 and 13 years, respectively, after primary HCV infection.[65] Both plasmas had high titres of antibodies against both structural and non-structural HCV proteins, including anti-envelope 1 (E1) and -E2 antibodies. As a negative control, plasma from a normal blood donor, whose blood repeatedly failed to transmit hepatitis after transfusion into humans, was used. For the neutralization test, the viral inoculum was mixed *in vitro* with each plasma previously heat-inactivated at 56 °C for 30 minutes. The virus–plasma mixtures were incubated overnight at 4 °C and then inoculated into a seronegative chimpanzee. No signs of HCV infection were observed in the animal inoculated with HCV mixed with plasma obtained 2 years after primary infection, providing evidence that infection with HCV does elicit a neutralizing antibody response that can prevent HCV infection in chimpanzees. However, no protection was seen when the virus was treated with plasma collected 11 years later. Thus, the two plasmas derived at different times during the chronic phase of infection differed markedly in their neutralizing capability against H77, although they both contained antibodies against the E1 and E2 envelope proteins.

To investigate the reasons for the differential neutralizing capability of the two plasmas, sequence analysis was conducted on the viral isolates obtained before and after inoculation in chimpanzees. Interestingly, a remarkable degree of genetic divergence was observed both among sequential isolates, documented as early as 2 years after infection, and within the viral quasi-species contained in the H77 inoculum. When the nucleotide sequences of the HVR1 of the viruses recovered from chimpanzees that had received the same virus inoculum were compared, none of the sequences was identical to the consensus sequence of the H77 strain used for inoculation, with differences observed at 2–21 sites. The degree of heterogeneity observed within the HVR1 suggested that the divergent strains were already present within the original viral quasi-species of the inoculum, rather than resulting from an exceedingly rapid mutation rate in the chimpanzees *in vivo*.

Remarkably, similar neutralization data were obtained by Shimizu *et al*.[233] using an *in vitro* system based on a human continuous cell line infected with murine leukaemia virus (MuLV). The H77 virus was neutralized by plasma obtained from patient H for the first 5 years after primary infection, but not by plasma obtained thereafter, including at year 13. Likewise, the virus obtained 13 years after primary infection was not neutralized by plasma obtained early in the disease course, but only by plasma obtained 14 years after infection. Altogether, these *in vitro* and *in vivo* data suggest that HCV does elicit NAbs, but that such antibodies are isolate-restricted and ineffective against some of the strains contained in the complex quasi-species of the inoculum or emerging over time *in vivo*. This strategy may allow HCV to evade the host immune response and may help to explain the development of persistent infection in the majority of infected individuals.

Although these results provided the first formal proof of the existence of NAbs against HCV, historical evidence suggesting their existence was obtained even before the discovery of HCV. Several studies conducted in the 1960s and in the 1970s had indeed documented a reduced incidence and severity of post-transfusion NANBH in subjects treated with serum immunoglobulins.[234–237] Such evidence was subsequently confirmed after the discovery of HCV, especially with the Gammagard accident, when a commercial immunoglobulin product prepared from plasma from which anti-HCV-positive units had been excluded transmitted HCV to recipients.[117,238] Epidemiological and laboratory studies suggested that the exclusion might have removed NAbs and hence compromised the safety of the resulting immunoglobulin product.[117] A direct demonstration of the mechanism by which the safety of Gammagard was compromised was recently provided by Yu *et al*. using chimpanzees and an *in vitro* assay based on neutralization of infectious HCV pseudoparticles.[239] Broadly reactive neutralizing and protective antibodies were detected in Gammagard lots made from unscreened plasma that did not transmit hepatitis C, as well as in experimental immunoglobulin preparations made from anti-HCV-positive donations, but not in Gammagard lots prepared from anti-HCV-screened plasma, which did transmit hepatitis C.

## Identification of the hypervariable region 1 as a major neutralization domain of HCV

As stated above, the limited spectrum of activity documented for anti-HCV NAbs may be directly related to the quasi-species nature of this virus, with the continuous emergence of viral variants that can escape antibody-mediated neutralization. Consistent with this concept, several lines of evidence indicate that the most variable region of the entire HCV genome, the HVR1,[91,92] is a critical target of NAbs. This assumption is based on the fact that the HVR1 contains linear epitopes recognized by patient antibodies,[240–245] and undergoes sequential mutations over time *in vivo*, suggesting that it is subjected to the selective immune pressure of the host.[85,86,246–250] That

an effective humoral immune pressure is required for driving HVR1 variability was elegantly demonstrated by the lack of genetic variation documented in patients with agammaglobulinaemia.[251,252] Moreover, using an *in vitro* test of virion-cell binding, antibodies specific for the HVR1 present in human sera were shown to block the binding of HCV to cells.[253] Another study has recently identified virus binding-neutralizing antibodies directed against putative conserved E2 epitopes, presumably located outside the HVR1.[254] Such antibodies were present at low titres in patients infected with different genotypes of the virus, but at high titres in chimpanzees vaccinated with recombinant E1 and E2 envelope glycoproteins expressed in mammalian cells in a vaccinia system,[255] which were protected from challenge with 10 chimpanzee infectious doses ($CID_{50}$) of the homologous virus.[256] Finally, the HVR1 has a marked similarity to the V3 domain of the gp120 envelope glycoprotein of HIV-1, a disulfide-bonded loop of 35–37 amino acids, which plays a critical role in the HIV life-cycle by directly interacting with the cellular co-receptor and by determining the viral co-receptor preference.[257] Like the HCV HVR1, the V3 loop mutates rapidly *in vivo* under the selective pressure of the host humoral immune response and is a major target of type-specific NAbs.

Conclusive evidence that the HVR1 is a critical target of NAbs was obtained in a study conducted in chimpanzees, which also provided the first *in vivo* model for the emergence of neutralization escape mutants.[94] A hyperimmune rabbit serum was raised against a synthetic HVR1 peptide of 21 amino acids (aa) representing aa 390–410 of the sequence of the predominant strain contained in the H77 inoculum. This antiserum was then used for *in vitro* neutralization of the homologous viral stock, and the residual infectivity was tested by intravenous inoculation of two HCV-seronegative chimpanzees. One animal did not show any signs of HCV infection, whereas the second developed acute hepatitis that progressed to chronicity. Strikingly, the analysis of the viral quasi-species recovered from the latter chimpanzee demonstrated that none of the molecular clones had the sequence identical to the predominant strain that was used to raise the hyperimmune rabbit anti-HVR1 serum. Instead, the viruses emerging *in vivo* were identical to the sequence of two minor variants that were already present within the original H77 inoculum (where they represented 6% and 2%, respectively, of the quasi-species). These findings demonstrated that the anti-HVR1 serum had neutralized the predominant variant bearing the sequence used for immunization but was ineffective against minor variants that were already present at the time of inoculation. These data support the concept that the genetic heterogeneity of the viral quasi-species is involved in immune escape.

The *in vivo* neutralization data are consistent with those reported by Shimizu *et al*.[95] using an *in vitro* system based on HPBMa10.2 human lymphoid cells. The hyperimmune serum raised against the homologous HVR1 peptide neutralized the H77 virus, but not a genetically divergent isolate (H90) obtained from the same patient 13 years after primary infection. This study also identified a smaller segment within the HVR1, spanning amino acid positions 398–410, as the epitope recognized by the hyperimmune anti-HVR1 antiserum.

## *In vitro* neutralization of HCV: pseudotype particle assays

Testing for anti-HCV NAbs has recently been expanded with the introduction of various *in vitro* assays based on pseudoparticles (pp)[258,259] and virus-like particles (VLP) bearing HCV envelope glycoproteins.[260] These recent developments have provided important new tools to determine the titre, breadth and duration of antibody-mediated neutralization against different HCV isolates, to identify the major neutralization epitopes, as well as to investigate the role of humoral immunity in the outcome of HCV infection (viral clearance or persistence). In addition, these assays will be a valuable tool for evaluating potential passive and active immunization approaches against HCV. One of the major concerns regards the cell types used for testing the pp or VLP infectivity, such as the hepatocarcinoma cell line Huh-7 or cultured primary hepatocytes, which are not the same as hepatocytes *in vivo*.

Bartosch *et al*. generated infectious HCV pp that were assembled in cell culture by displaying unmodified and functional HCV glycoproteins onto MuLV or HIV core particles.[258] These pseudotyped retroviruses were infectious for certain cell lines of hepatocyte origin, primarily Huh-7 cells, as well as for primary human hepatocytes maintained in culture. High infectivity of the pp required the presence of both the E1 and E2 glycoproteins of HCV. A similar system, utilizing pseudotyped HIV, was used by Hsu *et al*.[259] who confirmed the infectivity of the pp for hepatoma cells (Huh-7 and PLC/PR5). In both assay systems, specific rodent monoclonal antibodies against the E2 protein were able to specifically neutralize the infectivity of the pp.[259,261,262]

An encouraging result for the clinical validation of the *in vitro* pp assay is the fact that Bartosch *et al*. were able to reproduce most of the previously reported neutralization findings.[261] Using some of the same reagents employed in the chimpanzee studies,[231] as well as in the T-cell assay by Shimizu *et al*.,[233] they were able to confirm the existence of NAbs to HCV in patient H during the chronic phase of infection. The only discrepancy was the result obtained with serum H90, which strongly neu-

tralized the infectivity of H77 in the pp assay, but failed to neutralize in the chimpanzee and T-cell assays, even though all the tests were based on the neutralization of the same H77-derived viruses.[261] This discrepancy is most likely due to the fact that the pp threshold of positivity is only 50% neutralization, whereas the chimpanzee model requires a complete, 100% neutralization, as a single surviving particle escaping neutralization can initiate infection. Interestingly, no anti-HCV NAbs were detected by the pp assay in the serum of patients with resolving infections but relatively high titres were measured in chronically infected patients. In some patients, NAbs were broadly reactive as they cross-neutralized pp bearing different subgenotypes (1a and 1b).[261] The pp neutralization assay was also instrumental in confirming that the HVR1 is a neutralization domain.[259,261] However, NAbs were shown to be directed not only to epitope(s) in the HVR1 of the E2 envelope protein but also to one or more epitopes elsewhere in the viral envelope, suggesting the existence of other, more conserved, neutralization epitopes within the E2 protein outside the HVR1.[259] Thus, besides confirming the existence of NAbs in plasma or serum from chronically HCV-infected patients, these studies have also documented the broad spectrum of activity of such NAbs, suggesting the existence of conserved neutralization epitopes in the HCV envelope.

Using the HIV/HCV pp assay, the role of NAbs has been recently investigated in relation to the outcome of HCV infection in chimpanzees. Logvinoff *et al*.[263] examined the development of NAbs over time in 10 chimpanzees infected with the monoclonal H77 virus. Strikingly, no NAbs were detected in three animals that cleared the infection, whereas strain-specific NAbs were found in six of seven chronically infected animals after about 50 weeks of infection.[263] Likewise, NAbs were detected in only two of seven acutely infected health-care workers, without any association with subsequent viral clearance, while they were present in the majority of chronically HCV-infected patients. In the prototype patient H, longitudinal analysis showed an early but weak NAb response restricted to the autologous virus (H77), whereas cross-reactive NAbs appeared only after 33 weeks of infection.[263] Similar results were recently obtained by Meunier *et al*. who tested both chimpanzee and human sera against heterologous pp (unpublished data). Low-titre NAbs were detected in one of five acutely infected chimpanzees that later developed chronic infection, as well as in patient H during the acute phase of infection, but in only one of four chimpanzees and in none of three patients with acute resolving hepatitis C. By contrast, relatively high titres of NAbs were found in two of five chimpanzees and in patient H during the chronic phase. Interestingly, NAbs raised during infection with genotype 1a cross-neutralized HCV pp constructed with genotype 4a or 5a envelopes, but showed only a limited activity against genotypes 2a and 3a. Finally, both chimpanzee and human sera were shown to contain a still unknown factor(s) that enhances the infectivity of HCV pp.

## Cell-mediated immune responses to HCV in chimpanzees

The role of cell-mediated immune responses in the control of HCV infection has been the focus of extensive research over the past decade both in natural infection in humans and in the experimental chimpanzee model.[264–267] Even though there is a general consensus that the development of early, broad and persistent CD4+ and CD8+ T-cell responses is essential for the *in vivo* containment of HCV replication and, in the best scenario, for viral clearance, the data reported in the literature are not univocal, at least in part due to differences in the study design, in the selection criteria for patients and animals, and in the experimental techniques utilized. The two major settings in which cell-mediated immune responses have been investigated are the resolution of acute hepatitis C and the control of virus replication in patients with chronic HCV infection. In both instances, the primary aim of the studies was to ascertain whether specific CD4+ or CD8+ T-cell responses provide a reliable correlate of protection associated with viral clearance or with a sustained control of viraemia.

## Acute hepatitis C and its long-term outcome

Studies in chimpanzees have been essential for our understanding of the cellular immune responses during acute hepatitis C. In experimentally infected chimpanzees, unlike naturally infected humans, liver tissue can be collected frequently during the acute phase of hepatitis. Cells can be directly isolated from the organ where the virus primarily replicates, and used to quantify and functionally characterize HCV-specific T-cell responses. Furthermore, RNA can be extracted from liver tissue and the mRNA profiles can be determined either by microarray technology, which provides an exhaustive analysis of thousands of genes, or by RNase protection or real-time PCR assays, which permit analysis of a limited number of selected genes.

In acute HIV infection, which shares many similarities with the HCV model, the dramatic reduction of viraemia that commonly follows the peak viral replication has been temporally correlated with a remarkable expansion of virus-specific CD8+ T lymphocytes in blood (up to 10% of total CD8+ T cells, often with prominent clonal Vβ populations), which are therefore believed to play an essential role in virus control. This notwithstanding, definitive HIV clearance is never achieved,

possibly due to the lack of a sufficient helper function of CD4+ T cells, which represent the primary target for HIV replication.[266] In HCV infection, the study of the protective mechanisms and correlates is facilitated by the possibility of comparing individuals (humans or chimpanzees) who spontaneously clear the virus with those in whom the infection progresses to chronicity. The results obtained from the study of cells derived from chimpanzee peripheral blood have not been univocal. Whereas Cooper *et al*. showed a correlation between the appearance in blood of multi-epitope-directed CD8+ T-cell responses and subsequent resolution of primary HCV infection,[267] Thomson *et al*. failed to confirm such a correlation.[268] Strikingly, comparative analysis of liver-infiltrating and peripheral blood-derived HCV-specific CD8+ T lymphocytes demonstrated that only the former, but not the latter showed a correlation with disease outcome.[269] However, some animals in which the virus persisted also had vigorous intrahepatic CD4+ and CD8+ T-cell responses. In these animals a significant decrease in virus titre during the acute phase was followed by persistence at relatively low titres. A subset of animals in which the virus persisted at the same titres found during the acute infection did not have detectable intrahepatic T-cell responses. In contrast, all animals had detectable peripheral T-cell responses. In the animals with detectable intrahepatic responses, these were typically detected after several weeks of infection, prior to the initial decrease in virus titres. Overall, vigorous intrahepatic T-cell responses correlated with a significant decrease in virus titre during the acute phase, but they did not always result in viral clearance.

The relative role played by CD4 ('helper') and CD8 ('cytotoxic') T-cell responses in the control and clearance of acute HCV infection is still a matter of controversy. Experiments of multiple HCV challenges in chimpanzees have been essential in addressing this fundamental issue. The importance of CD8+ T lymphocytes in the resolution of HCV infection has been challenged by the observation that their *in vivo* depletion using a specific monoclonal antibody did not impede the eventual clearance of HCV reinfection in multiply challenged chimpanzees, even though the duration of the viraemic period was prolonged with respect to previous infections.[270] By contrast, antibody-mediated depletion of CD4+ T cells was shown to result in an incomplete control of HCV replication, with invariable progression to chronicity, in spite of the presence of functional intrahepatic CD8+ T lymphocytes, providing compelling *in vivo* evidence of the critical role played by this cellular subset in protective immunity.[271] Consistent with this observation, the development of HCV-specific CD4+ T-cell responses was shown to correlate with a positive outcome of HCV infection following rechallenge.[124,219,272] Strikingly, it has been documented that specific memory CD4+ T-cell responses persist for several years after definitive resolution of primary infection, and vigorous anamnestic responses are observed following rechallenge, whereas $CD8^+$ T-cell responses tend to disappear.[270,273]

The introduction of microarray techniques for the analysis of gene expression profiles has provided new tools for exploration of the early molecular events in the acutely HCV-infected liver, which is beginning to reveal the complexity of the pattern of virus–host interaction.[115,269,274,275] A strong induction of markers of the innate immune response, such as IFN-α-stimulated genes, was documented during the early phase of acute infection in chimpanzees, regardless of the infection outcome.[275] The role of these early responses both in the control of HCV replication and in the eventual outcome of HCV infection is still unclear. Conversely, during the phase of declining viraemia, an upregulation of markers of the acquired immune responses was observed, with high-level expression of IFN-γ-induced genes and other genes involved in antigen processing and presentation.[274,275] Such genes include MHC class II, TAP, selected immunoproteasome subunits (e.g. LMP2), CD8, granzyme A and various chemokines (e.g. Mig, IP10, RANTES).[275] Yet, it is noteworthy that such responses developed both in animals with subsequent viral clearance and in animals that became persistently infected. The difference in outcome could be associated with subtle qualitative and/or quantitative differences in the intrahepatic cellular immune responses, which may be difficult to appreciate using current methodologies. In particular, the nature of the immune cells that are specifically activated during this critical phase and their level of activation may be critical. Also, the timing of these adaptive responses, in relation to the virological events as well as to the early innate immune responses, might be crucial. Finally, it should be emphasized that a number of other genes not related to the innate or adaptive immune responses have been found to be upregulated during the early acute phase of HCV and could potentially play an equally important role for the early control of HCV viraemia or for the outcome. In particular, host genes involved in lipid metabolism were also upregulated in chimpanzees displaying the most effective immune responses, although the significance of these findings is still uncertain.

The emergence of escape mutants from CD8+ T cells may represent one of the most effective viral mechanisms for establishing persistent infection in the host. The relevance of genetic variability, which is one of the hallmarks of HCV, in the outcome of acute hepatitis C has been investigated using the chimpanzee model. An association between failure to resolve HCV infection in chimpanzees and the emergence of CTL-escape variants has been demonstrated. In acutely infected animals in which HCV persists, T-cell escape mutants are rapidly

selected following the initial intrahepatic HCV-specific T-cell responses. Weiner *et al*. described the early emergence, at week 4 after inoculation, of a virus variant bearing a single point mutation within a CTL epitope in the NS3 protein.[276] Such mutation was sufficient to determine loss of recognition by specific CTLs extracted from the liver and persisted for several years. Erickson *et al*. provided evidence that multiple CTL escape mutants appeared simultaneously in MHC class I-restricted epitopes during the acute phase of hepatitis C, remaining fixed in the surviving viral quasi-species for several years without further diversification.[277] Two epitopes were located in NS3, one in NS2 and one in NS4. By contrast, animals with acute resolving infection showed no amino acid changes in most of the CTL epitopes examined. These observations suggest that the CTL response, similar to neutralizing antibodies, may have a viral isolate-restricted spectrum of activity, which would be ineffective against mutant strains that continuously emerge *in vivo*. Thus, it is possible that failure to clear acute HCV infection may result from the selection of virus mutants that escape both humoral and cellular immune responses.

The host immune response was recently studied in two chimpanzees infected with an HCV strain derived from a patient with fulminant hepatitis C (HC-TN), in whom inoculation induced a classical acute hepatitis C that resolved in one animal (Ch 1579) while it progressed to chronicity in the other animal (Ch 1581). Despite their different clinical outcomes, both chimpanzees developed vigorous peripheral and intrahepatic cellular immune responses. Interestingly, intrahepatic CD4+ and CD8+ T-cell responses were stronger and appeared earlier in the animal that developed persistent infection. Sequence analysis of the virus recovered from the two chimpanzees at various time-points during the first year of follow-up showed high mutation rates with high proportions of non-synonymous substitutions, indicating that immune pressure and positive selection occurred in both animals. Changes were not selected until after the initial decrease in virus titres and until after the development of immune responses and hepatitis. Subsequently, however, mutations emerged repeatedly in both animals. Several of these were located within known T-cell epitopes. Thus, this study confirmed that the emergence of HCV mutants might represent an important mechanism for viral persistence, although it does not necessarily predict the final outcome. The emergence of mutant strains within the continuously evolving viral quasi-species would thereby lead to an endless 'cat-and-mouse' game between the host and the virus, with an invariably frustrating outcome for the former.

In conclusion, there is little doubt that the development of an early and broad-spectrum adaptive T-cell immunity constitutes a critical defence mechanism against HCV, which can lead to a sustained containment of viral replication. Convincing evidence has been provided that CD8+ T lymphocytes cannot properly develop and function in the absence of a strong CD4+ T-cell response. Nevertheless, there is also a growing conviction that such T-cell responses may not be sufficient to achieve ultimate clearance of viral infections, nor to maintain long-term control over viral replication in the absence of an equally broad antibody response, as clearly illustrated in the lymphocytic choriomeningitis virus mouse model.[278] Likewise, it is difficult to conceive that effective adaptive immune responses can be generated and sustained without the crucial help of innate immune mechanisms. These considerations emphasize the need to maintain a wide-angle perspective in the study of protective immunity.

## Functional analysis of the HCV genome

The ability to test infectivity of molecular HCV clones in chimpanzees has permitted functional analysis, in which the role of genomic regions believed to harbour important determinants of HCV pathogenesis, or relevant targets for drug development, can be determined. In the first such study, Yanagi *et al*.[127] analyzed the importance of various elements of the 3′ UTR of HCV. The 3′ UTR begins immediately after the ORF stop codon and consists of a short variable region, a polypyrimidine tract and a highly conserved sequence, which constitutes the 3′ terminus of the HCV genome. The conserved sequence of the 3′ UTR potentially forms three stem-loop structures, including a stable stem-loop of 46 nucleotides at the 3′ terminus. A chimpanzee was sequentially inoculated with RNA transcripts of mutants containing large deletions in the 3′ UTR. Mutants in which the entire 3′ terminal conserved region was deleted were non-viable. Furthermore, mutants with only the 3′ terminal stem-loop structure or with deletion of both proximal stem-loop structures of the conserved region failed to replicate in the chimpanzee, indicating that the conserved region was critical for infectivity *in vivo*. A mutant with deletion of the entire poly U-UC region was also non-viable. By contrast, a construct in which the proximal 24 nucleotides of the variable region of the 3′ UTR were deleted, was infectious. Thus, the conserved region and the poly U-UC region of the 3′ UTR, but not the variable region, appear to be critical for infectivity. Kolykhalov *et al*.[126] also found that deletion of the conserved region was deleterious for infectivity *in vivo*. The data obtained in these chimpanzee studies are in agreement with recent data generated in Huh-7 cells with the HCV replicon system,[279,280] in which the various structures of the conserved region of the 3′ UTR were shown to be critical for HCV RNA replication.[281] Furthermore, it was found that the polypyrimidine tract had to consist of at least 26 resi-

dues to permit replication, whereas the variable region of the 3′ UTR was not essential for replication.

The E2 HVR1 region is believed to play an essential role in HCV infection.[84,282] This region evolves rapidly in infected individuals, and there is evidence that the virus is able to escape the host immune response by accumulating mutations in HVR1, which does contain critical neutralization epitopes. Recent evidence in humans has demonstrated a significant increase in HVR1 diversity in acute progressing hepatitis C, whereas resolution was associated with a marked decrease in viral diversity.[149,283] In contrast with the pattern seen in humans are the observations made in chimpanzees infected with HCV molecular clones,[119,120] which demonstrated that chronic HCV infection may develop even in the absence of a viral quasi-species in the inoculum[128] and without the emergence of mutations within the HVR1. These data may appear difficult to reconcile with the evidence accumulated in humans on the role of HVR1 variation as a mechanism of immune escape. However, there are some differences between humans and chimpanzees, which may account for such a discrepancy. Despite similar HCV RNA levels, the HVR1 region in infected chimpanzees undergoes very little sequence variation compared with humans,[284,285] suggesting that chimpanzees exert a weaker positive selective pressure on this region. Also, although the chimpanzee model mirrors well the infection in humans, the disease is commonly milder: whereas the rate of chronicity is similar in both species,[286] in chimpanzees the ALT peak is significantly lower, necroinflammatory lesions are consistently mild and fibrosis is most often absent. Understanding the similarities and differences of hepatitis C in the two species will be important for the study of pathogenesis and the development of preventive and therapeutic measures to control HCV infection.

The biological role of the HVR1 was directly investigated by Forns and colleagues,[287] who inoculated a chimpanzee with RNA transcripts from an infectious clone lacking the HVR1. Serum HCV RNA was detected at week 1 and the animal became persistently infected. The animal, however, had an attenuated infection with unusually low titres of viraemia during the first several weeks after inoculation. The ALT remained completely normal and antibody seroconversion was delayed, occurring at week 37. Mild necroinflammatory lesions did not appear until week 34. However, coinciding with the appearance of five amino acid changes, including two changes in E2, the viral titres increased progressively to reach ~$10^4$ genome copies per mL of plasma, and remained at this level throughout follow-up. These amino acid changes were interpreted as compensatory mutations, as the replication of the deletion mutant without the mutations was impaired. The compensatory role of these mutations has been recently demonstrated by Scarselli *et al*.,[98] who investigated the binding of wild-type E2 and of E2 lacking the HVR1 to a novel putative HCV receptor, the human scavenger receptor class B type 1 (SR-B1). The mutant lacking the HVR1 had a reduced ability to bind to SR-BI+ human hepatoma cells, but this ability was restored by the introduction of one of the compensatory mutations observed in the chimpanzee study, presumably by inducing an HVR1-independent functionally competent conformation of the E2 glycoprotein. Thus, these findings suggested a functional role of HVR1 and confirmed that the genetic variability of HCV provides a rapid and effective mechanism to compensate for a decrease in biologic fitness. The virus recovered before the appearance of consensus mutations was transmissible to a naïve chimpanzee. The chimpanzee became viraemic at week 2 even though the virus titre was low. However, coinciding with the appearance of four amino acid changes in the viral genome, the titre increased rapidly to peak levels of $10^4$–$10^5$ genome copies per mL. One mutation in E2 was the same found in the original transfected chimpanzee. The infection nonetheless resolved at week 18. This *in vivo* study of HVR1 provided definitive evidence that the HVR1 is not essential for the life-cycle of HCV. However, the ΔHVR1 virus was markedly attenuated, indicating an important functional role of this region for HCV infectivity and/or pathogenesis. After compensatory mutations were selected, infection with the ΔHVR1 virus resembled wild-type HCV infection. This study also proved that a host immune response to HVR1 is not essential for viral clearance, as one chimpanzee infected with the ΔHVR1 virus was able to clear the virus. In contrast, HCV persisted in the other chimpanzee infected with ΔHVR1 virus, demonstrating that this region is not required either for clearance or for persistence of HCV in chimpanzees.

The *in vivo* function of the HCV p7 protein is unknown. However, recent *in vitro* data indicate that this 63 amino acid polypeptide has two transmembrane domains connected by a cytoplasmic loop. The amino- and carboxy-terminal tails are oriented toward the ER lumen.[288] In addition, it was reported that this protein has a hexameric form within cellular membranes and might function as a viral ion channel.[289] In a study by Sakai *et al*.,[290] p7 of an infectious genotype 1a clone was mutagenized and RNA transcripts of mutants were tested for infectivity in chimpanzees. Mutants with deletions of all or part of p7 and a mutant with substitutions of two conserved positively charged residues in the cytoplasmic loop were non-viable, demonstrating that p7 is essential for infectivity *in vivo*. Furthermore, the observation that a genotype 1a clone in which p7 was replaced with that of an infectious 2a clone was non-viable indicated a genotype-specific interaction between p7 and other genomic regions. To define which portions of p7 played the most significant role in this interaction, additional chimeras

with the 1a backbone in which only specific domains of p7 had the 2a sequence were tested. Only a p7 chimera with 2a transmembrane domains and cytoplasmic loop and 1a terminal tails was viable. The initially recovered viruses maintained the chimeric sequence. These data indicate that the amino- and/or carboxy- terminal intraluminal tails of p7 contain sequences that play an essential, genotype-specific function.

Kolykhalov *et al*.[126] confirmed the critical importance of the active sites of various enzymatic functions within the HCV genome, such as the NS3 protease, NS3 helicase and the NS5B polymerase. Also, infectious chimeric viruses have been generated from different strains or genotypes, which will permit further analysis of the function and interaction of different genetic components.[121,290,291] Finally, the role of adaptive mutations in the HCV replicon system,[279,280] the development of which was an important breakthrough for basic research on HCV RNA replication, has been examined *in vivo*. A study in chimpanzees, using an infectious clone of the HCV strain from which the replicon was developed, demonstrated that such adaptive mutations markedly attenuated the HCV infectivity *in vivo*.[292] This finding has implications for understanding the biological relevance of data obtained in this *in vitro* replication system and emphasizes the importance of confirming in a biologically relevant system data generated in the test tube or in cell culture systems. Despite important progress in developing novel investigation models, the chimpanzee continues to represent the only biologically relevant system for the study of HCV.

## The future

It is likely that chimpanzees will continue to play an important role in research on hepatitis C. In the absence of suitable cell culture systems in which HCV can be propagated, the chimpanzee model will continue to provide the only means of biologically amplifying rare or interesting strains of HCV. Although the recent development of *in vitro* assays based on pseudoparticles bearing HCV glycoproteins has provided new and valuable tools for studying the humoral immune response evoked by HCV in the host, the chimpanzee model will continue to be essential in validating the results obtained *in vitro* by comparison with *in vivo* studies using the same reagents. Moreover, it likely will continue to be essential for defining the role of immunoglobulins in preventing HCV infection and for testing the efficacy of passive immunoprophylaxis. The chimpanzee model has also been of unique importance for testing the infectivity of molecular HCV clones, thereby permitting for the first time studies of the importance of the genetic elements for virus infectivity, as well as pathogenesis. The high endemicity of HCV infection throughout the world and its high rate of progression to chronicity dictate that prevention should be a high priority in the control of hepatitis C. The chimpanzee model will undoubtedly be critical in attempts at vaccine development. Finally, it is likely that the future characterization of new candidate hepatitis agents will be facilitated by taking advantage of the unique biological amplification system provided by the chimpanzee model.

# Chapter 28
# Autoimmune disorders

Elmar Jaeckel, Michael P Manns

Acute and chronic viral infections have been implicated in the pathogenesis of numerous autoimmune diseases. Autoimmune diseases are defined by loss of tolerance of the adaptive immune response to self-antigens. Usually, autoreactive T cells recognize peptides of self-antigens in the context of self-MHC (major histocompatibility complex).

Our current concept as to the initiation of autoimmune diseases assumes that mostly unknown environmental factors can trigger autoimmune responses in genetically susceptible individuals. The genetic trait is polygenic and the disease-associated genes mostly represent polymorphic variants and not disease-defining genes (Fig. 28.1).

Most peripheral antigens are expressed in specialized epithelial cells in the thymus and the peripheral T-cell repertoire is negatively selected, e.g. self-reactive T cells with high affinity for self-antigen are deleted during thymic development. Therefore, autoimmune T cells usually have a very low precursor frequency and their T-cell receptor has a low avidity for the MHC peptide complex. This might explain why autoimmune diseases develop over extended periods of time (months to years), e.g. autoantibodies to β-cell antigens can be detected years before the onset of type I diabetes. It is therefore difficult to judge if a viral infection is initiating or just precipitating an already ongoing autoimmune disease (Fig. 28.2).

Thus, many viruses have been implicated in the pathogenesis of autoimmune diseases, but there is usually no single agent causing a certain autoimmune disease and a given pathogen can be implicated in various autoimmune disorders, indicating that the 'one organism–one disease' paradigm that is central to Koch's postulates might not invariably apply to microbially induced autoimmune diseases.

Compared with other hepatotropic viruses, hepatitis C virus (HCV) has been implicated in many extrahepatic/hepatic and autoimmune manifestations. The best documented associations are mixed cryoglobulinaemia and the presence of autoantibodies, while the rest remain largely controversial (Table 28.1). Lympho-

ma, renal disease, neuropathy and Sjögren's syndrome manifest incomplete overlaps with the cryoglobulinaemic syndrome. Unfortunately, most reports on autoimmunity caused by HCV used small numbers of patients, inappropriate controls or patient selection bias. In this chapter, we will discuss the mechanism of viral-induced autoimmunity followed by the autoimmune phenomena seen in chronic HCV infection and their therapeutic options.

## Mechanisms of viral-induced autoimmunity (Table 28.2)

It is very difficult to link an exact mechanism for induction of autoimmunity with HCV infection. This is because of the long time lag between HCV infection and onset of autoimmunity (Fig. 28.1), due to differing viral genotypes and quasi-species, and due to genetic heterogeneity and MHC polymorphisms of the host. Furthermore, the T-cell repertoire of patients at the time of HCV infection is not 'naïve', meaning that the pool and specificities of memory T cells has already been shaped by numerous infections during the lifetime of an individual.

The virus may share a sequence homology with self-proteins. Virus reactive lymphocytes might therefore trigger autoimmune responses to a mimicking self-peptide. The epitopes probably involved in molecular mimicry usually share a high sequence homology (especially of the MHC anchoring and the T-cell receptor [TCR] contact residues). Such epitopes are usually defined by searching protein databases followed by testing of cross-reactivity. Likewise a cross-reactive sequence between the hepatic autoantigen cytochrome P450 IID6 and NS5 of HCV has been detected (Fig. 28.3).[1] While such studies may define cross-reactivities of linear humoral epitopes, the disease relevance of this humoral cross-reactivity remains questionable. Molecular mimicry on the T-cell level is much more complex. The mere demonstration of peptide cross-reactivity is not sufficient to explain autoimmunity.[2]

It first has to be shown that the mimicking peptide is indeed generated from the virus and the self-protein and that it is presented by MHC molecules on the surface of antigen-presenting cells (APCs). Next, it has to be shown that T cells recognizing the mimicking peptide are indeed generated during the antiviral immune response. The last two mandatory experiments to prove molecular mimicry can just be performed in animal models. It is necessary to show that the cross-reactive T cell is capable of destroying the target tissue, and that altering the

**Table 28.2** Possible mechanisms of autoimmunity induced by infectious agents

| **Virus-specific factors** interacting with host immune system |

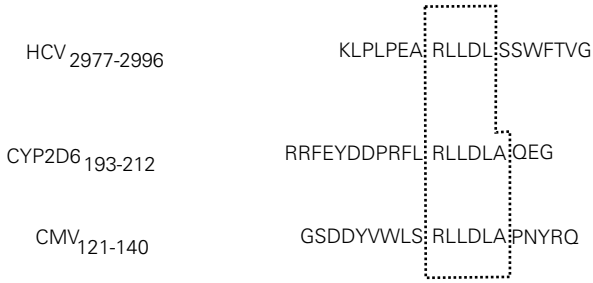

**Figure 28.3** Molecular mimicry between HCV, cytomegalovirus (CMV) and the cytochrome P450 2D6. Comparison of amino acid motifs.

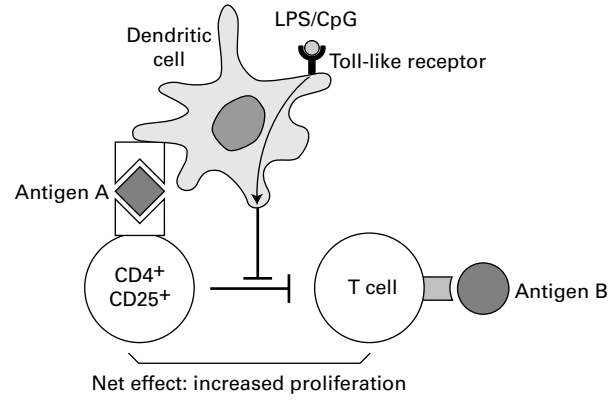

**Figure 28.4** Blockade of CD4+CD25+ T-cell mediated suppression of naïve and activated T cells by toll-like receptor ligation of dendritic cells.

viral epitope without altering viral replication abolishes the autoimmune disease.[2] Proof for an involvement of a viral infection by such criteria stems from infection with herpes simplex virus in autoimmune keratitis.[3] As for HCV, it has been shown that T cells expanded on HCV core protein can recognize and lyse target cells expressing the hepatic antigens cytochrome P450 2A7 and 2A6[4] – the latter is also the target of the humoral immune response in a few patients with chronic HCV infection.[5] The frequency and relevance of these cross-reactive T cells in HCV infection remain enigmatic. So far, there is no conclusive proof for molecular mimicry as the cause of autoimmunity in HCV infection apart from some antibody cross-reactivities.

While molecular mimicry describes cross-reactivities of lymphocytes to similar epitopes, heterologous immunity[6,7] means cross-reactivity of a given T cell to largely unrelated peptides which can even be presented by different MHC molecules.[7,8] Such a largely unpredictable cross-reactivity of virus-specific T cells is due to the degeneracy of the T-cell receptor (TCR)–MHC interaction, where a single TCR can react with up to $10^5$–$10^6$ various peptides. However, such interactions can be studied by use of positional scanning libraries and biometrical analysis.[9] T cells with high avidity, as usually seen in antiviral immune responses, are probably less degenerate in their antigen recognition than low avidity T cells.[10] Although such T-cell cross-reactivities are difficult to study in chronic HCV due to host and virus variants, cross-reactivities between influenza virus and HCV epitopes have been described,[11] suggesting that similar cross-reactivities with self-proteins might exist.

A further mechanism of induction of autoimmunity might be bystander activation of autoreactive T cells by cytokines or proinflammatory stimuli associated with the chronic hepatic inflammation. These non-cross-reactive T cells might be activated by altered and more mature APCs, by cytokine release through components of the innate immune response, e.g. natural killer T (NKT) cells and natural killer (NK) cells. The inflammation caused by HCV infection might further lead to release or modification of sequestered antigens. Although autoimmunity through bystander activation during virus infection can be experimentally demonstrated in animal models,[12] its role in viral infections in humans remains unknown.[13,14]

Microbial superantigens can activate a subset of T cells by cross-linking the MHC molecule with a certain Vβ-subset independent of the antigen specificity of the T cell. This might also lead to activation of autoreactive T cells. Although such superantigens of endogenous retroviruses were implicated in human autoimmune diseases, these results were not reproducible by several other groups. So far, no superantigen seems to be encoded in the HCV genome.

Autoreactive T cells are controlled by active, dominant tolerance involving regulatory cells besides central and peripheral deletion. It was recently shown that microbial infection engaging toll-like receptors on dendritic cells can block such a regulation (Fig. 28.4).[15] This loss of regulation could possibly lead to activation of autoreactive T cells, although this has not been investigated for HCV infection.

## HCV-specific factors predisposing to autoimmunity (Table 28.3)

It has been suggested that the chronic HCV infection with its evolving generation of quasi-species and immune escape mutants might lead to profound activation of the immune system, producing large amounts of immunoglobulins. On the other hand, it should be noted that T-cell responses in chronic HCV are usually rather low, arguing against a broad antigen-specific activation.

**Table 28.3** HCV-specific factors predisposing for autoimmunity

| HCV E1/E2–CD81 interaction |
| B cell, T cell and NK cells |
| (HCV core/apoptosis) |
| (Lymphotropism of HCV) |

Of great interest is the interaction between the tetraspannin molecule CD81 and HCV envelope protein. CD81 is expressed on most human tissues except red blood cells and platelets. A common characteristic of tetraspannins is their propensity to physically associate with a variety of other membrane molecules such as integrins, lineage-specific molecules and other tetraspannins.[16] In the immune system, they are involved in the organization of membrane microdomains of T, B and APCs,[17] thereby modulating the immunological synapse.[18] It has been shown that residues 613–618 of HCV E2[19] bind to the large extracellular loop of CD81,[20] although binding to the E1/E2 heterodimer seems to be stronger.[21]

On B cells, CD81 is part of the B-cell co-receptor besides CD19, CD21 and Leu-13 (Fig. 28.5). CD81 has a short cytoplasmic tail lacking signalling motifs. It is therefore thought that CD81 promotes cellular adhesion.[22] Studies with monoclonal antibodies have indicated that engagement of CD81 can lower the activation threshold of B cells in the presence of suboptimal concentrations of anti-IgM.[23] In T cells, cross-linking of CD81 provides a co-stimulatory signal to CD3, thereby lowering the activation threshold at low antigen concentration.[24] Likewise, it was shown that HCV-E2 can co-stimulate human T cells at suboptimal anti-CD3 stimulation.[25]

For NK cells, it was shown that cross-linking of CD81 by the major envelope protein of HCV (HCV-E2) or anti-CD81 antibodies blocks NK cell activation, cytokine production, cytotoxic granule release and proliferation.[26,27] Conversely, on NK-like T-cell clones, including those expressing NK cell inhibitory receptors, CD81 ligation delivered a co-stimulatory signal.[27]

All the above mechanisms (Table 28.4) might explain a lower activation threshold of B and T cells, possibly leading to autoimmunity. However, the CD81–E1/E2 interaction might even shape the repertoire of activated T cells in favour of self-reactive T cells by reorganizing microdomains on APCs.[17] Recent evidence suggests that the APC is equipped to preorganize MHC-peptide complexes in the absence of T cells (Fig. 28.6). To this end, MHC molecules become incorporated into two types of membrane microdomains: (1) cholesterol- and glycosphingolipid-enriched domains, denoted lipid rafts, that preconcentrate MHC class II molecules; and (2) mi-

**Table 28.4** CD81/HCV–E1E2 interaction

| Antigen-presenting cells | MHC molecules enriched for self-peptides |

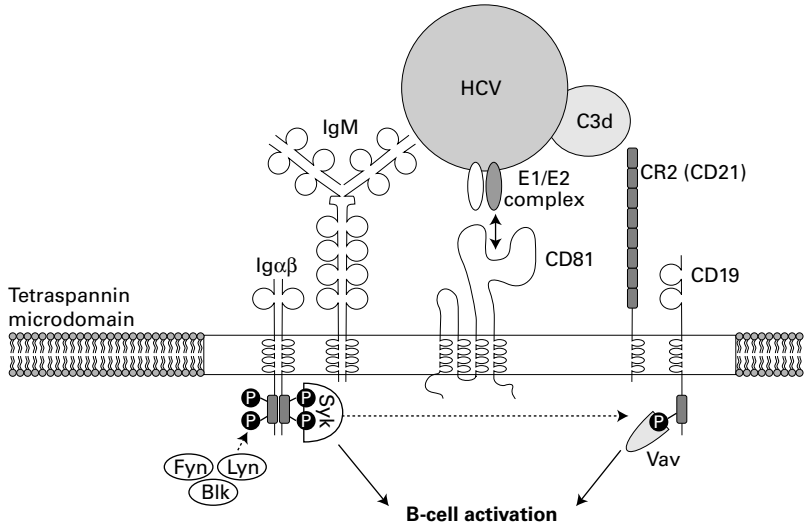

**Figure 28.5** Signal transduction of B cells through the B-cell receptor complex. Cross-linking of the membrane-bound IgM will lead to intracellular activation transduced by Igα and Igβ containing immune receptor tyrosine-based activation motifs (ITAM). A second signal is provided by binding of breakdown product of complement (C3d) to the type 3 complement receptor (CR2). This recruits CD19 into the complex, which contains additional ITAM motifs. The complex of CD19, CR2 and CD81 is called the B-cell co-receptor. CD81 organizes B-cell receptor microdomains and mediates adhesion. It cannot transduce signals by itself.

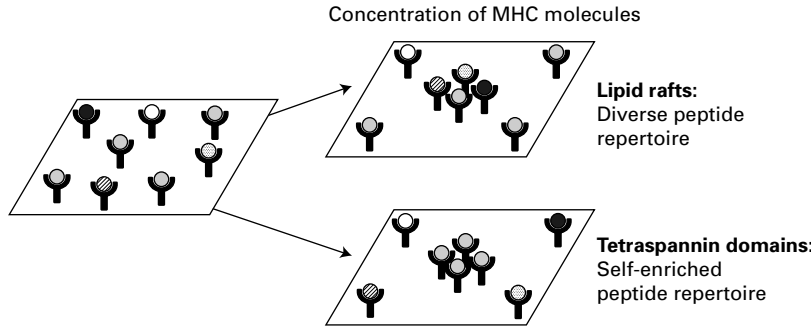

**Figure 28.6** Microdomains on antigen-presenting cells (APCs) are concentrating MHC-peptide complexes for more efficient presentation to T cells. While lipid rafts are concentrating MHC molecules with an unselected set of peptides, tetraspannin microdomains are enriched for MHC molecules containing self-peptides.

crodomains made up of tetraspannin proteins, such as CD9, CD63, CD81 or CD82 that mediate enrichment of MHC class II molecules loaded with a select set of peptides. This narrow repertoire of peptides in tetraspannin microdomains is enriched for self-peptides, thereby presenting self-antigens highly concentrated to T cells (Fig. 28.6).[28] As CD81 is overexpressed in CD5+ B cells of individuals with chronic HCV infection, this might further contribute to the above-mentioned effects of CD81–HCV/E2 interaction on B cells.[29]

It is still controversial as to whether CD81 acts as co-receptor for uptake of HCV. Likewise, it is questionable if there is a relevant lymphotropism of HCV. Finally, even if HCV replicates in lymphocytes the significance of this for virus-induced autoimmunity is uncertain. In various epithelial and mesenchymal cells lines, HCV core protein was able to promote or inhibit apoptosis,[30,31] although these functions have not been evaluated in cells of the immune system.

## Antigen-specific autoimmunity

### Autoantibodies in chronic HCV

The occurrence of autoantibodies is relatively common in patients with chronic hepatitis C infection[32] (Table 28.5). Although initial studies might contain some sampling bias and not represent the autoantibody prevalence in the general population of HCV-infected patients, the prevalence of patients with autoantibodies is higher in chronic HCV infection than it is in chronic HBV infection. However, there are significant variations in prevalence of patients with positive autoantibodies, which might represent ethnic or geographical differences. Also, the determination of autoantibodies is not standardized between laboratories. Most autoantibody titres in chronic HCV infection are lower than those reported in organ-specific autoimmune disease and their relevance for the course of HCV infection, the response to antiviral therapy and the development of organ-specific autoimmunity is generally low. There is, however, the chance that patients with the propensity to develop an autoimmune disease and patients with undiagnosed autoimmune diseases become infected with HCV. In these cases, therapy with interferon (IFN)-α might worsen the underlying autoimmune disorder. This is especially important if the autoantibodies are indicative of autoimmune liver disease, as deterioration of liver inflammation may occur despite reduction of viral load.

### Autoantibodies found in autoimmune liver disease

Anti-nuclear and anti-smooth muscle autoantibodies (aab) have the highest prevalence in chronic HCV infection (Table 28.5). Although these aabs are the hallmark of autoimmune hepatitis (AIH) type I,[33,34] they are frequently found in other autoimmune diseases and chronic inflammation. Their titre in chronic HCV is usually lower than in AIH and most of them have non-homogenous immunofluorescence staining pattern of the antinuclear antibodies (ANAs) and most anti-SMAs

**Table 28.5** Prevalence of autoantibodies (aab) in chronic HCV

| Strong association | Weak or no association |
|---|---|
| Antinuclear aab (ANA): 9–38% | IgG and IgM anti-cardiolipin aab (ACA) |
| Smooth muscle aab (SMA): 5–91% | Anti-neutrophil cytoplasmic aab (ANCA) |
| Liver-kidney microsomes I (LKM1): 0–10% | Anti-gastric parietal cells aab (GPC) |
| Liver cytosol aab type I (LC1): 0–5% | |
| Rheumatoid factor: 8–76% | |
| Anti-thyroid: 9–20% | |

(anti-smooth muscle autoantibodies) are not reactive with actin-containing microfilaments,[35] both diagnostic features of AIH. The exact antigen-specificity of ANAs in chronic HCV remains unknown. It has been suggested that autoantibody-positive patients have a more severe course of their HCV infections.[35,36] However, these findings have not been confirmed by others.

Autoantibodies to liver and kidney microsomes reactive with cytochrome P450 IID6 are one major diagnostic determinant in patients with AIH type II,[37] an autoimmune disease preferentially affecting children. However, it became clear that a substantial proportion of anti-LKM1-positive patients were infected with HCV[38] and did not suffer from AIH type II. The overall prevalence of anti-LKM1 in chronic HCV is low in adult patients (0–6%)[35,39–41] and tends to be higher in children (8–11%).[42,43] Anti-LKM1 aabs are less often seen in American[32,44] and Japanese[41] populations with HCV. The prevalence data might be due to a selection bias and variant expertise in autoantibody testing, as the highest prevalence has been reported from centres involved in studies of autoimmune liver diseases. Prevalence in unselected populations may be around 1%. Development of anti-LKM is not linked to viral genotypes.[45] Anti-LKM1 aab in chronic HCV usually present with similar titres to those seen in AIH type II (Fig. 28.7). However, they less frequently recognize the linear epitope amino acid 257–265 of CYP450 2D6, which is recognized by >60% of patients who are HCV-negative AIH type II (Fig. 28.8).[46,47] It thus seems that AIH type II and anti-LKM1-positive HCV infections present diverse disease entities with different therapeutic regimens.[48]

However, there might be an overlap between both entities in rare cases, which probably have an undiagnosed autoimmune liver disease in addition to HCV infection. One such patient is shown in Fig. 28.9.[47] She presented with chronic liver disease and was HCV RNA-positive. Anti-LKM1 titres, serum transaminases and serum IgG deteriorated under therapy with IFN-α-2b. After discontinuation of IFN therapy, the patient responded proper-

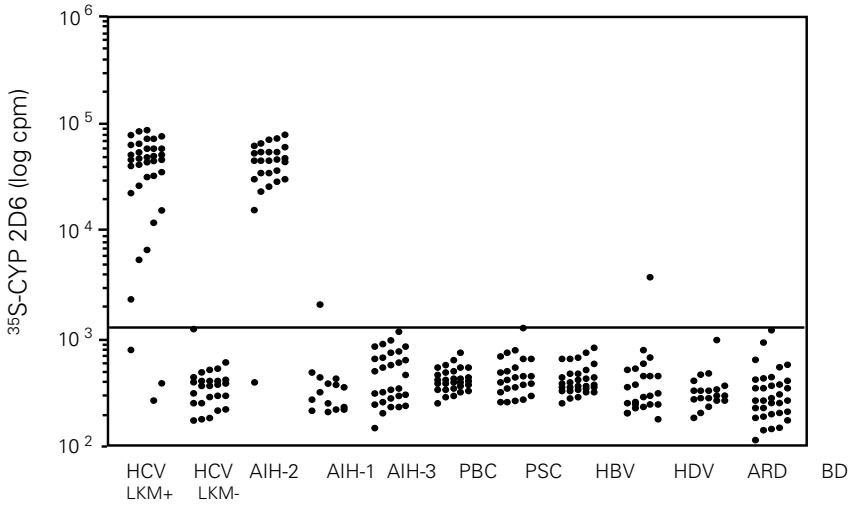

**Figure 28.7** Anti-LKM titres measured by immune precipitation with radiolabelled CYP 2D6 protein. There are similar LKM titres in AIH-2 and hepatitis C.

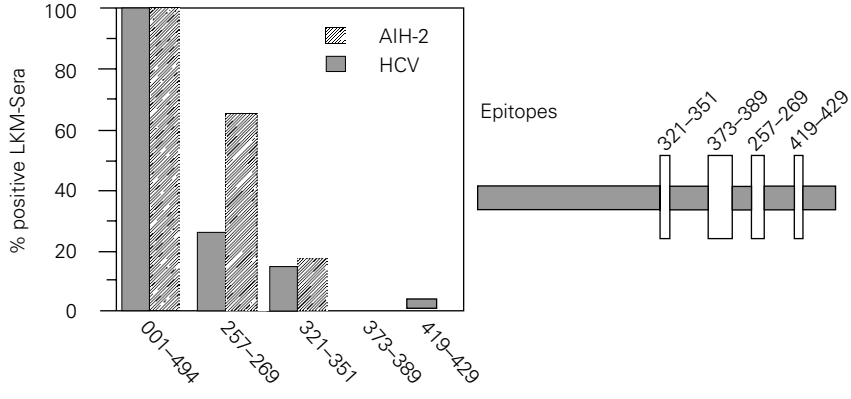

**Figure 28.8** The linear epitope of aa 257–269 is preferentially recognized in sera of patients with AIH type 2.

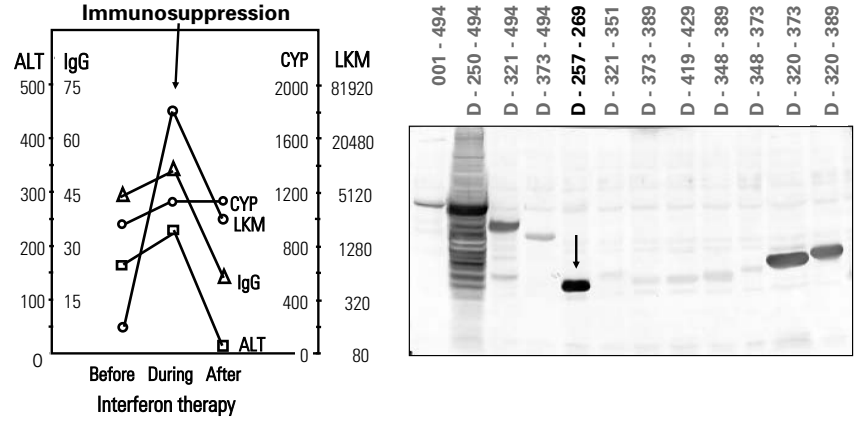

**Figure 28.9** Exacerbation of hepatitis under IFN therapy. The patient presented with chronic liver disease and was HCV RNA-positive. Anti-LKM1 titres, serum transaminases and serum IgG deteriorated under therapy with IFN-α-2b. After discontinuation of IFN therapy, the patient responded properly to immunosuppressive therapy with steroids. Epitope mapping confirmed reactivity with the linear 257–269 epitope, as usually seen in AIH.

ly to immunosuppressive therapy with steroids. Epitope mapping confirmed reactivity with the linear 257–269 epitope, as usually seen in AIH.[47]

In addition, anti-liver cytosol antibodies (LC1)[49] and anti-LKM3 aabs directed against UGT-1.1[50] have been reported in rare cases of patients with HCV infection.

### Thyroid-specific antibodies

Thyroid-specific antibodies (usually anti-thyroid peroxidase or anti-thyroglobulin) have been reported in up to 20% of patients chronically infected with HCV. However, many of these studies lacked proper age- and gender-matched controls. More recent studies using healthy controls rather showed that the prevalence of thyroid antibodies is comparable to age-matched controls.[51] Only 2–5% of these patients will develop thyroid dysfunction which is not different in age-matched controls. However, the prevalence of anti-thyroid autoantibodies increases during IFN therapy (up to 30%),[52,53] and 3–9% of patients develop clinical thyroid dysfunction during or after IFN therapy.[52,53] Positive autoantibodies before therapy, female gender and HLA-A2 are risk factors for the development of thyroid dysfunction under IFN therapy.[54,55] Screening for thyroid disease is therefore recommended in all HCV patients before IFN-α therapy.

### Other autoantibodies

Anti-cardiolipin antibodies occur with low titres in patients infected with HCV, they are not associated with thrombocytopenia or thrombotic events, and the anti-β2-glycoprotein antibodies usually associated with clinical manifestations are not present.[56,57]

Taken together, most autoantibodies found in HCV are probably due to chronic inflammation and B-cell stimulation as described above. However, a few organ-specific antibodies, if occurring at high titres, should raise suspicion of underlying autoimmune diseases. This is of special importance if therapy with IFN-α is planned, as this might lead to exacerbation of the autoimmune disorder.

Likewise type I diabetes, vitiligo and autoimmune thrombocytopenic purpura have been seen in patients with HCV. However, these cases are extremely rare in HCV-infected patients and a pathogenetic role of HCV has not been established in those cases.

Taken together, positive autoantibody titres for aab frequently seen in other diseases and usually presenting with low titres rather present an epiphenomenon. Nevertheless, detection of rare aab of higher titre which are usually specific for a small clinical entity warrants close observation under antiviral therapy, as these might be indicative of underlying autoimmune diseases.

## Antigen non-specific autoimmunity

### Cryoglobulinaemia

Cryoglobulinaemia is defined by the presence of circulating immunoglobulins (Ig) that reversibly precipitate at temperatures below 37 °C. Mixed cryoglobulinaemia (MC) describes cryoglobulinaemia types II and III, which contain a mixture of two different kinds of antibodies as compared with cryoglobulinaemia type I which is found in lymphoproliferative and myeloproliferative diseases where a monoclonal IgG is found in precipitates (Table 28.6). Cryoglobulins can precipitate *in vivo* in small blood vessels (venules, capillaries, arterioles), causing a vasculitis. The link between HCV and cryoglobulinaemia is strong and is supported by epidemiological, molecular and virological studies.

### Prevalence

HCV accounts for almost 70% of all cases of cryoglobu-

**Table 28.6** Classification of cryoglobulinaemias

| Cryoglobulinaemia type | Immunoglobulin | Disease |
|---|---|---|
| I (10%) | Monoclonal Ig, no RF activity | Primary cryoglobulinaemia<br>Lymphoproliferative and myeloproliferative diseases |
| II (60%) | Polyclonal IgG + monoclonal IgM with RF activity IgA, Bence Jones | Secondary mixed cryoglobulinemia; often associated with HCV |
| III (30%) | Polyclonal IgG + polyclonal IgM | Secondary mixed cryoglobulinaemia; associated with infectious, autoimmune and lymphoproliferative diseases |

RF, rheumatoid factor.

**Table 28.7** Prevalence of cryoglobulinaemia in HCV-infected individuals

| Country | HCV-positive (n) | Cryoglobulinaemia-positive (%) | RF-positive (%) |
|---|---|---|---|
| Sweden | 21 | 0 | ND |
| Israel | 90 | 11 | 44 |
| Germany | 132 | 28 | 42 |
| France | 58 | 36 | 70 |
| France | 321 | 56 | 38 |
| Korea | 49 | 59 | 14 |

RF, rheumatoid factor. ND, not done.

linaemia; 0–60% of patients chronically infected with HCV have cryoglobulins (Table 28.7). Besides regional differences in prevalence with high prevalence in southern Europe, some differences might be related to the various sensitivities in testing for cryoglobulins. MCs in HCV are often present at low concentrations (<1%) and are therefore not detected with standard methods. Long-term incubation (8 days) at low temperatures with extensive washing might enhance sensitivity of detection.[58] Meanwhile in situations in which the sensitivity of the cryoglobulin test is known to be low, determinations of rheumatoid factor (RF) may be used as a surrogate marker, as the IgM component of the cryoprecipitate possesses a high level of RF activity. However, if the sensitivity of the cryoglobulin test is expected to be high, the additional determination of RF will not detect many more cases of MC.

There is a slight female predominance in HCV-related MC (60–70%), and patients with MC tend to be older with a longer disease duration.[59] While the presence of HLA-DRB1*11 (DR11) was positively correlated with development of MC, HLA-DR7 seemed to be protective.[60]

## Symptoms

The clinical signs of purpura, arthralgia and weakness were originally described as Meltzer's triad.[61] However, the disease manifestations caused by this systemic vasculitis are more diverse (Table 28.8). Lymphoma, renal disease, neuropathy and Sjögren's syndrome manifest an incomplete overlap with the cryoglobulinaemic syndrome (Table 28.1). However, many HCV patients with MC are asymptomatic. The classical sign of leucocytoclastic vasculitis is palpable purpura of the lower extremities, although other locations might be found as well. A severe systemic vasculitis as seen in polyarteritis nodosa (PAN), often associated with HBV infection, is rarely seen (Table 28.9). MC-related arthritis is usually an intermittent, non-destructive mono- or oligo-arthritis affecting the interphalangeal and metacarpophalangeal joints and the knees. Occasionally, joint pain might be precipitated by exposure to cold. It is important to note that arthralgias are common in HCV, while MC-related arthritis is not. Likewise, weakness might be due to HCV infection rather than to MC-related symptoms.

Peripheral neuropathies caused by MC are frequently under-recognized. They usually present as a peripheral moderate axonal sensory polyneuropathy involving bilateral nerves symmetrically or multiple isolated nerves. They are often painful long before motor deficits develop. As compared with PAN, motoneuropathies are less

**Table 28.8** Symptoms of cryoglobulinaemia

| Symptom | % |
|---|---|
| Skin disease (purpura, urticaria, ulcers, oedema) | 50–90 |
| Arthralgia | 16–60 |
| Weakness | 65 |
| Raynaud phenomenon | 3–40 |
| Neuropathy | 8–40 |
| Renal disease | 25–30 |
| Sicca syndrome | 20 |
| Lymphadenopathy | 3 |
| Fever | 3 |

**Table 28.9** Clinical features of polyarteritis nodosa and mixed cryoglobulinaemia in patients infected with HCV

| Polyarteritis nodosa | Mixed cryoglobulinaemia |
|---|---|
| Life-threatening systemic disease | ... |
| Severe multifocal, asymmetric neuropathy | Moderate, distal, symmetrical neuropathy |
| Malignant hypertension | ... |
| Cerebral angitis | ... |
| Kidney and liver microaneurysms | ... |
| Renal insufficiency | Renal insufficiency |
| Medium size artery | Small and medium size artery |
| Necrotizing vasculitis (occlusion) | Perivascular infiltrates |

common, lesions are distal symmetrical without necrotizing vasculitis (Table 28.9). As involvement is discontinuous lesions may be missed by biopsy.

Renal involvement is common and usually caused by membranoproliferative glomerulonephritis (MPGN) and to a lesser degree by membranous glomerulonephritis or focal segmental sclerosis: 15% (USA)[62] to 60% (Japan)[63] of all MPGN might be related to HCV infection and most but not all HCV-related renal disease is related to MC. Liver disease in patients with MC-related MPGN may be occult,[64,65] and just 40% have other systemic manifestations of MC. Therefore, the diagnosis of MPGN should always be followed by investigation of markers of HCV infection. Patients usually present with nephrotic syndrome. Often, the serum albumin is <3 g/dL with mild renal insufficiency. Few patients progress to dialysis.[62,65] Renal biopsy reveals distinct morphological features consistent with immune complex disease.

The numbers of patients with fever and lymphadenopathy is small. These patients might present the progression of the MC syndrome to non-Hodgkin's lymphoma.

Renal disease, arthralgia and neuropathy may also occasionally be found in HCV-positive patients without MC or RF activity.

## Pathogenesis

Pathology of MC is caused by vascular deposits of cryoprecipitate containing HCV RNA, low-density lipoprotein, IgG and a highly restricted IgM with RF activity (Table 28.10). Virus and anti-HCV concentrations are 10- and 100-fold higher in cryoprecipitates than in serum, respectively.[66] In all, 80% of the monoclonal IgMs found in HCV patients share a major complementarity region named WA (initials of the patients in which these were first described). This WA cross-idiotype is associated with a high degree of rheumatoid activity (formation of immune complexes by avid binding to IgG). These antibodies often express a Vκ light chain derived from a single germinal gene (K325 VL gene). Thus, the repertoire is highly limited with the same cross-reactive idiotype and is encoded by few genes, probably due to close antigenic stimulation. Most of the IgM RF is generated in the liver and in the bone marrow.[67] It is of interest that formation of intrahepatic lymphoid follicles is a characteristic feature of chronic HCV infection[68] and that most intrahepatic mononuclear cells in chronic HCV are B cells expressing IgM.[69] Besides a controversial lymphotropism of HCV,[70] the interaction of CD81 with E1/E2 proteins described above may contribute to the generation of B-cell activation and production of IgM by lowering the activation threshold of B cells. To this end, it is interesting that the CD81 expression of B cells is increased in chronic HCV[71] and highest in patients with MC.[72] Besides this, certain amino acid sequences within the E2 region possessing a high binding affinity to CD81 *in vitro*[19] are associated with the development of MC.[72]

By itself, this process could lead to a type III (polyclonal) MC. Emergence of a dominant clone would subsequently result in a type II (monoclonal) MC. Therefore, type III MC might be the precursor of MC II in some patients.

Emergence of dominant B-cell clone might be due to alterations enhancing B-cell survival. To this end, translocation of the bcl-2 gene from chromosome 18 to 14 results in overexpression of the anti-apoptotic bcl-2 (Fig. 28.10). This translocation has been found in 88% of patients with HCV-related MC compared with 8% in HCV-positive patients without MC and 2–3% in control populations of chronic liver or autoimmune disease.[73] A further genetic alteration by a stochastic hit like a c-myc

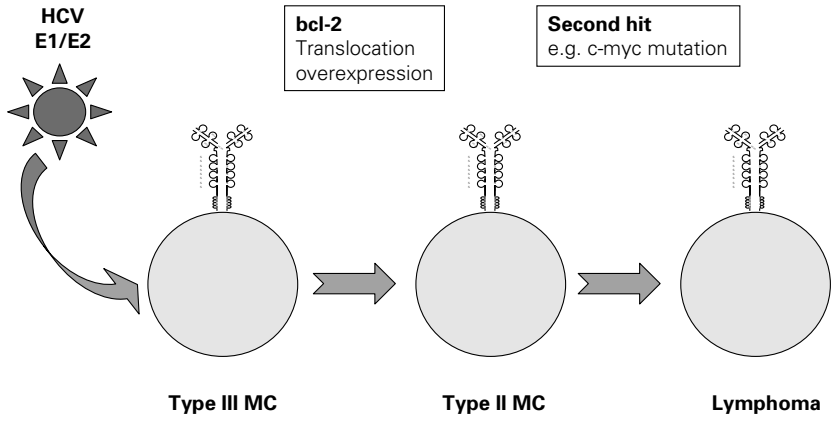

**Figure 28.10** Possible mechanism of HCV-related lymphoma.

mutation might then be sufficient to transform the B cell into a malignant lymphoma blast (Fig. 28.10). Although the aetiological role of HCV in the development of B-cell non-Hodgkin's lymphomas (B-NHL) is controversial, it was shown that up to 56% of chronic HCV patients with MC present with abnormal bone marrow morphology.[74,75] A recent meta-analysis estimated the HCV prevalence in patients with B-NHL to be approximately 15%, higher than that reported not only in the general population (1.5%) but also in patients with other haematological malignancies (2.9%), suggesting a role of HCV in the aetiology of B-NHL. The striking geographic variation in this association suggests that genetic and/or environmental factors are also involved in the pathogenesis of this disorder.[76] Extranodal involvement is common with significant over-representation of liver and salivary glands.[77] Another extranodal site being reported is the stomach, and HCV has been suggested to be a possible cause of mucosa-associated lymphoid tissue lymphoma (MALT).

## Therapy

Before chronic HCV was discovered as the major cause of MC, symptomatic disease was treated with plasmapheresis and/or steroids and/or cyclophosphamide to decrease production of cryoglobulins and inhibit vascular inflammation. More than 50% of patients with HCV-related MC will respond to antiviral therapy with IFN-α, with decreased cryocrit, RF level and improvement in symptoms. However, almost all patients not achieving a sustained response (lasting HCV clearance) will relapse with their MC symptoms after therapy is stopped. The treatment response to IFN in terms of viral clearance is independent of the presence of MC. Most studies were performed with IFN monotherapy using 3 million units tiw. So far, there have been no large studies with pegylated IFNs and ribavirin. However, in most small trials improvement of symptoms was usually linked to suppression of viral replication. It can therefore be assumed that response rates to modern therapeutic regimes might be substantially better than IFN monotherapy. Although a small trial reported an effect of ribavirin monotherapy on MC symptoms,[78] these results have never been confirmed by others. Long-term IFN therapy is effective in controlling symptoms of MC in partial virological responders, particularly for symptoms of cutaneous vasculitis. In the latter patients, a combination of IFN with steroids does not improve results compared with IFN monotherapy. However, combined antiviral and immunosuppressive therapy may be indicated in patients with severe renal disease.

Various disease manifestations respond differently to antiviral therapy. Cutaneous vasculitis responds best to antiviral therapy. Skin lesions disappear in sustained viral responders and improve significantly in the rest under long-term therapy. Improvement is usually seen early.

The influence of HCV treatment on the course of HCV cryoglobulinaemic MPGN is controversial.[79] A recent published study demonstrated that after first-line treatment with prednisone, furosemide or plasmapheresis, antiviral therapy with standard or pegylated IFN-α and ribavirin could improve proteinuria and stabilize creatinine clearance in sustained virological responders.[80] However, in the presence of acute cryoglobulinaemic glomerulonephritis, IFN does not prevent progression of renal damage. Instead, combination therapy with cytotoxic and anti-inflammatory drugs, and sometimes plasma exchange, is recommended.[79] Combined antiviral and immunosuppressive therapy may be indicated in patients without sustained virological response.

The response of MC-related peripheral neuropathy to therapy has been discouraging. Most patients showed either no response or continued with the progression of symptoms under antiviral therapy, although occa-

sionally an improvement may be observed in sustained virological responders.[81] Some gradual improvement might also be expected with long-term IFN therapy (>24 months).[82,83] It might be possible that the poor response of neuropathies compared with skin lesions might be due to the slow speed of regeneration of the target organ. Patients with MC-related neuropathies should be carefully monitored under antiviral therapy, as several cases of dramatic worsening under IFN therapy have been reported. Plasmapheresis might be effective in halting the disease in severe cases.[84]

Low grade B-NHL can regress with IFN therapy and viral clearance, very much like MALT lymphomas may respond to *Helicobacter pylori* eradication.[85] This further supports a possible role for HCV in the pathogenesis of NHL. However, high grade malignancies require systemic chemotherapy. The anti-CD20 antibody rituximab has been shown to be an option in selected patients.[86]

Rare cases of renal disease, skin disease and neuropathies may be seen in chronic HCV infection without the presence of MC. The treatment response in these cases is variable.

### Sialadenitis

A lymphocellular infiltration of the salivary glands has been described in chronic HCV.[87] It resembles Sjögren's syndrome, although it presents with lymphocytic pericapillaritis of milder intensity. The characteristic anti-Ro/SSA and anti-La/SSB autoantibodies are normally lacking, thereby calling into question the autoimmune origin. Up to 10% of patients with chronic HCV infection (mostly of them female) might have xerophthalmia or xerostomia,[88,89] and there might be an incomplete overlap with sicca symptoms seen in MC patients (Table 28.1.). On the other hand, only 5% of patients with classical Sjögren's syndrome are infected with HCV,[90] suggesting that HCV-related sialadenitis and Sjögren's represent distinct entities.

A direct role of the virus has been suggested by studies expressing the HCV envelope proteins E1, E2 in liver and glands; 84% of these mice develop sialadenitis, compared with 2% in control littermates and 0% in HCV core transgenic animals.[91]

### Porphyria cutanea tarda (PCT)

PCT is the most common form of porphyria. The reported prevalence of HCV in patients with PCT varies considerably, but averages around 45%. However, the pathogenesis of the disease is not autoimmune. HCV may be the trigger for clinical expression but is by itself insufficient to cause porphyrin metabolic derangements. Alcohol consumption is an important co-factor to HCV for the development of PCT. In addition, hepatic iron and fat accumulation and increased oxidative stress during chronic HCV infections might be involved in the pathogenesis.

### Diabetes

It is now clear that HCV conveys a risk of developing diabetes mellitus (DM), particularly type 2 DM.[92–94] Hepatic steatosis, insulin resistance and oxidative stress caused by HCV might be involved in pathogenesis, which is not autoimmune. In terms of type I DM, antibodies against β-cells (anti-GAD65, anti IA-2) and against adrenals (anti-21OH) have been found in patients with HCV infection and their titres increased during therapy. However, none of these patients developed clinical disease.[53] Although there are single case reports of type I DM under IFN therapy, these cases seem to be rare[95] and rather represent HCV infection in patients with underlying β-cell autoimmunity.

### Other disorders

Lichen planus, Mooren ulcer's of the eye, idiopathic pulmonary fibrosis, rheumatoid arthritis, autoimmune hepatitis, fibromyalgia and many more have been reported in HCV-positive patients. The prevalence of many of these diseases has either not been studied in larger populations, or has not been investigated in control populations or not confirmed by others.

## Conclusion

In summary, HCV affects many other organ systems besides the liver. Long-term infection is usually necessary for the development of extrahepatic manifestations, some of which are of autoimmune origin. Development of autoantibodies and MC is strongly associated with HCV infection. Renal disease and skin disease, as well as sialadenitis, neuropathy and lymphoma, represent incomplete overlaps with the MC syndrome and some of these entities respond well to antiviral therapy. Organ-specific autoantibodies and other organ-specific autoimmune diseases might represent underlying previously unrecognized autoimmunity rather than induction of autoimmunity by the HCV infection itself. These cases have to be followed closely, as autoimmunity might deteriorate under IFN therapy. The interaction of the HCV envelope proteins E1/E2 with CD81 might be of major importance in the pathophysiology of HCV-related autoimmunity.

Future reports of disease associations with HCV should contain control groups well matched for age, sex, weight, alcohol consumption, disease duration and severity of the liver disease, because these are confounding variables.

# Chapter 29
# Central nervous system complications

Daniel M Forton, Simon D Taylor-Robinson, I Jane Cox, Howard C Thomas

Chronic hepatitis C virus (HCV) infection is a major cause of liver-related morbidity and mortality, with hepatic fibrosis, cirrhosis and hepatocellular carcinoma (HCC) as the dominant clinical sequelae.[1] Hepatic encephalopathy as a consequence of cirrhosis and portal-systemic shunting is the clearest example of central nervous system (CNS) involvement in chronic HCV infection.[2] Neurological involvement due to HCV-associated mixed cryoglobulinaemia most commonly presents as a peripheral sensory or motor neuropathy,[3] but there are also rare case reports of cryoglobulin-associated CNS vasculitis.[4,5] Recently, there has been interest in the possibility of a link between chronic HCV infection and cerebral dysfunction, occurring at an early stage of chronic infection, prior to the development of cirrhosis and unrelated to cryoglobulinaemia. In this chapter, we review the current evidence for such a link and examine the possibility of CNS infection by HCV.

## CNS involvement in HCV-related vasculitis

Chronic HCV infection accounts for between 80% and 98% of cases of mixed cryoglobulinaemia,[6] a condition characterized by the presence of immune complexes between monoclonal or polyclonal immunoglobulin (Ig) M (rheumatoid factor) and polyclonal IgG. These complexes precipitate at low temperatures *in vitro* and contain anti-HCV IgG, HCV RNA and rheumatoid factor.[6] The prevalence of cryoglobulinaemia in chronic HCV infection varies widely and has been reported to be between 0.8% and 66%.[7] This variation is probably explained by varying sensitivity of the methods used to measure cryoglobulins, geographical variation of cryoglobulinaemia and, most importantly, case mix. Cryoglobulinaemia is associated with longer durations of infection and more advanced liver disease. In one study, cryoglobulins were present in 33% of HCV-infected patients with cirrhosis but only in 1.8% of patients with chronic persistent hepatitis.[8] Although cryoglobulins may be frequently detected, the majority of patients do not show clinical or physical signs of the cryoglobulinaemia syndrome, which include vasculitic skin rash, arthralgias, glomerulonephritis and peripheral neuropathies. CNS involvement is unusual but there have been sporadic reports of vasculitic involvement of the brain in HCV-positive patients, usually in the context of detectable cryoglobulins. Reported presentations have included hemiparesis or tetraparesis,[9,10] dysarthria,[11] encephalopathy,[5,12,13] dizziness[14] and communicating hydrocephalus.[15] The main pathophysiological mechanisms are ischaemia or haemorrhage due to diffuse or segmental vasculitis of the small cerebral vessels.[4] Ischaemic lesions may be detectable with cerebral magnetic resonance imaging as hyperintensities, most commonly in the white matter.

Non-specific symptoms of fatigue, arthralgias and weakness are common in patients with detectable cryoglobulins, but in the absence of clinical signs or symptoms of vasculitis, these patients are not labelled as having cryoglobulinaemia syndrome. No relationship has been found between the presence of cryoglobulins and severity of fatigue when vasculitis is absent.[16,17] The clinical significance of low levels of cryoglobulins in chronic HCV infection is not known.

## Evidence for a cerebral effect in HCV infection

The suggestion that chronic HCV infection might cause cerebral dysfunction resulted from initial, anecdotal observations that HCV-infected patients complain of a variety of non-specific symptoms, often in the absence of histologically advanced liver disease.[18] Complaints of fatigue, depression, mental clouding ('brain fog') and a perceived inability to function effectively led to a number of published reports documenting the prevalence of such symptoms and their impact on health-related quality of life (HRQL) scales in cohorts of patients with HCV infection.[17,19–25] However, the presence of these symptoms in the context of HCV infection does not nec-

essarily imply causality, as there are many associated factors which may independently affect patients' perceptions of well-being, e.g. anxiety regarding diagnosis, prognosis and treatment, previous or ongoing substance abuse and associated emotional problems or personality traits.[26] The evidence for a causal relationship between HCV infection and these predominantly neuropsychological symptoms is reviewed below.

## Health-related quality of life

Health related quality of life (HRQL) questionnaires have been used extensively to study both the effect of HCV infection on patients' well-being and the effect of antiviral therapy. The SF-36 questionnaire, a generic health instrument, has been used most widely in this context and generates a health profile, divided into eight separate categories, reflecting physical and emotional performance.[27] The results from several large studies challenge the perception that HCV infection is an 'asymptomatic' disease, with general agreement that HRQL is significantly reduced in HCV-infected patients, independent of the severity of the liver disease.[19,22,23,28] Furthermore, in one study, SF-36 scores were lower in patients with HCV infection compared with those with chronic hepatitis B virus (HBV) infection and were unrelated to the mode of acquisition, i.e. the presence of previous intravenous drug usage.[21] These findings, together with large studies which have shown significant improvements in quality of life (QOL) in combined cohorts of many thousands of patients after successful antiviral therapy, suggest that the viral infection itself is an important determinant of reduced QOL.[22,23,29] There are, however, other relevant determinants of HRQL, which have been described in the literature.[30–32] For clear practical reasons most of the above studies did not blind their subjects to HCV PCR status. The impact of diagnosis is likely to impair HRQL, as has been shown in a small study where patients who were unaware of their diagnosis reported less impaired QOL than patients who knew their HCV status.[30] Despite this, the patients who did not know their diagnosis were still impaired on three scales of the SF-36 questionnaire. It is also possible that some of the improvement in HRQL, seen after successful antiviral therapy, is due to the patients' knowledge of their response. Other studies have demonstrated an association between depression and other co-morbidities and reduced HRQL.[31,32] HRQL studies have been useful in quantifying the impact of chronic HCV infection on patient well-being and in monitoring a response to treatment. However, these studies tell us little about the nature of the symptoms or of the underlying cause of the perceived disability, and are influenced by a large number of factors, many of which are difficult to control for in clinical studies

## Fatigue

Fatigue is the commonest symptom in patients with chronic HCV infection. Numerous surveys have reported the prevalence of fatigue to be between 20% and 80% in HCV-infected patients[16,17,20,24,25,33–35] and have found no association between the severity of fatigue and the degree of hepatitis[17,21,25,31] Furthermore, a number of studies have reported improvements in fatigue after treatment,[16,34,35] although it appears to persist in some individuals despite a virological response. These studies are subject to the same shortcomings as described earlier, as fatigue is a multidimensional symptom and is influenced by multiple inter-relating social, behavioural, psychological and personality factors[31,36,37] and the relative contribution of a biological mechanism remains unclear. Thus, in the context of investigating the presence of a cerebral effect of HCV infection, measured fatigue is likely to be a poor marker.

## Depression

Depression is a common finding in HCV-infected patients.[20,31,32,38–40] It is of considerable clinical importance, as depression may limit the tolerability of treatment with α-interferon (IFN-α)[41] and reduce compliance.[42] The relationship between HCV and depression is complex. Patients with depression may have a higher incidence of HCV infection. The greatest reservoir of HCV infection is in intravenous drug users, many of whom have clinical depression.[43] Conversely, depression may exist as a secondary phenomenon to HCV infection. This may take the form of a reactive depression related to the diagnosis and concerns over long-term health or may be secondary to symptoms such as fatigue and cognitive impairment.[36,40] Finally, a biological effect of HCV infection itself may underlie depression. There is currently little evidence for this theory, although in one blinded study of intravenous drug users, HCV-positive individuals had significantly lower positive affect scores than HCV-negative drug users.[43] In another study, there was no difference in psychological morbidity between HCV-positive and HCV-negative drug users,[44] although in both these studies the effect of HCV may have been masked by the high background prevalence of depression in active drug users. Although depression is an important variable in the context of HCV infection, its occurrence alone is unlikely to be useful in determining whether HCV has a biological effect on cerebral function.

## Cognitive function

A number of studies have evaluated whether HCV infection has an impact on cognitive function.[40,45–48] It is

well established that cognitive impairment is frequently detectable in patients with cirrhosis, even in the absence of clinical encephalopathy and is termed minimal encephalopathy.[2] It is therefore imperative to either exclude patients with advanced liver disease or to study sufficiently large numbers to allow subgroup analyses in any study that tests for a direct effect of HCV infection on cognitive function.

Using a computer-based cognitive battery, selective impairments of concentration and working memory were reported in patients with histologically proven minimal HCV hepatitis.[40] These impairments were not seen in patients who had recovered from HCV infection, either spontaneously or after successful therapy. Furthermore, the presence of fatigue, depression or a history of substance abuse did not explain these findings. In a study by Hilsabeck and colleagues, impairment of various neuropsychological tasks was seen in up to 49% of HCV-infected patients without cirrhosis.[46] The authors found no excess of neuropsychological impairment in HCV-infected patients compared with patients with liver disease from other causes. However, the comparison group included patients with alcoholic liver disease and was small, with only six patients without cirrhosis. Perhaps unsurprisingly, patients with HCV infection and a second chronic medical condition, such as alcoholic hepatitis or human immunodeficiency virus 1 (HIV1) infection, showed greater levels of cognitive dysfunction. Furthermore, patients with more hepatic fibrosis were more likely to show greater cognitive impairment. Whether this was a direct consequence of increased fibrosis or whether it was somehow related to duration of infection was not addressed in the study. The findings of this study were replicated by the same investigators in an independent sample of HCV-infected individuals.[49] Impairments were detected in areas of complex attention, concentration and working memory, with a frequency of between 9.5% and 38%. There were no associations between subjective complaints of cognitive dysfunction or fatigue and performance on the neuropsychological tests, although a relationship was shown between depression, fatigue and cognitive complaints. Krause and colleagues studied a cohort of patients with chronic HCV infection and normal liver function tests (who were therefore unlikely to have cirrhosis) and found distinct attention deficits which were related to measurements of fatigue severity.[45] More recently, the prevalence of mild cognitive impairment was found to be 39% in a cohort of patients recruited for a pharmaceutical trial of antiviral therapy.[48] This study found no relationship between cognitive impairment and hepatic fibrosis or duration of infection. Furthermore, there was no relationship between cognitive impairment and substance abuse, depression and anxiety, in agreement with an earlier study.[40] The pattern of cognitive dysfunction in the above studies is similar, with mild impairments in the domains of attention and working memory. Such findings have also been reported in the medically asymptomatic stages of HIV infection[50] and are consistent with the involvement of subcortical brain systems.[51]

In contrast to these studies, Cordoba and colleagues found no evidence of cognitive impairment in HCV-infected patients without cirrhosis and in those with compensated cirrhosis.[47] Impairments were only detected in patients with previous hepatic decompensation, which were almost certainly due to hepatic encephalopathy. A number of factors may explain this finding. The majority of patients in the non-cirrhotic and compensated cirrhotic groups were enrolled after HCV infection was diagnosed at blood donation. Hence, these groups were positively selected for good health, as symptomatic individuals are unlikely to volunteer to give blood. Furthermore, this study used more stringent criteria for cognitive impairment than the other studies, by performing statistical analyses on raw scores compared with a healthy control group, rather than defining impairment by comparison to population norms. Therefore, a number of questions remain, regarding the prevalence, pattern and significance of cognitive impairment in patients with chronic HCV infection and further studies are required.

Two recent studies have investigated the neuropsychiatric impairment of HCV co-infection in HIV-infected patients. Ryan and colleagues tested the hypothesis that in patients with AIDS, co-infection with HCV results in greater cognitive impairment than matched HCV-negative patients.[52] There was a trend for co-infected patients to perform worse neurocognitively, with impairments of executive functioning. The co-infected patients were also more likely to be diagnosed with HIV-associated dementia. However, this group also had higher rates of previous opiate or cocaine dependence than the HIV-positive, HCV-negative patients. A second study that examined HCV/HIV co-infected patients reported significant impairments in psychomotor speed compared with uninfected controls.[53] However, similar impairments were also seen in HIV and HCV mono-infected patients.

In summary, the above studies show evidence of mild neurocognitive impairment in a proportion of patients infected with HCV, with complex attention, concentration and working memory being most affected. However, with respect to determining whether HCV infection *itself* can cause cognitive dysfunction, the studies described above were all complicated by one or more of a large number of potential confounding factors, e.g. previous substance abuse, co-morbid conditions, HIV co-infection. Although strict entry criteria were observed in some studies and appropriate controls have been employed, it could still be argued that the observed

cognitive impairment in HCV infection resulted from confounding factors, rather than the virus itself, and that an objective physical or physiological measure of cerebral function is required.

## Cerebral magnetic resonance spectroscopy

Magnetic resonance (MR) techniques provide one of the most important tools for quantitative analysis of composition and structure. Importantly, the technique is non-invasive and over the last two decades MR techniques have been applied *in vivo* to image the human brain (magnetic resonance imaging – MRI) and to study biochemical processes (magnetic resonance spectroscopy – MRS). Interpretation of a clinical MR spectrum from the brain can provide information about cellular energetics, neuronal function, osmoregulation, selected neurotransmitter activity, inflammation, membrane turnover and intracellular pH.[54] The proton ($^1$H) nucleus is the commonest nucleus in biological systems and has the highest absolute sensitivity for MR studies. Cerebral metabolites that can be measured with $^1$H MRS include N-acetylaspartate (NAA), an amino acid derivative thought to be located in neurons, choline-containing compounds (Cho) such as phosphoryl- and glycerophosphoryl-choline which participate in membrane synthesis and breakdown, creatine and phosphocreatine (Cr), glutamine and glutamate, which usually form a composite resonance (Glx) and *myo*-inositol (mI), a sugar involved in osmotic regulation within the brain.[55] Semi-quantitative measurements of MR metabolites are often expressed as ratios to Cr.

Several studies have reported characteristic spectral appearances from the brains of patients with cirrhosis, typified by a reduction in the mI and Cho resonances and an increase in the Glx composite resonance relative to the Cr resonance.[56–64] This pattern has only been reported in cirrhosis, usually complicated by hepatic encephalopathy and in patients with hyperammonaemia due to urea cycle diseases.[58] A resonance cannot be specifically assigned to ammonia using cerebral proton MRS but the increase in Glx is likely to reflect ammonia incorporation into glutamine. Elevated cerebral glutamine levels have been interpreted as a consequence of chronic hyperammonaemia. Reduced mI levels may reflect the function of inositol as an osmolyte regulating cell volume in astrocytes. Reduced Cho levels may also be related to a disturbance in cerebral osmoregulation.[65]

To date there have been three cerebral $^1$H MRS studies in patients infected with HCV but without cirrhosis.[40,66,67] In the first study of 30 HCV-infected patients with histologically mild liver disease, there were significant elevations of Cho/Cr in the basal ganglia and frontal white matter, compared with both normal controls and patients with chronic hepatitis B infection (Fig. 29.1).[66] There were no differences in NAA/Cr. Similarly, in the cerebral white matter, Cho/Cr was significantly increased and NAA/Cho was significantly reduced, compared with both other groups. These results suggest that Cho-containing compounds were increased in the basal ganglia and white matter in the HCV patients. There were no statistically significant differences between the HBV group and the healthy volunteers. The elevation in Cho/Cr was unrelated to a history of drug abuse or hepatic encephalopathy. In a second study, patients who performed worse on neurocognitive testing

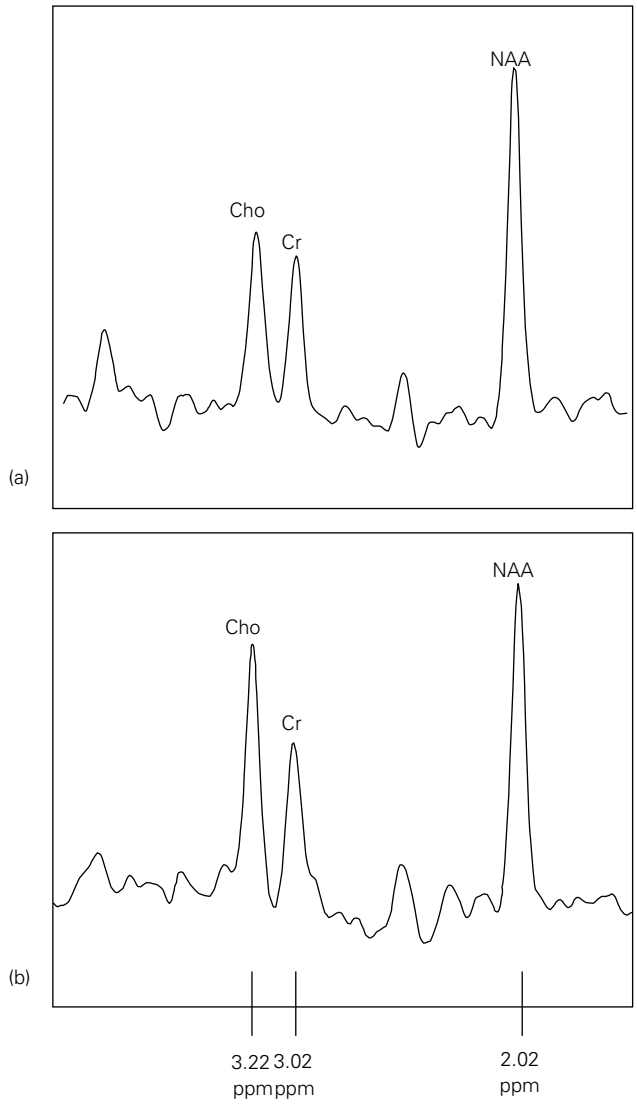

**Figure 29.1** Representative proton magnetic resonance spectra acquired from the frontal white matter. (a) A healthy control. (b) A patient with histologically defined mild hepatitis due to hepatitis C infection. The choline/creatine ratio is elevated in the patient with hepatitis C infection. Cho, choline; Cr, creatine; NAA, N-acetylaspartate; ppm, parts per million.

had significantly higher basal ganglia Cho/Cr ratios, although there were no significant associations between MRS metabolites and specific cognitive functions.[40] The MRS sequences used in these studies precluded the measurement of mI. However, in a subsequent study of HCV-infected patients with mild liver disease, abnormal elevations in frontal white matter mI have been detected, which are significantly correlated with impairments in working memory (unpublished data).

These results suggest, for the first time, that a cerebral metabolic abnormality does exist in a proportion of patients with histologically proven mild HCV infection.[40] It is therefore possible that chronic HCV infection may cause both cognitive impairment and altered brain metabolism by an, as yet, unknown mechanism.

Taylor and colleagues used MRS to determine whether HCV infection may exacerbate methamphetamine-associated neuronal injury.[67] In a small study, reductions in frontal white matter NAA were detected in abstinent HCV-positive methamphetamine users compared to HCV-negative users. No abnormalities were seen in Cho or mI. The authors conclude that HCV may exacerbate drug-induced brain injury, but in the absence of an HCV-positive, metamphetamine-negative group, they were unable to examine the effect of HCV infection in isolation.

Similar $^{1}$H MRS metabolite abnormalities to those reported in HCV infection have been extensively documented in cerebral HIV infection, both in neurosymptomatic and neuroasymptomatic individuals.[68] MRS has been applied to cerebral HIV infection more extensively than any other infection, although data exist on subacute sclerosing panencephalitis (measles),[69,70] cerebral nocardiosis,[71,72] pyogenic and tuberculous brain abscesses,[73] Nipah virus encephalitis[74] and herpes simplex encephalitis.[75] In general, the small number of studies that have examined non-HIV viral encephalitides report reduced NAA/Cr and increased Cho/Cr, which may or may not be reversible.[69,70,74,75]

In cerebral HIV infection, subcortical grey matter and frontal white matter are the principal sites of the metabolic abnormalities, detected using $^{1}$H MRS.[76,77] These findings are consistent with the neuropsychological deficits in minor cognitive-motor disorder (MCMD) and HIV-associated dementia (HIAD) and the predilection of HIV for the basal ganglia.[50,78] In early disease, the most common finding is increased mI/Cr in the frontal white matter.[79,80] Elevated Cho/Cr and decreased NAA/Cr in both the white matter and basal ganglia have also been reported, even in asymptomatic patients.[68,76,77,81] In advanced disease, these metabolic abnormalities are all commonly reported.[82–84] The interpretation of the MRS data has been consistent with the neuropathological findings, i.e. neuronal loss (reduced NAA) and CNS inflammation (increased mI and Cho).[77,82,83]

A finding in the study by Forton and colleagues was the absence of associations between fatigue, depression or QOL measures and cerebral metabolite ratios, despite the presence of impairments in these domains.[66] Although, at first sight, this finding appears to run counter to the possibility of a causative relationship between abnormal cerebral biochemistry and neuropsychological symptoms in these patients, it is important to note that MRS metabolites and neuropsychological test scores do not represent the same phenomenon. MRS metabolites are a direct, biological measure reflecting 'brain pathology' when abnormal. Although neuropsychological tests and symptom scores may be sensitive for detecting brain dysfunction, they do not directly reflect brain injury and may be affected by education, socio-economic and cultural influences, all of which may be relevant confounding variables in this patient group.

Further evidence of subclinical impairment of brain function in chronic hepatitis C infection comes from Kramer and colleagues, who used P300 event-related potentials, a neurophysiological test of cognitive processing, in a large cohort of patients with chronic HCV infection.[85] Although cirrhotic patients were not excluded, subgroup analyses were made. HCV-infected patients had delayed P300 peak latencies and reduced amplitudes compared with age-matched healthy subjects; 17% of HCV-infected patients had P300 latencies outside the age-adjusted normal range, suggesting slight but significant neurocognitive impairment. Subgroup analyses indicated that the findings were not accounted for by a history of substance abuse, cirrhosis or alcohol. Prolonged P300 latencies have also been reported in HIV infection.[86]

The parallels in the MRS and P300 data between HCV and HIV infection, where infection of cerebral microglia,[78] possibly via infected monocytes entering the brain, and subsequent microglial activation occur, raises the prospect that the HCV might also infect the CNS.[18]

## Virological studies

### Evidence for extrahepatic replication

The detection of markers of HCV infection and replication in human tissue is complicated by a number of factors. First, the level of viral replication in the liver, the major site of productive HCV infection, is relatively low. Viral kinetic studies have shown that, although approximately $1 \times 10^{12}$ virions are produced daily by the infected liver, this only corresponds to a virion production rate of 50 particles per hepatocyte per day, if it is assumed that a liver contains $2 \times 10^{11}$ hepatocytes and 10% are infected.[87] Second, cytoplasmic viral RNA degrades rapidly, necessitating rapid freezing of tissue specimens after biopsy. Madejon and colleagues have shown that

a delay of between 4 and 30 minutes before freezing of fresh liver biopsies resulted in a 20% and 64% loss in detection of positive- and negative-strand HCV RNA, respectively, by RT-PCR.[88] The rapid degradation of viral RNA is especially relevant when analyzing post-mortem tissue, where there is invariably a significant period between death and sample collection. The detection of HCV RNA in tissue is further complicated by relatively high titres of circulating virus. Demonstration of HCV RNA by RT-PCR in a tissue or cell lysate does not prove viral infection and replication in that tissue as contamination from serum-derived virus is likely.

Two main strategies have been developed to address these issues, each with its own methodological difficulties.

### *HCV quasi-species*

The analysis of HCV quasi-species has been used to support the hypothesis that HCV replicates in various extrahepatic sites, including B and T lymphocytes, monocytes/macrophages and dendritic cells.[89–98] These studies presuppose that different HCV variants are tropic to different cellular compartments, as is the case for HIV.[99,100] Hence, the demonstration of different viral sequences in extrahepatic cell or tissue extracts compared to liver and serum is considered indicative of viral replication in those sites. An alternative explanation is that certain HCV variants are adsorbed to or are phagocytosed by PBMCs, and that the mere presence of different viral sequences does not prove viral replication. This issue has been addressed by some of the studies outlined below.

Molecular cloning of RT-PCR products, followed by sequencing of individual clones, is the most accurate method currently available for analysing quasi-species. Although labour-intensive, this method allows precise analysis of the genetic diversity of the quasi-species, provided that sufficient clones are sequenced. It has been calculated that 20 clones are necessary to prevent artifactual simplification of the quasi-species.[101] The genomic region most commonly cloned has been the hypervariable region 1 (HVR1) within the envelope protein E2. This technique has generated conflicting results regarding the relative complexity of the quasi-species distribution in liver and serum. Cabot and co-workers reported that the viral complexity of the HCV quasi-species in liver was greater than in serum.[102] In a later study, the same group argued against quantitatively important extrahepatic replication on the basis of their sequence analysis.[103] In contrast, Navas *et al*. reported greater genetic complexity and diversity of the HCV quasi-species in serum compared with both liver and peripheral blood mononuclear cells (PBMCs), implying that extrahepatic sites may release HCV into the circulation.[92] Using the same methodology, Okuda *et al*. reported unique HCV amino acid sequences in PBMCs in eight of thirteen patients with chronic hepatitis C.[94] To exclude an effect of viral adsorption to PBMCs, this study pretreated the PBMCs with trypsin and used appropriate negative controls. The distribution of HCV within subsets of PBMCs was addressed by a study which found a non-random distribution within B lymphocytes and monocytes/macrophages, consistent with viral replication.[95] However, the negative strand was not detected by RT-PCR in these subsets. More recently, phenetically distinct variants have been reported in B cells and monocytes. HCV variants complexed to immunoglobulin were removed from these preparations and differed from the cell-derived sequences, suggesting that variants complexed to immunoglobulin and bound to Fc receptors on the cell surface were not being detected.[97]

In common with a number of other positive-stranded RNA viruses within and outside the Flaviviridae, the 5′ untranslated region (UTR) of the HCV genome contains a highly conserved element, the internal ribosomal entry site (IRES).[104,105] This element consists of three stem-loop structures (domains II, III, IV) and a pseudo-knot, and is recognized by ribosomes, thus allowing translation of the viral polyprotein in a cap-independent manner.[106,107] Although this region is the most invariant of the HCV genome, it does exhibit a quasi-species distribution in human serum.[108] Naturally occurring mutations within this region are likely to be of biological significance and have been shown to lead to important differences in translation efficiency, both in cell-free systems and in cell culture.[108–111] Furthermore, the effect of these mutations may be to either enhance or abrogate translational efficiency in different cell lines, suggesting that interactions between specific cellular factors and the IRES may be important in determining cellular tropism.[108,109,111] A parallel may be drawn with poliovirus (PV) where mutations within the PV IRES result in reduced translational efficiency in neural but not HeLa cells, in association with a reduction in neurovirulence.[112]

Several groups have reported nucleotide substitutions in the HCV IRES, which are associated with lymphoid replication.[90,109,113,114] Long-term cultures of HCV in lymphoblastoid lines (HPBMa and Daudi cells) resulted in the selection of three nucleotide substitutions (G to A at position 107, C to A at position 204, G to A at position 243), which were not detected in the wild-type inoculum.[113] In a subsequent experiment, these mutations increased IRES translational activity in lymphoid cell lines.[109] These polymorphisms have also been detected in HCV sequences from extrahepatic compartments in patients with wild-type sequences in the serum. The A204 polymorphism has been detected in PBMCs[114] and monocyte/macrophages,[115] and the A107, A204, A243

polymorphisms have been detected in monocyte-derived dendritic cells.[111]

Single-stranded conformation polymorphism (SSCP) is an alternative, less laborious method to analyze HCV quasi-species. It relies on the differential gel mobility of PCR products containing different nucleotide mutations, and thus provides a general representation of the quasi-species complexity but not diversity. Laskus *et al*. used this technique in addition to sequencing in patients co-infected with HCV and HIV, and demonstrated unique 5′ UTR sequences in PBMCs, adrenal, pancreas and lymph nodes.[116] Negative-strand HCV RNA was detected in the same tissues by strand-specific RT-PCR. This widespread distribution of HCV was attributed to immunosupression due to HIV infection. However, the same group has more recently reported SSCP data in immunocompetent individuals, supporting the presence of HCV in PBMCs, thyroid and pancreas.[114] Experiments were also performed to exclude the possibility that PBMCs can concentrate a subset of circulating virus, differing in the 5′ UTR region. The authors concluded that adsorption of specific variants to PBMCs and other cells did not explain their results. Interestingly, they were unable to conclude that this is also the case for the HVR1. Several other studies have used SSCP to demonstrate quasi-species differences between serum and PBMCs.[89,91,93] Finally, SSCP has been used to analyze HCV quasi-species detected in cerebrospinal fluid (CSF) in both HIV-positive and HIV-negative patients.[117] Although there was no microscopic evidence of blood contamination of the CSF, the quasi-species analysis suggested that the virus was serum-derived.

### *Detection of negative-strand HCV RNA*

The very low levels of HCV found in infected individuals have meant that RT-PCR is often the only suitable method to detect viral RNA. There are few reports of HCV RNA detection from liver extracts by Northern blot hybridization analysis.[118,119] In order to demonstrate viral replication in the liver, many workers have demonstrated the presence of HCV negative-strand RNA, the postulated replicative intermediate, by RT-PCR.[120,121] Indeed, soon after the discovery of HCV, the negative strand was widely reported to be present in serum and PBMCs.[120,122–124] However, the strand specificity of these early studies was questioned in subsequent work.[125,126] Three main mechanisms were proposed to explain the lack of strand specificity, based on the demonstration that excess positive-strand HCV RNA may act as a template for the synthesis of a 'false' negative strand: false priming of the positive strand, self-priming of the positive strand and random priming by extraneous nucleic acids.[126] These factors were particularly important as the reverse transcriptase reactions were generally performed at 42 °C, a temperature at which the secondary structure of the template RNA is preserved. This has special relevance for the 5′ UTR, which has a hairpin secondary structure that predisposes to self-priming.[127]

Several solutions to these problems have been proposed including the use of rTth, a thermostable enzyme with both reverse transcriptase and DNA polymerase activity under different conditions. False priming is prevented because cDNA synthesis can occur at high temperatures,[128] allowing a 10 000-fold discrimination between the detection of the correct and incorrect strands.[129]

Although the initial reports that HCV readily replicates in substantial numbers of PBMCs and serum have been questioned,[128] data from other strand-specific RT-PCR studies and other experimental evidence have led to an emerging consensus that HCV either replicates at a low level in PBMCs or that the proportion of infected PBMCs is low, in both immunocompetent[127,130,131] and immunocompromised individuals.[115,132] Other studies have demonstrated HCV-negative strand in bone marrow and haematopoietic progenitor cells.[133,134] It has recently been suggested that even after apparently successful clearance of HCV RNA leading to undetectable serum HCV RNA using standard clinical assays and normal liver function tests, PBMCs may still harbour low levels of replicating strains.[98] In this study, positive- and negative-strand HCV RNA was detected in PBMC fractions using a highly sensitive RT-PCR nucleic acid hybridization technique and strand-specific RT–PCR of PBMCs after culture with a T-cell proliferation-stimulating mitogen. These results imply that HCV RNA can persist at very low levels in PBMCs, and that an intermediate replicative form of the HCV genome can persist for many years after apparently complete spontaneous or antiviral therapy-induced resolution of chronic hepatitis C.

## Detection of HCV RNA in the CNS

The above techniques have recently been applied to examination of autopsy brain samples to seek evidence of HCV replication in the CNS. Radkowski and colleagues used a strand-specific method and detected HCV negative-strand RNA in a number of brain structures including subcortical white matter, medulla oblongata and cerebellum in three of six patients who died from complications of chronic HCV.[135] In one of these patients, the A204, A243 polymorphisms were present in the positive and negative strands isolated from the cerebellum but were absent from serum. In this patient, a negative-strand sequence obtained from a mesenteric lymph node was identical to the cerebellum-derived sequence, suggesting a lymphoid origin for the brain variants. In a second patient, who was HIV-positive, analysis of the NS5 region indicated that the genotype

of the brain strain was 3a, whereas the circulating serum genotype was 1b. In a second autopsy study, the same group detected negative-strand RNA in subcortical white matter and cerebral cortex from two patients who died after liver transplantation for chronic HCV infection.[136] In these two HIV-negative patients, the A204, A243 polymorphisms were present in both tissue and serum sequences.

The same group have also analyzed cell pellets from cerebrospinal fluid (CSF) obtained from HIV-positive patients with meningitis or cerebral toxoplasmosis.[137] In three patients the A107, A204, A243 polymorphisms were detected in CSF cell pellets and circulating PBMCs. Genotyping by sequencing of the NS5b region revealed different genotypes in the CSF pellets and PBMCs compared with serum in two of three cases (serum 3a, PBMC/CSF cells 1a; serum 1a, PBMC/CSF cells 4c; serum 1b, PBMC/CSF cells 1b). Although the authors suggest that their results show that HCV neuroinvasion could be related to trafficking of infected leucocytes across the blood–brain barrier by a mechanism analagous to HIV infection, it seems likely that in these patients, the sequences were derived from PBMCs that had crossed a blood–brain barrier, compromised by the unrelated meningitis/toxoplasmosis.

In another autopsy study which used cloning and sequencing to define quasi-species for the IRES and HVR1 in brain, liver, lymph node and serum samples, there was evidence of tissue compartmentalization of sequences in the brain in two of three patients[138] Between 24% and 55% of brain-derived IRES sequences were not seen in the serum, and there was significant phylogenetic and phenetic clustering of the brain and lymph node HVR1 sequences, consistent with tissue derivation as opposed to serum contamination. The A204, A243 polymorphisms were again detected exclusively in the brain in one patient. A dicistronic reporter vector was used to test whether brain-derived variants showed altered IRES-mediated translational efficiency, which might favour CNS infection. The translational efficiencies of the brain-derived IRES sequences were generally reduced compared with the master serum and liver sequences in rabbit reticulocyte cell lysates and human liver and brain cell lines: HuH7 (liver) and CHME3 (microglial). The A204, A243 mutations showed preserved translational efficiency in HuH7 but reduced efficiency in CHME3 cells. These data suggest that IRES polymorphisms, including A204, A243, may be important as a viral strategy of reduced translation to favour latency in the CNS as well as other extrahepatic sites, such as dendritic cells.[111]

## Conclusions

The possibility of a cerebral effect of HCV has been investigated at three different levels: neuropsychological, metabolic and virological. The findings support the concept of a biological effect of HCV infection on cerebral function, which may be mediated by low-level infection of the CNS by HCV (Fig. 29.2). However, there are many unresolved questions, which can only be addressed by further research.

The significance of mild impairments in cognitive function, which do not progress to dementia, remains unclear and may cause some to question their clinical significance. These impairments may, however, begin to explain the high prevalence of neuropsychological symptoms in this patient group, many, if not the majority of whom, do not have liver dysfunction. As a result, chronic infection with HCV may come to be regarded as an infectious disease, with liver complications, rather than a primary liver disorder and the indications for antiviral therapy may be broadened. The long-term effect of antiviral therapy on cognitive function is unknown. Studies to examine this could shed further light on the relationship between HCV viraemia and cognitive function. Such studies would be complicated by the neurological effects of IFN-α treatment itself[139] and would require a long wash-out phase after the end of treatment. Indeed, there is emerging evidence that gains in QOL and symptoms only occur some time after cessation of treatment.[16] However, evidence that successful viral eradication reverses the mild cognitive impairments in HCV infection would provide convincing evidence that the virus is key in their aetiology.

The demonstration of elevated cerebral Cho/Cr ratios in patients with chronic HCV infection, using $^{1}H$ MRS, again supports the central biological hypothesis. However, these findings are not highly specific for any pathological process. Elevations in choline-containing compounds have been reported in cerebral HIV infection,[140] but also in bipolar depression[141] and chronic fatigue syndrome.[142] Although it is postulated that increased cerebral Cho/Cr ratios may be due to altered membrane fluidity in activated microglia, as in HIV infection,[143] the data do not prove this. At present, it can only be concluded that a cerebral metabolic abnormality occurs in some patients with histologically mild hepatitis C and that the cellular mechanism is unknown. Longitudinal studies to investigate the effect of antiviral treatment on cerebral metabolism could provide evidence regarding reversibility of the observed effects but, again, could be complicated by the neurotoxicity of IFN-α.

The presence of unique HCV RNA sequences in autopsy brain tissue, which are phylogenetically distinct from liver and serum variants, raises the possibility that brain-specific HCV variants may infect the CNS. However, there is currently no experimental evidence to suggest how HCV may enter the CNS. The evidence for HCV

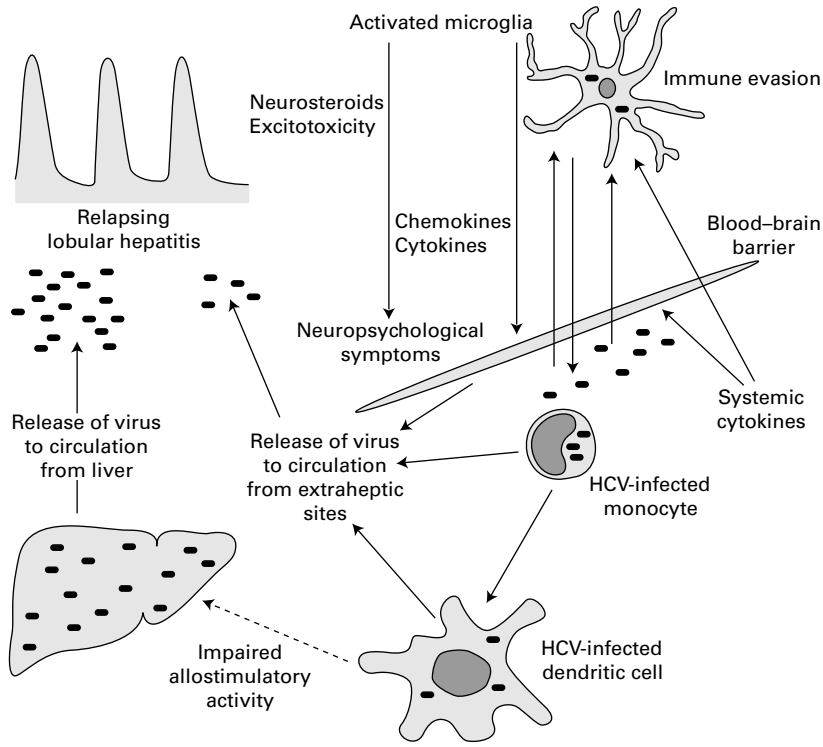

**Figure 29.2** Proposed model for hepatitis C infection of cells of monocytic lineage. Infection of circulating monocytes and/or bone marrow precursors, microglial cells and dendritic cells may explain a number of clinical and virological features of chronic hepatitis C infection. Low-level immune activation within the brain may explain to some degree the neuropsychological symptoms and cognitive impairments observed in some patients.[40,46,49,66,85] CNS immune activation may result from direct infection of the brain,[135,136,138] possibly introduced from infected monocytes[95,97] to microglial cells and/or as a result of elevated circulating and cerebral cytokine levels.[26] Together with other potential sanctuary sites, such as dendritic cells,[96,111] the brain may allow low-level viral replication to occur without eliciting an immune response sufficient to terminate it. The pattern of relapsing lobular hepatitis seen in HCV infection may represent a repeated cycle of immune lysis of infected hepatocytes, followed by repopulation by virus from low replication sites.[138] Similarly, it is possible that the relapse seen after initially successful antiviral treatment may be a result of persistent low-level replication in sites such as the brain and dendritic cells, which may be less responsive to therapy.[8]

infection of monocytes and bone marrow precursors has been reviewed. There is good evidence that microglial cells and resident perivascular macrophages within the brain turn over continuously and originate from bone marrow-derived precursors and monocytes.[144,145] It is therefore conceivable that HCV-infected monocytes or progenitor cells may introduce the virus into the CNS by a 'Trojan horse' mechanism, triggering a number of pathways that may result in neuronal dysfunction.

The immune response to HCV viral proteins within the CNS may underlie the cerebral dysfunction, as is the case in early HIV infection. Activated microglia are thought to liberate neurosteroids such as pregnenalone,[146] which may have an upregulatory role on neuroinhibitory pathways in the brain. Activated microglia also release excitatory amino acids, which can induce neuronal apoptosis through a process known as excitotoxicity,[147] and are potent producers of neurotoxins such as nitric oxide. These processes may be amplified by the release of cytokines and chemokines,[148,149] as well as recruiting further virally infected PBMCs across the blood–brain barrier.

Peripherally derived cytokines may also be implicated, either in the facilitation of viral transfer across the blood–brain barrier[150] or independently, in the absence of HCV infection of the CNS. Although cytokines are large peptides, animal studies have demonstrated passage of cytokines across the blood–brain and blood–spinal cord barriers.[151] Peripherally derived cytokines may also be passively transported into the brain at circumventricular sites which lack a blood–brain barrier. Intracerebral cytokines have been associated with immunological, neurochemical, neuroendocrine and behavioural activities,[152] probably through the pathways described above. It is clear that treatment with IFN-α is associated with depression and complaints of memory impairment and cognitive slowing,[153] but whether elevated endogenous cytokines in chronic inflammatory and infective conditions exert a significant cognitive effect is unclear. A study found no correlation between

levels of circulating interleukin (IL)-1, IL-6, tumour necrosis factor (TNF) and patients' fatigue in chronic HCV infection,[154] although no study exists to date on circulating cytokine levels and cognitive function in chronic HCV infection.

The above mechanisms remain hypothetical. Clinical, imaging and further virological studies may ultimately answer these questions.

# Chapter 30
# *In vitro* replication models

Ralf Bartenschlager, Sandra Sparacio

## Introduction

In 1989 Choo and co-workers discovered the hepatitis C virus (HCV) as the causative agent of a liver disease which at that time was called non-A, non-B hepatitis.[1] Since then, numerous HCV isolates have been cloned molecularly and grouped together in the genus Hepacivirus that belongs to the *Flaviviridae* family. Based on the genomic heterogeneity, six major genotypes and a large number of subtypes have been defined. While genotype 1 viruses have almost worldwide prevalence, HCV of genotypes 4–6 can only be found in distinct geographical regions.

HCV is mainly transmitted via blood, blood products and parenteral risk factors. Blood screening assays developed soon after the discovery of the virus reduced the rate of transfusion-related transmissions significantly.[2,3] Nevertheless, HCV is still a major public health problem, as 170 million people worldwide are infected with this virus. Up to 80% of all infections become persistent, with approximately 20% of these patients developing liver cirrhosis within 20 years post-infection. The current antiviral treatment in most cases consists of the combination of a polyethylene glycol (PEG) conjugated form of interferon (IFN)-α and ribavirin.[4] However, the success rate depends very much on the genotype of the infecting virus. While up to 90% of HCV genotype 2- and 3-infected patients develop a sustained virological response, only about 45% of patients infected with genotype 1 viruses do so. Furthermore, neither a protective nor a therapeutic vaccine is available, emphasizing the requirement for alternative antiviral treatments.

The development of new HCV-selective drugs or vaccines requires a detailed understanding of the viral lifecycle as well as a profound knowledge of the interplay between the virus and the host. An essential prerequisite for studies in this direction is the availability of a robust and convenient cell culture system. This chapter gives a brief introduction to the biology of HCV and then describes the various cell-based replication models.

## Genome organization and replication cycle of HCV

HCV has a single-stranded RNA genome of positive polarity with a length of about 9.6 kb. The 5′ non-translated region (NTR) contains an internal ribosome entry site (IRES), mediating translation of an open reading frame (ORF), which encodes a polyprotein of about 3000 amino acids. The order of the individual proteins within the polyprotein is C-E1-E2-p7-NS2-NS3-NS4A-NS4B-NS5A-NS5B (Fig. 30.1a). The structural proteins core, envelope protein 1 (E1) and E2 are located within the amino-terminal part of the polyprotein, whereas the non-structural (NS) proteins NS2 to NS5B are encoded in the remainder. With the exception of the F protein, the 10 viral products arise from co- and post-translational processing of the polyprotein by cellular and viral enzymes. Translation of the F protein initiates also at the AUG start codon of the ORF, but due to ribosomal frame shifting, an alternative reading frame is utilized.[5,6] The 3′ NTR is composed of a variable region, a polypyrimidine tract and the 98 nucleotides long highly conserved 3′ terminal X-tail. Both the 5′ NTR and the 3′ NTR contain RNA elements that are required for replication (reviewed by Bartenschlager *et al*.[7]).

The HCV particle consists of at least the genomic RNA, the core protein and the two envelope proteins E1 and E2 that are embedded into the viral envelope. The core protein forms the internal viral capsid that shelters the RNA genome. The two envelope proteins mediate attachment and entry of the virions into the host cells. *In vitro* studies suggest that the p7 protein can function as a virus-encoded ion channel and therefore it was grouped into the viroporin-protein family.[8,9] Moreover, a recent chimpanzee study demonstrated that this protein is essential for infectivity of HCV.[10] The NS2 protein together with the amino-terminal protease domain of NS3 is responsible for the autocatalytic cleavage of the NS2–NS3 junction. The same NS3 protein domain carries a serine-type protease that after association with its co-factor NS4A

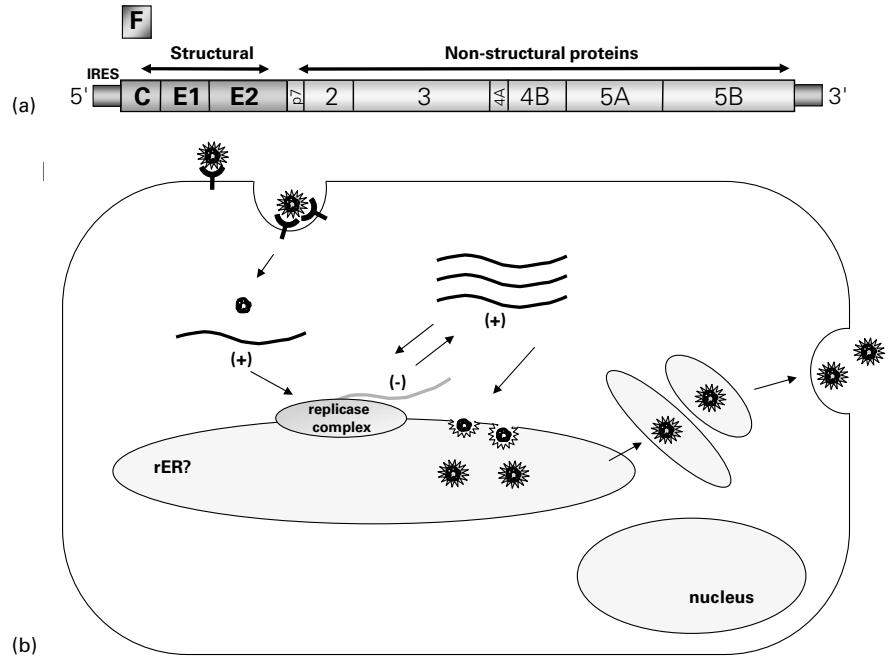

**Figure 30.1** HCV genomic organization and hypothetical HCV replication cycle. (a) Schematic representation of the HCV genome indicating the positions of the structural and non-structural proteins within the polyprotein as well as the 5′ NTR that contains the internal ribosome entry site (IRES) and the 3′ NTR. The F protein generated by ribosomal frame shifting is drawn above. (b) Hypothetical model of the HCV replication cycle. Upon binding of the virus particle to the appropriate cellular receptor and entry by receptor-mediated endocytosis, the genomic plus-strand RNA is liberated into the cytoplasm. After translation and processing of the viral polyprotein a membrane-associated replicase complex is formed. Minus-strand RNA is synthesized by this complex and serves as a template for production of excess amounts of plus-strand RNA. The newly synthesized RNAs either are translated or are packaged into the nucleocapsid. After budding into the lumen of the rough endoplasmic reticulum (rER) progeny viruses are presumably transported via the Golgi complex to the cell surface, where after fusion of the transport vesicle with the cellular membrane the virus particles are released.

cleaves the remaining junctions between the NS proteins. Two additional enzymatic activities, RNA helicase and nucleoside triphosphatase, reside in the carboxy-terminal two-thirds of NS3. Alterations of intracellular membranes, in particular membranous vesicles, are induced by NS4B. These alterations, which are the site of viral RNA synthesis, are called the membranous web.[11,12] So far, the role of the highly phosphorylated NS5A protein in the viral life-cycle is unclear. In addition to a potential function in RNA replication, NS5A may contribute to IFN-α resistance that is often observed with genotype 1 and 4 viruses (reviewed by Tan and Katze[13]). The membrane-associated NS5B protein is the RNA-dependent RNA polymerase (RdRp) and like other viral RdRps contains a 'GDD' amino acid sequence motif.

A brief summary of the HCV life-cycle may read as follows (Fig. 30.1b). Infection of the host cell starts by binding of the envelope glycoprotein E1/E2 complex to its cognate receptor(s), presumably leading to receptor-mediated endocytosis.[14] Upon release of the RNA genome into the cytoplasm the polyprotein is translated via the IRES in the 5′ NTR at the rough endoplasmic reticulum (rER). After or during cleavage of the polyprotein, the membrane-associated replication complex forms, which catalyzes the RNA amplification via negative-strand RNA intermediates. Newly synthesized plus-strand RNAs either are used for translation or serve as templates for further RNA syntheses or interact with the core protein to form the viral nucleocapsid. The E-proteins are retained at rER membranes, indicating that viral envelopes are generated by budding into the lumen of this organelle. Progeny particles are thought to be exported by the secretory pathway and after fusion of the transport vesicle with the plasma membrane, virions are released. It should be pointed out that most of these steps are poorly understood or hypothetical, and most often based on studies with heterologous expression systems and analogies to closely related viruses.

## HCV cell culture systems

In principle, three different approaches have been used to propagate HCV in cell culture and to study its replication cycle: first, the inoculation of primary cells or continuous

cell lines of hepatic or lymphoid origin with serum from HCV-infected individuals; second, the transfection of cell lines with genomic HCV constructs or *in vitro* transcribed genomic RNA; third, the transfection of cell lines with subgenomic or genomic replicons. These experimental approaches will be described in detail below.

## Infection of hepatocytes

As hepatocytes are considered to be the natural target cells for HCV *in vivo*, several attempts have been undertaken to establish an efficient HCV replication system by infecting primary hepatocytes from humans and chimpanzees with HCV-positive patient sera.[15–19] Although successful HCV replication has been shown in primary cell cultures, the common drawback is the extremely low efficiency. Moreover, when using primary cells from different donors experimental results are subject to variations that are difficult to control for. Finally, problems in handling and limited availability of primary cells impede their usefulness for experimental analyses. Thus, it is not surprising that much effort has been invested in developing cell culture systems based on immortalized hepatocytes. Several liver cell lines have been tested for their ability to support HCV replication. Among these, PH5CH cells immortalized with the simian virus large T antigen were found to be most susceptible.[20] Single cell clones were generated that are capable of supporting HCV replication more persistently than the parental PH5CH cells. In fact, when these cells were cultured at 32 °C, HCV RNA was detected up to 100 days post-infection.[21]

The human liver cell line FLC4 cultured in a three-dimensional radial-flow bioreactor (RFB) is the basis for an HCV infection system that was described by Aizaki and co-workers.[22] Upon inoculation with serum from an HCV-positive patient, viral RNA was detected by RT-PCR with peak RNA titres between day 19 and 23 in the range of $10^4$–$10^5$ HCV RNA copies/mL. However, this system is extremely inefficient, because at best only about 0.0001 HCV RNA copies/mL were released. Moreover, the equipment required to support cell growth in these 3D cultures is expensive, technically difficult and not readily available.

## Infection of lymphocytes

Although hepatocytes are considered the primary target cells of HCV, peripheral blood mononuclear cells (PBMCs) as well as B- and T-cell lines have also been used for infection studies. For instance, Cribier *et al*.[23] incubated HCV-positive sera with PBMCs isolated from healthy donors. Using RT-PCR and *in situ* hybridization, viral RNA was detected in infected cells as well as in cell culture supernatant until day 25 post-infection. HCV RNA contained in these supernatants could be transferred to naïve PBMCs, indicating the presence of infectious particles. However, the overall replication level of HCV in PBMCs is very low and not always reproducible.

Several human lymphocytic cell lines including the B-cell lines CE, TOFE and Daudi as well as the T-cell lines MOLT-4, HPB-Ma and MT-2 have also been used for the establishment of *in vitro* HCV culture systems. Among these, HPB-Ma and the MT-2 cells are the best characterized. The first is a murine retrovirus-infected human T-cell line that was shown to support HCV replication to some extent.[24] The isolation of single cell clones of HPB-Ma cells by limiting dilution revealed clonal differences in permissiveness. HCV replication, which was sensitive to IFN-α and IFN-β,[25] could be maintained in an isolated single cell clone (HPB-Ma clone 10–2) for more than 1 year.[26]

MT-2 cells, a human T-cell line immortalized with human T-lymphotropic virus 1 (HTLV-1), are also susceptible to HCV infection.[27] By means of limiting dilution, five MT-2 cell clones were obtained that support HCV replication more persistently than the parental MT-2 cells. One of these five clones, designated MT2-C, was shown to support HCV RNA replication until day 11 post-infection. Furthermore, negative-strand RNA was detected and an HCV-specific antisense oligonucleotide reversibly blocked replication. Treatment of cells with IFN-α for 2 days led to a reduction of HCV RNA down to 90%. In accordance with what was described for PH5CH, when cells were cultured at 32 °C instead of 37 °C, HCV RNA persisted much longer and could be detected up to 198 days post-infection.[28–30]

Very recently, a B cell line derived from the spleen of an HCV-infected patient was established.[30a] These cells support continuous replication and production of viruses that appear to be infectious in PBMCs and the B cell line Raji. However, the efficacy of this system is also limited with HCV RNA copy numbers being in the range of 0.01 to 0.1 per cell.

## Transfection of cell lines with genomic HCV constructs

In comparison with the infection of cells with authentic HCV particles contained in serum samples, the transfection of cell lines with viral cDNA constructs or *in vitro* transcripts corresponding to full-length HCV genomes has the major advantage of using a well-defined homogenous starting material that can be generated in large quantities. Moreover, mutational analyses can be performed to gain insights into the viral life-cycle. One prerequisite of this approach is the availability of cloned infectious genomes. Although several such HCV genomes have been described, productive replication in cells transfected with these RNAs turned out to be very difficult.[31–33] Initial reports describing HCV replication in the cell lines HepG2 and Huh-7 upon transfection with near full-length HCV RNAs must be viewed with caution because the used genomes lacked the 3′ terminal

X-tail.[34,35] This RNA element, however, is essential for replication *in vivo* and in cell culture (see below).

More recently, Aizaki and colleagues[22] performed the transfection of FLC4 cells with full-length HCV RNA of the genotype 1a isolate H77. Upon passage of these cells in a radial-flow bioreactor, intracellular viral RNA was detected. Culture supernatant transferred to naïve FLC4 cells initiated a second round of infection, indicating the production of infectious HCV particles in transfected cells. However, this culture system is complicated not commonly available and, the overall yield of HCV is very low.

In 2001, Chung and co-workers reported a DNA-based HCV replication system.[36] A plasmid containing the T7 promoter upstream of a full-length HCV genome of the genotype 1a and the ribozyme of the hepatitis delta virus at the 3′ end that generates an authentic HCV 3′ end was transfected into CV-1 and HepG2 cells. Transfected cells were subsequently infected with a recombinant vaccinia virus expressing T7 RNA polymerase. In these cells HCV negative-strand RNA was detected by strand-specific RT-PCR and ribonuclease protection assay. Furthermore, replication of HCV was sensitive to IFN-α and the emergence of distinct quasi-species in transfected cells was consistent with an error-prone replication mediated by the NS5B RNA polymerase. However, no evidence for the production of infectious HCV particles from these cells was obtained, arguing that this system does not support a full replication cycle. Further studies are required to elucidate the usefulness of this system, as the cytopathic vaccinia virus that delivers the T7 RNA polymerase may interfere with HCV.

## Transfection of cell lines with replicons

Up to now, the most efficient and reliable *in vitro* replication model for HCV is the replicon system that is based on the autonomous replication of selectable subgenomes in the human hepatoma cell line Huh-7.[37] These replicons were originally derived from a genotype 1b consensus genome, designated Con-1, that was isolated and cloned from a chronically infected patient who had undergone liver transplantation. The overall structure of the replicons is depicted in Fig. 30.2a. The sequence encoding for core to p7 or core to NS2 was replaced by a gene cassette consisting of the selectable marker neomycin-phosphotransferase (*neo*) which confers resistance to the cytotoxic drug G418 and by the IRES of the encephalomyocarditis virus (EMCV) that directs the translation of the NS3 to NS5B coding region of HCV. Translation of the *neo* gene is controlled by the IRES in the HCV 5′ NTR. Authentic 5′ and 3′ ends are generated by the proper positioning of the T7 RNA polymerase promoter at the 5′ end and by introducing a unique restriction site at the 3′ end of the replicon sequence. After electroporation into

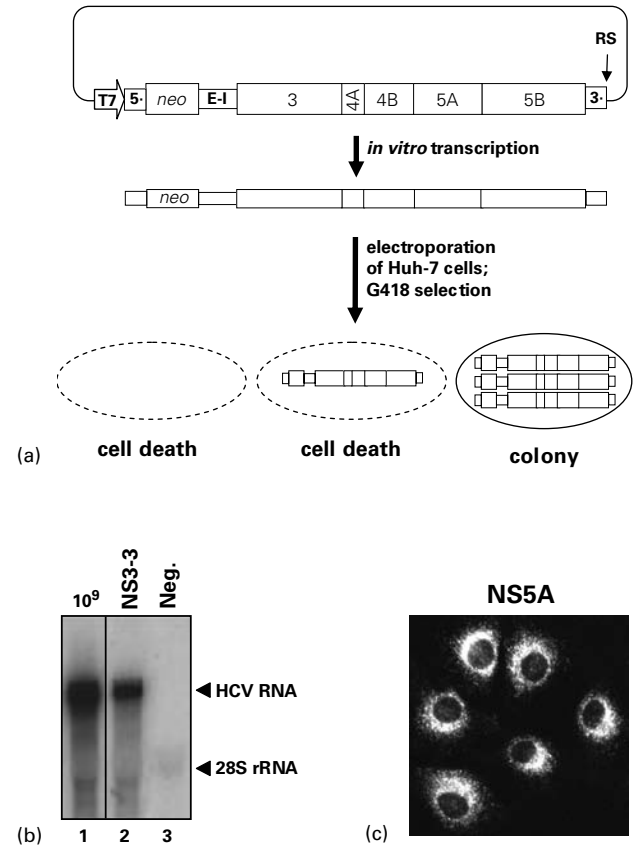

**Figure 30.2** Experimental strategy to generate stable replicon cell clones and demonstration of HCV RNA and protein in Huh-7 replicon cells. (a) Schematic illustration of the method used to establish subgenomic replicon harbouring Huh-7 cells. The DNA construct consists of a T7 RNA polymerase promoter (T7), the HCV 5′ NTR (5′), the selection marker neomycin phosphotransferase (*neo*), the internal ribosome entry site of the encephalomycarditis virus (E-I), the NS3 to NS5B coding sequence and the 3′ NTR (3′). After linearization of the DNA construct at an engineered restriction site (RS), *in vitro* transcription is used to synthesize replicon RNA molecules, which are transfected via electroporation into Huh-7 cells. Upon selection with G418, only those cells that support efficient RNA replication will survive. Cells which were either not transfected or which do not support efficient RNA replication are eliminated. (b) Detection of plus-strand RNA in subgenomic replicon harbouring Huh-7 cells. Total RNA isolated from a replicon cell clone (lane 2) and from naïve Huh-7 cells (lane 3) was analyzed by Northern blot using a plus-strand specific RNA probe. As a size marker, $10^9$ molecules of the corresponding *in vitro* transcripts were analysed in parallel (lane 1). The positions of the HCV-specific RNA and the 28S rRNA are indicated to the right. (c) Demonstration of NS5A in a cell clone carrying a subgenomic replicon by indirect immunofluorescence.

Huh-7 cells, replicon RNAs are translated and the HCV proteins build up active replication complexes that catalyze the amplification of the replicon RNAs. Positive-strand RNA progeny are used as mRNA for translation

of further HCV proteins as well as neomycin-phosphotransferases. Thus, when transfected cells are cultured in the presence of G418, untransfected cells and cells in which the replicons do not amplify to sufficient levels will die. Only those cells supporting RNA replication to high levels will express sufficient neomycin-phosphotransferase to confer resistance against G418. These cells will grow under such selective pressure and form colonies (Fig. 30.2a).

Thorough analyses of these colonies confirmed the presence of self-replicating HCV RNAs. About $10^8$ positive-strand RNA copies per µg RNA were detected, corresponding to approximately 1000–5000 molecules per cell (Fig. 30.2b). A 5–10-fold lower amount of negative-strand RNA was determined, supporting the assumption that this RNA species serves as a template for the generation of excess amounts of positive-strand RNA genomes. Consistent with the fact that replication is dependent on the NS5B RdRp, replicon RNA synthesis was not affected by actinomycin D, whereas the synthesis of cellular RNAs was blocked. Viral proteins could easily be detected, e.g. after metabolic radiolabelling and immunoprecipitation or by immunofluorescence analyses (Fig. 30.2c). These results demonstrated the high efficiency of the replicon system as compared with the previously described *in vitro* infection systems, where these kinds of assays did not allow the detection of viral proteins and RNAs due to the low replication levels of HCV RNAs in these cells.

### *Cell culture adaptation*

As described by Lohmann and co-workers,[37] only a low number of colonies were obtained after transfection with replicon RNA transcripts and G418 selection, even though a high copy number of replicon RNA was detected within a selected cell clone. There are two potential explanations for this discrepancy. First, only a small subpopulation of Huh-7 cells supports RNA replication to a level that is sufficient to confer G418 resistance. This would be consistent with the observation made with *in vitro* infection systems (see above) that subcloning of cells leads often to more permissive cell clones. Second, the replicon RNA has to gain cell culture adaptive mutations that enhance RNA replication. Indeed, detailed analyses of RNAs isolated from several replicon cell clones revealed amino acid exchanges in the HCV coding region that were conserved among the majority of replicon RNAs isolated from a given cell clone (Fig. 30.3).[38,39–41] Depending on the particular mutation, its introduction into the parental replicon increased the number of G418 resistant cell colonies to various extents in comparison with the wild-type replicon, showing that these mutations enhance RNA replication and confer cell culture adaptation. Taking advantage of this discovery, highly efficient replicons were developed that could be analysed in transient replication assays. For instance, replicons were constructed in which the selectable marker *neo* was replaced by easily detectable reporter genes like the one encoding the luciferase of the firefly (Figure 30.4a**)**. In this setting, RNA replication is measured by using luciferase assays and it was shown that luciferase activity closely correlates with replicon RNA levels.[39,42]

Although cell culture adaptive mutations have been found at various positions in the HCV coding sequence, with the exception of a single amino acid substitution in NS5B (R2884G), they cluster in three distinct regions (Fig. 30.3). The major cluster resides in the centre of NS5A protein,[38,41] often affecting serine residues that are involved in NS5A hyperphosphorylation (reviewed in Pawlotsky and Germanidis[43]). This result implies that a reduction of hyperphosphorylation enhances RNA replication, at least in Huh-7 cells. In fact, it was shown recently that reduction of heperphosphorylation by using an inhibitor of the NS5A kinase enhances replication of wild type RNAs.[38b] However, a minimum of hperphosphorlated NS5A is required as treatment of adapted replicons with the same kinase inhibitor blocked RNA replication.[38b]

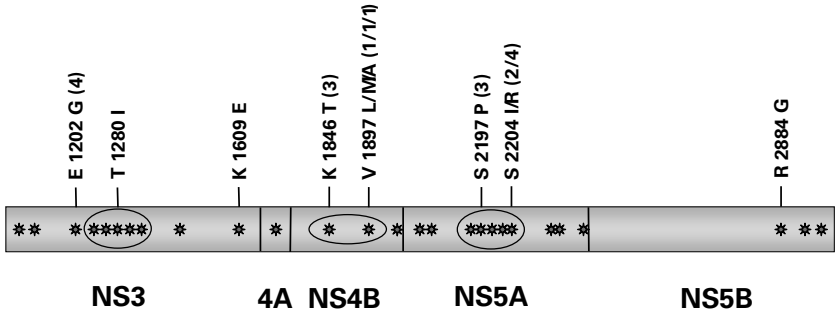

**Figure 30.3** Identification of clusters of cell culture adaptive mutations. Amino acid substitutions that were found to be conserved in 26 independently selected replicon cell clones are indicated by (✶). Distinct mutations described in the text are specified above with numbers referring to the polyprotein of the HCV Con-1 isolate. Numbers in parenthesis indicate the frequency with which a given mutation was found in independent replicon cell clones. The circles illustrate clusters of adaptive mutations.

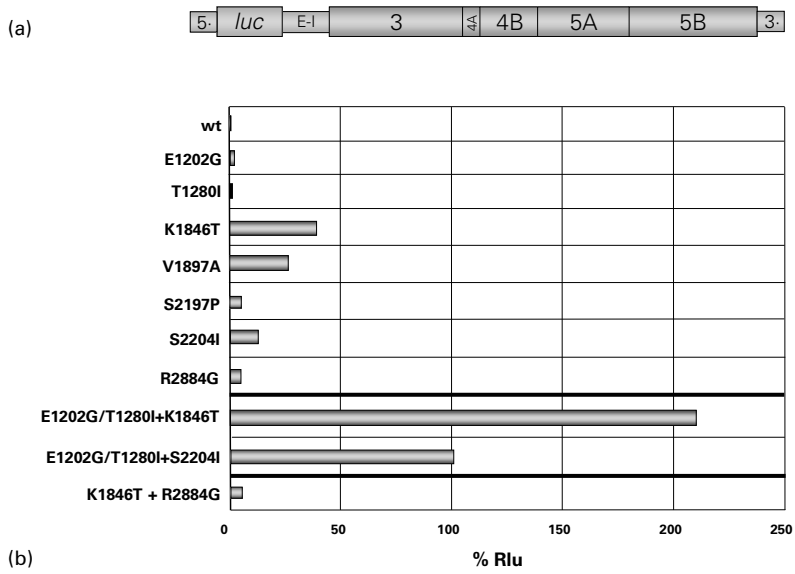

**Figure 30.4** Effect of amino acid substitutions in the HCV coding sequence on transient RNA replication. (a) Schematic representation of the luciferase reporter replicon. Its structure is analogous to the selectable replicon shown in Fig. 30.2a, but the selection marker *neo* is replaced by the gene encoding the luciferase from the firefly (*luc*). (b) Huh-7 cells were transfected with replicons containing the mutations specified on the left and harvested 4 hours (h) and 48 h later. Luciferase activity is expressed as percentage relative light units (% Rlu) determined in lysates of cells at 48 h compared with those at 4 h after electroporation. Note that the 4-h value reflects translation of the input RNA and, therefore, is a marker for transfection efficiency.

Two distinct positions in NS4B represent the second hot spot for cell culture adaptive mutations (Fig. 30.3). It was found that single substitutions affecting these positions (amino acid 1846 or 1897 of the Con-1 polyprotein) enhance RNA replication dramatically (Fig. 30.4b).[41] The third cluster resides in the helicase domain of the NS3 protein (Fig. 30.3).[39,42] Mutations in this region have only a low impact on RNA replication (Fig. 30.4b).[39–41] However, when highly adaptive mutations in NS4B (e.g. K1846T) or NS5A (e.g. S2204I) were combined with mutations in NS3, the combination was beneficial and replication of the replicon was enhanced cooperatively (Fig. 30.4b), at least with Con-1 derived replicons.[39,41,42,44] In fact, the combination of the K1846T substitution with two NS3 mutations (E1202G and T1280I) yielded the most efficient Con-1-derived replicon (Fig. 30.4b). This is consistent with the observation that mutations in NS3 were only found in combination with other adaptive substitutions in the NS4B to NS5B region. However, when highly adaptive mutations in the NS4B to NS5B region were combined with each other, RNA replication was much lower compared with replicons that carried these mutations individually (Fig. 30.4b).[41] These results are consistent with the fact that none of the highly adaptive mutations in NS4B, NS5A or NS5B were found in combination with each other in the same HCV replicon RNA. This led to the suggestion that mutations in this region mediate cell culture adaptation via the same or a very similar mechanism.

One particular amino acid exchange within NS3, K1609E, was found independently by three groups that used two different genotype 1b[40,45] and a chimeric 1a/b replicon.[46] In the latter, the 5′ NTR and 75 amino-terminal residues of the NS3 protein were taken from the Con-1 (1b) isolate and the remainder from the H77 (1a) isolate. Another remarkable adaptive mutation within NS3 is E1202G that resides at the very carboxy-terminus of the NS3 protease domain. This mutation is present in about 5% of published HCV sequences and it represents the only adaptive mutation that is also found *in vivo*. All other substitutions affect highly conserved residues and have not been observed within HCV genomes isolated from patients.

At present, we can only speculate about the mechanisms underlying cell culture adaptation. Based on the available X-ray crystal structures of NS3 and NS5B, the locations of some of the substitutions have been mapped. Interestingly, most of them reside on the solvent-exposed surface of the molecules.[39,40,42] These sites might therefore be involved in interactions with other viral or cellular proteins. The identification of such interaction partners will be an important task.

To analyze the impact of adaptive mutations on infectivity *in vivo*, the two mutations E1202G and T1280I in NS3 and S2197P in NS5A were introduced into the infectious HCV genome Con-1 and RNA transcripts were inoculated into the liver of a chimpanzee. In three independent attempts, no productive infection could be established.[47] When a chimpanzee was inoculated with a Con-1 genome containing the single adaptive mutation in NS5A, the animal became viraemic after a delay of about 1 week. However, all HCV genomes isolated from this chimpanzee had reverted to wild-type. This led to the conclusion that cell culture adaptation is closely associated with attenuation *in vivo*. In line with this observation is the fact that the HCV-N isolate (also genotype 1b) has a low infectivity *in vivo*,[47,48] but replicons derived from this isolate are highly efficient.[49,50] A four amino acid insertion within the NS5A protein is responsible for the inherent ability of the HCV-N isolate to replicate

efficiently without further adaptive mutations.[50] These findings imply an inverse correlation between cell culture adaptation and attenuation *in vivo*, but this view has recently been challenged by the development of a novel genotype 2a replicon (see below) that replicates with high efficiency without the need for adaptive mutations. Although the infectivity of the HCV genome from which this replicon was derived has not yet been tested, the genome was isolated from a patient with a fulminant hepatitis C, arguing that it might be replication-competent *in vivo*.

### *Host cell permissiveness*

Recently, it was shown that in addition to cell culture adaptive mutations the host cell itself contributes very much to the efficiency of RNA replication. Blight and co-workers as well as Murray and colleagues demonstrated that within a given population of naïve Huh-7 cells only a subpopulation is capable of supporting high-level RNA replication.[51,52] When replicon-harbouring cells were treated with IFN-α or a selective inhibitor to remove the replicon, the resulting cured cells supported HCV replication more efficiently than naïve control cells. This result suggests that the selective pressure used to generate a replicon cell clone leads to the selection of both cell culture adaptive replicons and to Huh-7 cells that are more permissive.

Different levels of permissiveness were also observed between various passages of naïve Huh-7 cells originating from the same cell stock.[41] These differences (up to 100-fold) were not due to variations in IRES-dependent translation or RNA stability. One explanation might therefore be that the expression levels of cellular factors required for RNA replication differ between these passages. In line with this assumption is the fact that an increase in the amount of transfected replicon RNA leads to a decrease of replication efficiency per transfected replicon RNA molecule,[41] indicating that cellular factor(s) required for the formation or activity of the HCV replicase complexes limit viral RNA replication.

### *Genomic replicons and cell culture adapted full-length genomes*

In an attempt to produce infectious replication-competent HCV particles in cell culture, selectable genomic replicons were constructed and used to generate stable Huh-7 cell clones. Ikeda and colleagues[50] demonstrated the replication competence of a selectable genomic replicon derived from the HCV-N isolate by using Northern blot and immunofluorescence analyses. However, the efficiency of genomic RNA replication was reduced in comparison with replication of subgenomes and the transfer of filtered supernatant from genomic replicon cells to naïve Huh-7 cells did not lead to a detectable infection (Table 30.1).[42,50,52,53]

Pietschmann and colleagues conducted a more detailed analysis. They took advantage of three cell culture adaptive mutations that cooperatively increase RNA replication (E1202G and T1280I in NS3 and S2197P in NS5A) and constructed a selectable genomic replicon (Fig. 30.5A).[53] However, despite efficient RNA replication and protein expression in several independent Huh-7 cell clones, no conclusive evidence for the production of virus particles has been obtained (Fig. 30.5b, c). Transfer of cleared supernatant from these cells to naïve Huh-7 cells did not lead to a detectable infection. Although nuclease-resistant HCV RNA with the same low-density profile reported for infectious HCV[54] was found in the supernatant of genomic replicon cell clones, HCV RNA with the same characteristics was also detected in the supernatants of cell clones with subgenomic replicon RNAs. Several rea-

*Stable, establishment of replicon harbouring cell clones by a selection process; transient, transient replication assay.

†Method used to verify HCV replication: (+) RNA, detection of plus-strand HCV RNA; IF or IP or WB or FACS, detection of HCV antigens by immunofluorescence or immunoprecipitation after metabolic radiolabelling or Western blot or FACS, respectively.

‡Method used for detection of virus particles: infection assay, transfer of cleared supernatant from cell clones carrying selectable full-length replicons to naïve Huh-7 cells and subsequent selection for G418 resistance; density gradient, supernatant from cell clones carrying selectable full-length replicons were subjected to density gradient centrifugation and analyzed by quantitative RT-PCR.

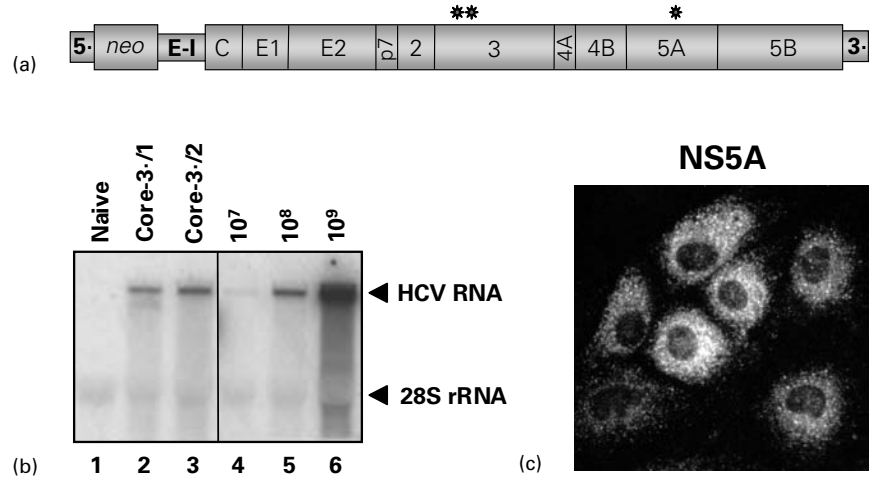

**Figure 30.5** Structure of genomic replicons and demonstration of HCV RNA and protein in Huh-7 cells. (a) Schematic representation of a selectable full-length replicon composed of the 5′ NTR (5′), the selection marker neomycin phosphotransferase (*neo*), the internal ribosome entry site of the encephalomycarditis virus (E-I), the core to NS5B coding sequence and the 3′ NTR (3′). The asterisks (✶) represent the positions of adaptive mutations that were introduced into the HCV coding sequence. (b) Detection of self-replicating genomic replicon RNA. Total RNA isolated from two full-length replicon cell clones (lanes 2 and 3) and from naïve Huh-7 cells (lane 1) were analyzed by Northern blot using a plus-strand specific RNA probe. As a size marker, $10^7$ up to $10^9$ molecules of the corresponding *in vitro* transcripts were analyzed in parallel (lanes 4–6). The positions of the HCV RNA and 28S rRNA are indicated to the right. (c) Demonstration of NS5A in a cell clone carrying a genomic replicon by indirect immunofluorescence.

sons may account for the lack of virus production in stable cell clones carrying genomic replicons. For instance, the presence of heterologous sequences in the 5′ region of these replicons may have destroyed an RNA packaging signal or led to an increase of the genome length beyond the packaging limit. Alternatively, it is possible that the high genetic drift rendered the structural proteins non-functional due to the accumulation of inactivating mutations. To circumvent these problems a transient replication assay of cell culture adapted full-length genomes was established. However, despite efficient transient replication, no infectious particles could be detected.[54]

By using an analogous approach, Blight and co-workers assessed the ability of cured Huh-7 cells to support replication of a Con-1 genome containing an adaptive mutation in NS5A (S2204I).[52] Furthermore, a genotype 1a full-length genome derived from the HCV isolate H77 and carrying two cell culture adaptive mutations (P1496L in NS3 and S2004I in NS5A) was established in the same laboratory.[42] Replication of both genomes was demonstrated by RNA quantification and metabolic radiolabelling of HCV-specific proteins. However, release of replication-competent HCV was not observed in any of the described approaches (Table 30.1). So far, it is not clear where the block for virus particle production or secretion resides. For instance, the lack of host cell factors in Huh-7 cells might lead to an inefficient assembly process. Alternatively, cell culture adaptive mutations may interfere with asembly and/or virus release. As described below, this appears to be the the primary reason for the lack of virus production.

### *Replicons derived from non-genotype 1 HCV isolates*

An inherent complication of the HCV replicon system is the unpredictability as to whether or not an HCV isolate will replicate. As deduced from the appearance of cell culture adaptive mutations, slight variations in the HCV sequence can have dramatic effects on replication fitness. Until recently, only replicons derived from genotype 1 isolates have been established and attempts to develop replicons of other genotypes have failed (reviewed in Lanford and Bigger;[55] Windisch and Bartenschlager, unpublished results). An important contribution was therefore the establishment of a genotype 2a replicon derived from an HCV isolate (JFH-1) that was obtained from a patient with fulminant hepatitis C.[56] This replicon has a remarkably high efficiency of RNA replication, in fact up to 20-fold higher than Con-1-derived adapted replicons, and does not require cell culture adaptive mutations. The reasons for this highly efficient replication are unclear, but it seems possible that the JFH-1-derived replicon carries some inherent adaptive mutations that were already present in the isolate cloned from the patient. If that is true, one might expect that these adaptive mutations are compatible with infectivity *in vivo*. In fact, the genotype 1b HCV-N isolate carries a natural

four amino acid insertion in NS5A that confers cell culture adaptation and that seemingly does not completely block a productive infection *in vivo*.[50]

### *Host range of HCV replicons*

In addition to Huh-7 cells, replicon cell clones derived from HuH6 were recently established using cell culture adapted subgenomic HCV replicons of the Con-1 isolate (Windisch *et al*., 10th International Meeting on the Hepatitis C Virus and Related Viruses, Kyoto, Japan, 2003). Furthermore, Zhu *et al*.[57] demonstrated HCV replication in a non-liver cell line as well as in a liver cell line of murine origin (Table 30.2). The approach that they used was based on the assumption that cell culture adaptive mutations observed in Huh-7 cells represent an adaptation to a specific cellular environment, and that further mutations might be required to adapt HCV replicons to other cell lines. Consequently, they screened a panel of different cell lines using total RNA isolated from replicon-containing Huh-7 cell clones. Owing to the high error rate of the HCV replicase, replicon RNA that is present in a given cell clone has a high genetic complexity. Therefore, the chances of selecting an adapted variant are higher as compared to the use of rather homogenous *in vitro* transcripts that are derived from a cloned template. By using this approach, Zhu *et al*. were able to establish clones from HeLa cells, a human cervix carcinoma cell line, and from Hepa1-6 cells, a murine liver cell line.[57] Sequence analysis of the RNA isolated from these HeLa and Hepa1-6 clones revealed a number of mutations that might be involved in fine-tuning of replicon adaptation.[57] These results show for the first time that HCV RNA replication does not depend on liver cell-specific factors and they may open a way to develop a mouse model for HCV replication by using adapted HCV sequences.

Overall, the properties of HeLa replicon cells (only these have thus far been analyzed in some detail) are very similar to those described for Huh-7 cells. However, distinct differences exist. First, in Huh-7 cells the replicon RNA copy number very much depends on host cell confluency. RNA levels are highest in well proliferating cells, but drop significantly when cells are resting.[61] In contrast, no such dependence was found with replicons in HeLa cells.[57] Whether this is due to some different requirements for host cell factors that vary in abundance in Huh-7 cells but not in HeLa cells remains to be determined. Alternatively, HeLa cells may have a much less pronounced cell contact inhibition. Another difference between Huh-7 and HeLa replicon cell clones relates to their IFN-α sensitivity. No morphological changes but efficient inhibition of replicons has been described for Huh-7 cells, whereas about 30% of HeLa cells undergo apoptosis.[57] The fact that inhibition of replicons by an NS5B selective drug prior to treatment with IFN-α pre-

vents apoptosis suggests that HCV RNA replication or proteins stimulate an innate cellular response that sensitizes HeLa cells towards apoptosis.

Beside HeLa cells, the human embryonic kidney cell line 293 was also shown to support HCV RNA replication.[60,60a] In one approach by co-cultivation of Huh-7 cells with 293 cells, rare replicon-containing colonies were obtained, which morphologically resembled 293 cells. Total RNA isolated from these cells and transfected into naïve 293 cells gave rise to replicon harbouring cell clones, as shown by antigen and RNA detection assays as well as inhibition of HCV replication with IFN-α (Table 30.2). These findings corroborate that HCV replication is not dependent on hepatocyte- or primate-specific factor(s) and point out the unpredictable nature of the search for new cell lines that support HCV RNA replication. Nevertheless, these novel replicon cell lines will be instrumental in understanding the mechanism of cell culture adaptation and, eventually, help to produce authentic HCV particles in cell culture.

### *Applications of the HCV replicon system*

Taking advantage of cell culture adaptive mutations and highly permissive cell lines, transient replication systems were developed that avoided the cumbersome and time-consuming process of selection for G418 resistant colonies when using selectable replicons. To facilitate transient replication assays, an easily detectable reporter gene like the one encoding the firefly luciferase was inserted instead of the selectable marker *neo* (Fig. 30.4a). In this setting, RNA replication can be measured by luciferase assays and it was shown that luciferase activity correlates well with the level of RNA replication.[39] An alternative assay for transient replication is based on replicons that carry the *tat* gene of the human immunodeficiency virus (HIV), which activates the transcription of a tat-dependent reporter gene that is stably integrated into the Huh-7 cell.[44] Alternatively, replicons that express the beta-lactamase gene have been developed. In this case, the reporter activity can be measured with a cell-permeable substrate, which greatly facilitates the analyses.[51] Finally, transient replication of cell culture adapted replicons can be measured by using nuclease protection or Northern blot assays as well as quantitative RT-PCR.

The availability of these assays enabled for the first time detailed molecular studies of HCV RNA replication. For instance, *cis*-acting elements in the 5′ and 3′ NTRs required for RNA replication have been mapped and characterized.[62–66] Another interesting application is to study the mode of action of antiviral cytokines such as IFN-α, -β, or -γ and tumour-necrosis-factor (TNF)-α, and to identify cellular factors involved in viral replication.[38,49,67–70]

Finally, the replicon system encodes all viral enzymes that are required for HCV replication and thus are potential targets for therapy. In this respect, the replicon system is an important tool for the screening and evaluation of antiviral drugs. Furthermore, it also provides a means to develop novel therapeutic strategies (reviewed in Bartenschlager[71]). One example that nicely illustrates the latter is the inhibition of HCV replication by RNA interference (RNAi). Small duplex RNA molecules, so-called small interfering RNAs (siRNAs) target homologous sequences for degradation (reviewed in Hannon[72]). In plants, this is an important antiviral defence mechanism, which so far has not been discovered in mammalian cells. However, the artificial introduction of siRNA molecules into mammalian cells can inhibit replication of several viruses in cell culture (reviewed in Joost Haasnoot *et al*.[73]). In case of HCV, the replicon system provided a suitable model to test this antiviral approach. It was found that HCV replication was sensitive to siRNA molecules generated either by chemical synthesis, or by intracellular transcription of short hairpin RNAs (shRNAs) from transfected plasmids or stably integrated retroviral vectors.[74–77] Alternatively, HCV-specific esiRNAs can be prepared by enzymatic digestion of *in vitro* transcribed, double-stranded RNAs with RNaseIII from *Escherichia coli*. These highly heterogeneous esiRNAs that can target multiple sites within an mRNA were shown to be efficient in inhibition of HCV replication in Huh-7 replicon cells.[77]

## Surrogate models of HCV

As so far genomic replicons and cell culture adapted full-length HCV genomes do not lead to virus production, until very recently aspects of early stages (virion attachment, entry and uncoating) and late stages (assembly, egress) of the HCV life-cycle could not directly be addressed. Therefore, several laboratories used surrogate model systems. The GB viruses (especially GBV-B) and the pestiviruses are the closest relatives of HCV. In addition to a productive infection and replication in tamarins (*Saguinus* species), GBV-B replicates efficiently in primary tamarin hepatocytes.[78] The genome of this virus has a genetic organization that is very similar to that of HCV including an IRES in the 5′ NTR, an almost superimposable genomic organization of the coding region and a 3′ NTR that is indispensable for replication and *in vivo* infectivity.[79–81] The functional similarities between these viruses were demonstrated by the correct processing of the HCV polyprotein by the GBV-B NS3 protease and the creation of functional chimeric NS3 proteins between HCV and GBV-B.[82,83] However, there is a striking difference in the course of infection between HCV and GBV-B. The latter usually causes an acute self-limiting

hepatitis in tamarins, whereas HCV infection of humans frequently becomes persistent. Whether this is due to differences in the viruses or the host is not known.

Pestiviruses, especially the bovine viral diarrhoea virus (BVDV), have also been used as surrogate model systems. BVDV shares a similar genomic organization with HCV and both viruses generally cause persistent infections in their respective hosts. Furthermore, it is easy to culture BVDV *in vitro*, where the virus performs a complete replication cycle both after infection of cells and after transfection of RNA derived from cloned infectious genomes. However, also in this case, there are some differences in the biology of both viruses. For instance, BVDV has a much broader host range in cell culture than HCV and, in contrast to HCV, cytopathic and non-cytopathic BVDV strains exist.

HCV chimeric viruses have been used for genetic and biochemical analyses of the functions of HCV gene products and RNA structures. For instance, chimeric HCV/polioviruses have been constructed in which the poliovirus replicates under the translational control of the HCV IRES.[84] Another example is a BVDV/HCV chimera in which BVDV replication is conditionally dependent on the activity of the NS3/4A protease that was fused with the amino terminus of BVDV core protein.[85] However, HCV protein functions and RNA structures involved in replication can now be studied in the more authentic context of replicons and cell culture-adapted full-length genomes (see above).

A major step towards the study of early steps in the HCV life-cycle is the HCV pseudoparticle system that was recently described by Bartosch and colleagues.[86] These pseudoparticles are composed of the HCV envelope glycoproteins E1 and E2 and either retroviral or lentiviral nucleocapsids. They were generated by co-transfection of 293T cells with the following three different plasmids (Fig. 30.6). First, the packaging construct coding for the structural and enzymatic proteins of the corresponding retrovirus; second, a viral transfer vector encoding a reporter gene like the green fluorescence protein (GFP); and third, an expression vector carrying the two HCV envelope glycoproteins E1 and E2. Upon transfer of the pseudoparticles to a panel of different target cells, a preferential tropism for liver-derived cell lines or primary hepatocytes and a requirement for both E1 and E2 was observed.[86] Furthermore, the infection process was blocked by antisera from HCV-positive patients and by monoclonal antibodies directed against E2. Taken together, these data clearly show that the pseudoparticles carry functional E1 and E2 complexes, thus allowing the analysis of the early steps in the HCV life-cycle.

By using the HCV pseudoparticle system, it was demonstrated that CD81, an E2-binding molecule,[87] is an important component of the receptor complex, but is insufficient to confer entry of the pseudoparticles into the cell.[14,86] Hsu and colleagues also studied the role of two further HCV receptor candidates, namely scavenger receptor class B type 1 (SR-B1) and the low density lipoprotein receptor (LDLR).[14] They found that infection of target cells by HCV-E1/E2 pseudoparticles was not blocked by antibodies directed against SR-B1 or LDLR. However, the inability of LDLR-specific antibodies to inhibit pseudoparticle infection may be attributed to the fact that LDL is not associated with the particles that were generated in 293T cells. Irrespective of that, these pseudoparticles were useful to confirm the existence of HCV neutralizing antibodies. Surprisingly, these antibodies turned out to be broadly cross-neutralizing and to block the infection of pseudoparticles carrying genotype 1a or 1b envelope glycoproteins. Such neutralizing antibodies were only found in chronic but not in resolving infections.[88]

### A novel system for the production of infectious virus in cell culture

As mentioned above, the reason for the lack of virus production might be an interference of adaptive mutations with particle assembly and/or release. Based on this assumption it was interesting to see whether the newly established genotype 2a isolate JFH-1 (see above), which replicates efficiently in the absence of adaptive mutations, will allow virus production. Indeed, very recently, the production of infectious HCV in cell culture was achieved by transfection of Huh-7 cells with the full length 2a JFH-1 genome as well as chimeric genomes that carry the JFH-1 replicase and the core to NS2 region from other genotypes.[89,90] Sucrose density gradient centrifugation of the supernatant from the transfected cells revealed cosedimentation of viral RNA and core protein at a density of 1.17 g/ml. Furthermore, supernatants from such transfected cells contain infectious HCV that enters naive Huh-7 cells in a CD-81 dependent manner. Electron microscopy showed virus particles of 50-65nm in diameter reacting with an anti-E2 antibody. Moreover, inspection of a luciferase reporter gene into the JFH-1 genome allowed the production of virus particles that upon infection of naive target cells express high levels of the reporter gene.[91] This method should allow detailed analyses of the early steps in the HCV life cycle and facilitate the development of antiviral compounds interfering with the infection process.

## Conclusion

Significant progress has been made in the development of cell culture models for HCV. Among the cell-based replication models, the replicon system is most widely used. It is robust and efficient and it allows the study of

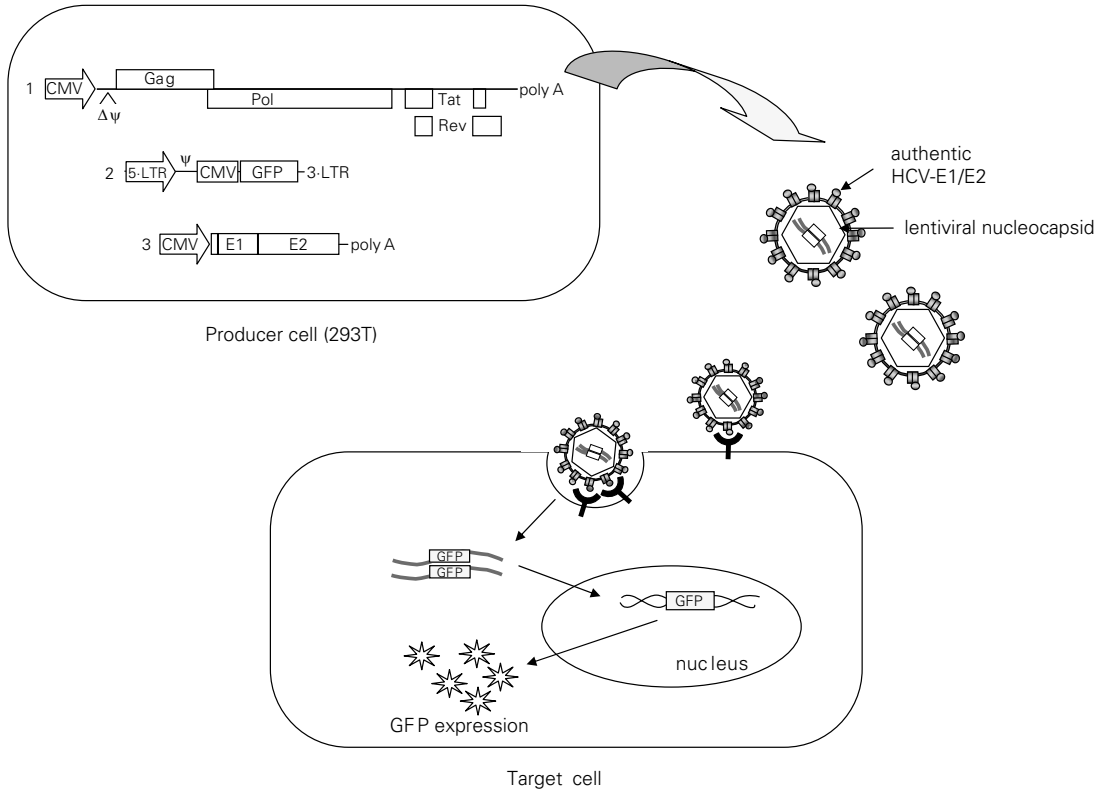

**Figure 30.6** Experimental approach for the production of HCV pseudoparticles. Producer cells (293T) are co-transfected with three different plasmids: (1) the HIV-1-based packaging plasmid composed of the human cytomegalovirus (CMV) promoter, the structural proteins (Gag), the enzymatic proteins (Pol) and the two regulatory proteins Tat and Rev upstream of the polyadenylation signal (poly A). RNA generated from this construct lacks the packaging signal ψ (Δψ) and therefore is not incorporated into the HIV-1 nucleocapsid; (2) the transfer vector composed of the two long-terminal repeats (LTR), the RNA packaging signal ψ and an expression cassette containing the CMV promoter upstream of the GFP marker gene; (3) the plasmid for the expression of the HCV glycoproteins E1 and E2. Upon transfection of 293T cells, the GFP-encoding RNA is packaged into the HIV-1 nucleocapsid, which acquires by an unknown mechanism its viral envelope into which native E1/E2 complexes are incorporated. Supernatant of these cells contains the HCV pseudoparticles that are used for infection of appropriate target cells, e.g. Huh-7 cells. Pseudoparticles enter the cell, the transfer vector is reverse transcribed and integrated into the genome of the target cell. Successful transduction of the reporter gene GFP, which is a marker for successful infection, can then be measured by FACS analysis of the target cells.

different aspects of the HCV life-cycle. In addition, production of infectious HCV particles in cell culture from a cloned genome has been recently achieved allowing studies of the complete viral life-cyle. These achievements open new avenues for the development of novel antiviral therapies and they will hopefully stimulate further research which will help to gain a better understanding of the interplay between HCV and its host.

# Chapter 31
# Progression of fibrosis

Thierry Poynard, Vlad Ratziu, Yves Benhamou, Dominique Thabut, Joseph Moussalli

## Natural history of hepatitis C fibrosis progression

The major hepatological consequence of hepatitis C virus (HCV) infection is the progression to cirrhosis and its potential complications: haemorrhage, hepatic insufficiency and primary liver cancer.[1]

Current understanding of HCV infection has been advanced by the concept of liver fibrosis progression (Figs 31.1 and 31.2).[2,3] Fibrosis is the deleterious but variable consequence of chronic inflammation. It is characterized by the deposition of extracellular matrix component leading to the distortion of the hepatic architecture with impairment of liver microcirculation and liver cell functions. It is increasingly recognized that HCV can directly exert profibrogenic effects on the liver. Recent and exciting experimental data provide evidence that the core protein of HCV acts on hepatic stellate cells resulting in increased proliferation, release of profibrogenic cytokines and enhancement of type I collagen secretion.[4] Moreover non-structural proteins of HCV contribute to the local inflammatory reaction by triggering the synthesis of stellate cell-derived chemokines and increasing the expression of adhesion molecules involved in the recruitment of inflammatory cells.[4]

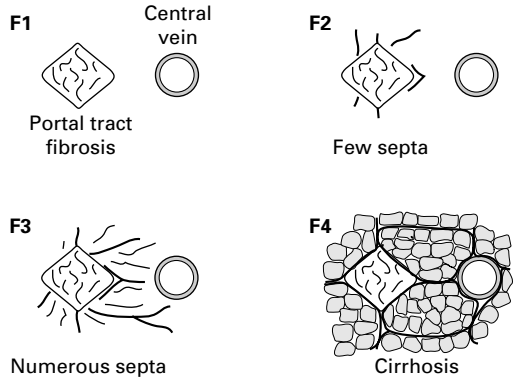

**Figure 31.1** The METAVIR fibrosis staging system. F0 is normal liver (no fibrosis); F1 = portal fibrosis; F2 = few septa; F3 = many septa; F4 = cirrhosis

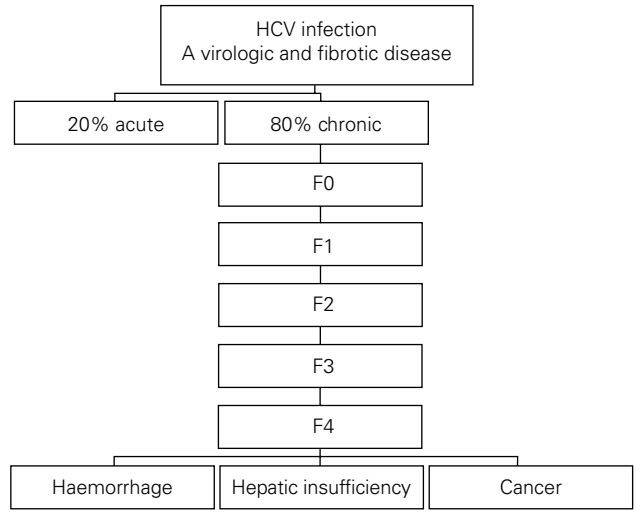

**Figure 31.2** The model of fibrosis progression from infection to complications. Estimated key numbers of HCV natural history from literature and our database are as follows. The median time from infection (F0) to cirrhosis (F4) is 30 years. The mortality at 10 years for cirrhosis is 50%. The transition probability per year from non-complicated cirrhosis to each of the complications is around 3%.

Infection by HCV is usually only lethal when it leads to cirrhosis, the last stage of liver fibrosis. Therefore, an estimate of fibrosis progression represents an important surrogate end-point for evaluation of the vulnerability of an individual patient and for assessment of the impact of treatment on natural history.[2,3]

## Fibrosis stages and necroinflammatory activity grades

Activity and fibrosis are two major histological features of chronic hepatitis C, which are included in different proposed classifications.[5–8] One of the few validated scoring systems is called the METAVIR scoring system.[5,8] This system assesses histologic lesions in chronic hepatitis C using two separate scores, one for necroinflammatory grade (A for Activity) and another for the stage of

fibrosis (F). These scores were defined as follows. Stages of fibrosis (F) (Fig. 31.3): F0 = no fibrosis, F1 = portal fibrosis without septa, F2 = portal fibrosis with rare septa, F3 = numerous septa without cirrhosis, F4 = cirrhosis. Grade for activity (A): A0 = no histologic activity, A1 = minimal activity, A2 = moderate activity, A3 = severe activity. The degree of activity was assessed by integration of the severity of the intensity of both piecemeal (periportal) necrosis and lobular necrosis as described in a simple algorithm.[5] The intra- and inter-observer variations of this METAVIR scoring system are lower than those of the widely used Knodell scoring system.[7] For METAVIR fibrosis stages there is an almost perfect concordance (kappa = 0.80) among pathologists. The Knodell scoring system has a non-linear scale. There is no stage 2 for fibrosis (range 0–4) and the activity grade ranges from 0 to 18 with the sum of periportal necrosis, intralobular and portal inflammation grades. The modified Histological Activity Index is more detailed, with four different features and continuous grades, and the modified fibrosis staging includes six stages.[6]

Activity grade, which represents the necrosis feature, is not a good predictor of fibrosis progression.[2,9] In fact, fibrosis alone is the best marker of ongoing fibrogenesis.[2,3,9,10] Fibrosis stage and inflammatory grade are correlated, but for one-third of patients, there is discordance. Clinicians should not take a 'significant activity' as a surrogate marker of 'a severe disease'. The clinical hallmarks of major necrosis and inflammation, i.e. severe acute hepatitis and fulminant hepatitis, are finally very rare in comparison with hepatitis B. Even in immunologically compromised patients there are very few acute flare-ups in patients with chronic hepatitis C.

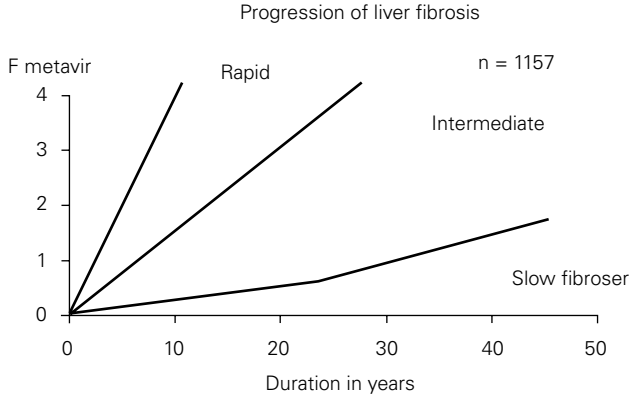

**Figure 31.3** Progression of liver fibrosis in patients with chronic hepatitis C. Using the median fibrosis progression rate, in untreated patients, the median expected time to cirrhosis is 30 years (intermediate fibroser); 33% of patients have an expected median time to cirrhosis of <20 years (rapid fibroser); 31% will progress to cirrhosis in >50 years, if ever (slow fibroser). Adapted with permission from Poynard *et al*.[2]

## The dynamic view of fibrosis progression

Fibrosis stage summarizes the vulnerability of a patient and is predictive of the progression to cirrhosis (Fig. 31.3).[2,3,10,11] There is a strong correlation for fibrosis stages, almost linear, with age at biopsy and duration of infection. This correlation was not observed between activity grades.[2,3,10]

Because of the informative value of fibrosis stage it is of interest for the clinician to assess the speed of the fibrosis progression. The distribution of fibrosis progression rates suggests the presence of at least three populations: a population of 'rapid fibrosers', a population of 'intermediate fibrosers' and a population of 'slow fibrosers' (Fig. 31.2). Therefore, the expression of a mean (or median) fibrosis progression rate per year (stage at the first biopsy/duration of infection) and of a mean expected time to cirrhosis does not signify that the progression to cirrhosis is universal and inevitable. Using the median fibrosis progression rate, in untreated patients, the median expected time to cirrhosis is 30 years; 33% of patients have an expected median time to cirrhosis of <20 years and 31% will progress to cirrhosis in >50 years, if ever (Fig. 31.1).[2,3,10,11]

Limitations of any estimate of fibrosis include (1) the difficulty in obtaining paired liver biopsies, (2) the necessity for large numbers of patients to achieve statistical power and (3) the sample variability in fibrosis distribution. Because the time elapsed between biopsies is relatively short (usually between 12 and 24 months), the number of events (transition from one stage to another) is rare. Therefore, the comparisons between fibrosis progression rates require a large sample size to observe significant differences. The slope of progression is difficult to assess because there is no large database with several biopsies. Therefore, the real slope is currently unknown and even if there is a linear relationship between stages and age at biopsy or duration of infection, other models are possible.[12–14] On a larger database we confirmed that the fibrosis progression was mainly dependent of the age and the duration of infection with four different periods with very slow, slow, intermediate and rapid slopes[10,11] (Fig. 31.2).

Furthermore, liver biopsy has its own limits in assessing liver fibrosis. Although it was the gold standard for scoring fibrosis, its value is limited by very high sample variability.[15–17] Future studies using validated non-invasive biochemical markers, such as FibroTest, should improve modelling of fibrosis progression.[18–21]

## Factors associated with fibrosis progression

Factors associated and not associated with fibrosis are summarized in Table 31.1. Several factors have been shown to be associated with fibrosis progression rate:

**Table 31.1** Factors that are or are not associated with fibrosis progression

| Associated in univariate and multivariate analysis | Not sure | Not associated |
|---|---|---|
| Fibrosis stage | Inflammation | Last serum viral load |
| Age at infection | Haemochromatosis heterozygote | Genotype other than genotype 3 |
| Duration of infection | Cigarette consumption | Mode of infection |
| Age at biopsy | Moderate alcohol consumption | Liver viral load |
| Consumption of alcohol >50 g per day | Genotype 3 | |
| HIV co-infection | Schistosomiasis | |
| CD4 count <200/mL | | |
| Male gender | | |
| Necrosis | | |
| Body mass index and/or diabetes and/or steatosis | | |

duration of infection, age, male gender, heavy consumption of alcohol, human immunodeficiency virus (HIV) co-infection, low CD4 count and necrosis grade.[2,2,10,11,22–24] The progression from infection to cirrhosis depends strongly on age as expressed by duration of infection, age at infection or age at last biopsy.[10,11] Metabolic conditions such as overweight, steatosis and diabetes are emerging as independent co-factors of fibrogenesis.[25,26]

### *Age*

The role of ageing in fibrosis progression could be related to higher vulnerability to environmental factors, especially oxidative stress, to reduction in blood flow, in mitochondria capacity, or in immune capacities.[27]

The effect of age on fibrosis progression is so important that modelling the hepatitis C epidemic without taking into account the age is not possible (Table 31.2). The estimated probability of progression per year for men aged between 61 and 70 years was 300 times greater than that for men aged between 21 and 40 years (Fig. 31.4).[10,11] Age of the transplanted liver has also been associated with higher fibrosis progression rates.[28]

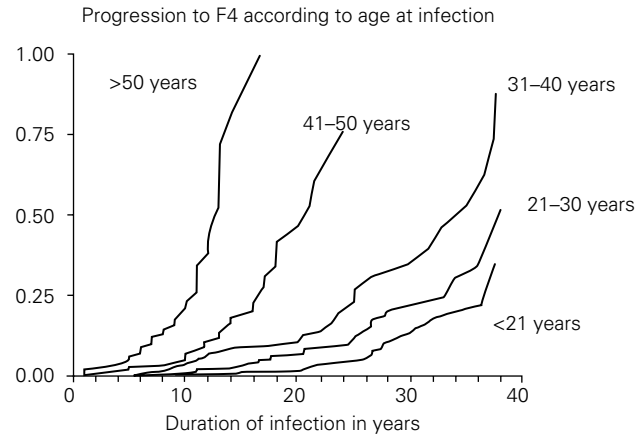

**Figure 31.4** Probability of fibrosis progression to cirrhosis (F4) according to age at infection. Modelling in 2313 patients with known duration of infection. Adapted with permission from Poynard *et al*.[10]

### *Male gender*

Male gender is associated with 10 times more rapid progression to cirrhosis than female, whatever the age.[11] Oestrogen modulates fibrogenesis in experimental in-

**Table 31.2** Multivariate analysis of risk factors by proportional hazards regression model for each fibrosis stage 20 years after HCV infection in 2313 patients

| | Stage F1 | | Stage F2 | | Stage F3 | | Stage F4 | |
|---|---|---|---|---|---|---|---|---|
| Risk factor | Relative hazard | *p* value | Relative hazard | *p* value | Relative hazard | *p* value | Relative hazard | *p* value |
| Infection after 30 years | 4.4 | <0.001 | 4.8 | <0.001 | 11.5 | <0.001 | 27.1 | <0.001 |
| Infection for 21–30 years | 2.3 | <0.001 | 1.8 | <0.001 | 2.5 | <0.001 | 5.3 | <0.001 |
| Alcohol >50 g | 1.3 | 0.20 | 3.0 | <0.001 | 2.3 | 0.008 | 4.5 | 0.001 |
| Male gender | 1.0 | 0.76 | 1.3 | 0.03 | 1.9 | <0.001 | 2.0 | 0.003 |
| Intravenous drug use | 1.6 | <0.001 | 1.2 | 0.22 | 1.4 | 0.11 | 1.2 | 0.55 |
| Activity A2,A3 | 0.8 | 0.009 | 1.2 | 0.21 | 2.0 | <0.001 | 1.4 | 0.16 |

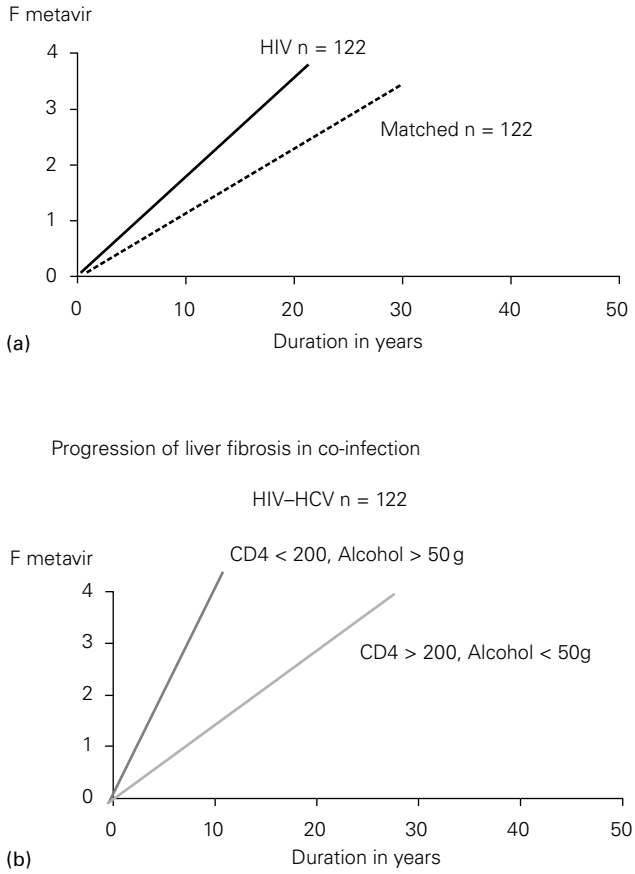

**Figure 31.5** (a) Progression of liver fibrosis among patients co-infected by HCV and HIV. There is a significant increase of fibrosis progression rate among HIV in comparison with matched controls infected by HCV alone. (b) Progression of liver fibrosis among patients co-infected by HCV and HIV. There is a very significant increase of fibrosis progression rate among patients with CD4 <200 per $mm^3$ and drinking >50 grams of alcohol per day. Adapted with permission from Benhamou *et al*.[33]

jury. Oestrogen blocks proliferation and fibrogenesis by stellate cells in primary culture. Oestrogen could be modifying the expression of transforming growth factor and other soluble mediators.[23] Recently, we observed that when the metabolic factors were taken into account the association between male gender and fibrosis was reduced.[29]

### *Alcohol*

The role of alcohol consumption has been established for daily doses >40 or 50 grams per day.[2,10,22,24] For lower doses there are discordant results, with even preliminary studies suggesting a protective effect of very small doses. Alcohol consumption is difficult to quantify and conclusions must be prudent. However, it seems from these studies that the influence of alcohol is independent of other factors, weaker than that of age, and is exerted only at toxic levels of intake.

### *HIV co-infection*

Several studies have demonstrated that patients co-infected with HCV and HIV have one of the most rapid fibrosis progressions in comparison with mono-infected patients or other liver diseases even after taking into account age, sex and alcohol consumption (Fig. 31.5a).[10,30–33] An HIV-infected patient with <200 CD4 cells/μL and drinking >50 grams of alcohol daily has a median expected time to cirrhosis of 16 years versus 36 years for an HIV-infected patient with >200 CD4 cells/μL, drinking 50 grams or less of alcohol daily (Fig. 31.5b).[22]

### *HCV viral genotype*

Viral factors such as genotype, viral load at the time of the biopsy and quasi-species are not associated with fibrosis.[2,10,31,34,35] Only genotype 3 is suspected, because of the steatosis associated with this genotype.[10,36,37]

### *Risk of fibrosis in patients with normal transaminases*

Patients with repeated normal serum transaminase activity have lower fibrosis progression rate than matched control patients with elevated transaminases (Fig. 31.6).[10,38,39] However, 15–19% of these patients do have moderate or high fibrosis progression rates. Therefore, we recommend assessment of the fibrosis stage by performing liver biopsy or biochemical markers in these polymerase chain reaction (PCR)-positive patients. If the patient has septal fibrosis or portal fibrosis with a high fibrosis rate, a treatment should be considered. FibroTest

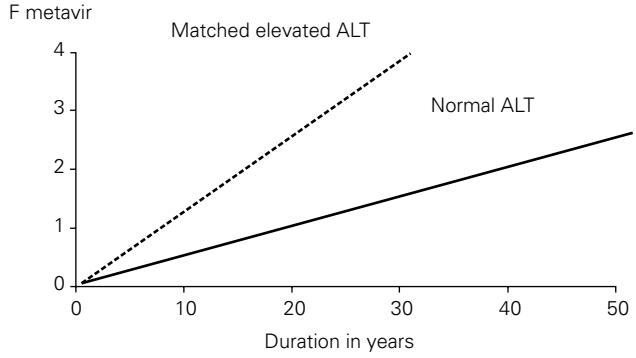

**Figure 31.6** Progression of liver fibrosis in patients who are HCV PCR-positive with repeated normal alanine aminotransferase (ALT). There was a significant reduction of fibrosis progression rate in comparison with matched controls with abnormal ALT. Adapted with permission from Mathurin *et al*.[39]

has the same predictive values in patients with normal or elevated transaminases.[19] In patients aged 65 years or older, there are even more patients with extensive fibrosis and normal transaminases and this population is particularly at risk of high fibrosis progression rates.[40]

## Metabolic factors

### *Impact of steatosis on the pathogenesis of chronic hepatitis C*

With a few exceptions,[41,42] steatosis is associated with a more severe necroinflammatory activity[43,44] or fibrosis.[1,43–48] Steatosis is associated with more advanced fibrosis, even after adjustment for age.[42] In a small number of patients with a known duration of infection, the fibrosis progression rate appeared to be higher when marked steatosis was present than when steatosis was mild or absent.[42] In addition to these transversal studies, some studies with follow-up biopsies in untreated patients are available. A faster progression of fibrosis in patients with steatosis on the first biopsy has been observed, but the small sample size precludes an analysis according to the genotype.[47] It is possible that these relationships can be specific for unknown HCV characteristics, as differences were observed for genotype 3.[47] Other studies suggested that the increase in steatosis rather than its amount could be indicative of fibrosis progression,[49] although a convincing demonstration of this challenging hypothesis is lacking.[50]

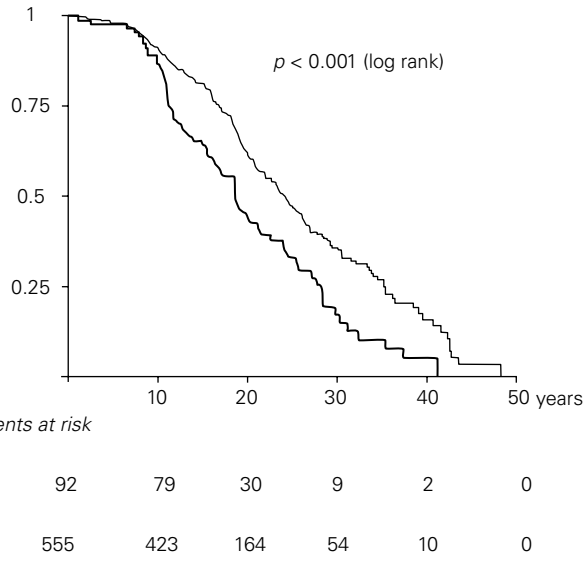

**Figure 31.7** Fibrosis progression according to serum glucose levels. The time-dependent variable was the duration of infection in years. The thick and thin lines represent patients with high or normal serum glucose, respectively. The percentage of patients free of significant fibrosis (F2, F3, F4) is plotted against the duration of infection. Adapted with permission from Ratziu *et al*.[29]

No study documented an association between steatosis and fibrosis independent of other confounding factors such as body mass index (BMI), blood serum glucose levels or serum triglycerides. In one study, the strong association between steatosis and fibrosis disappeared after adjustment for serum glucose and BMI, thus casting doubt on the true relevance of steatosis *per se* to fibrogenesis.[29]

In a single study, steatosis was associated with a higher cumulative incidence of hepatocellular carcinoma, independent of age, cirrhosis and treatment by interferon (IFN).[51]

### *Impact of diabetes on the pathogenesis of chronic hepatitis C*

Although many studies have documented the epidemiological association between hepatitis C and type II diabetes, only a few have focused on its consequences for liver injury.[52] In a small series, the necroinflammatory activity was higher in diabetics than in non-diabetics.[52] Fibrosis stages are usually higher in diabetics, although results are discordant when taking into account other well identified risk factors of liver fibrosis.[46,52–55] In the largest study to date, performed on 710 patients with a known duration of infection, a high serum glucose (as well as overt, drug-treated diabetes) was associated with more advanced liver fibrosis as well as a higher fibrosis progression rate, independent of other risk factors for fibrosis such as age at infection, duration of infection, male sex and alcohol consumption (Fig. 31.7).[29] The fibrogenic impact of a high serum glucose was higher than that associated with overweight, suggesting that measurement of blood glucose could provide more accurate information on the fibrogenic potential of underlying insulin resistance than the mere measurement of the BMI.[29]

A common caveat of these transversal observational studies is that cirrhosis-induced alterations of glucose homeostasis may confound the relation between a high serum glucose/diabetes and liver fibrosis. While this cannot be ruled out, some studies still documented a significant association after exclusion of cirrhotic patients.[29] High serum glucose is associated with intermediate and advanced stages of fibrosis but not with early stages, thus suggesting a more important role in the perpetuation and progression of fibrogenesis rather than its initiation.[29] This should be confirmed in further studies.

### *Impact of obesity on the pathogenesis of chronic hepatitis C*

Overall, obesity seems to worsen liver histology in

chronic hepatitis C. One study has documented a highly significant association between obesity and steatosis as well as between steatosis and fibrosis, although no direct association was found between obesity and fibrosis.[56] Obese patients have more advanced fibrosis stages than lean patients, but this does not appear to be independent of other confounding factors such as a high serum glucose/diabetes.[29,53,54] These discrepancies could result from the fact that none of these studies make the distinction between visceral and peripheral obesity: only the former entity is correlated to insulin resistance and its complications, hepatic steatosis in particular.[57,58]

As a consequence of the complex interactions between insulin resistance and liver injury, it is difficult to analyze the specific contribution of obesity. Therefore, several authors have attempted to identify, on histological grounds alone, the presence of lesions compatible with non-alcoholic steatohepatitis in obese patients with chronic hepatitis C.[46,59,60] Their assumption is that these two fibrogenic conditions would increase liver fibrosis when occurring together, which in turn would demonstrate the contribution of obesity in fibrosis in HCV-infected patients. Unfortunately, the two conditions share many common histological lesions, which make it difficult to assert the presence of non-alcoholic steatohepatitis (NASH) in chronic hepatitis C. The attributable risk of NASH in liver fibrosis of obese patients with hepatitis C may not be determined until more specific markers of NASH than histology or exposure to risk factors such as obesity or diabetes are identified.

Some preliminary data on the possible contribution of obesity to liver injury in chronic hepatitis C come from the demonstration that after a 3-month period of controlled weight loss through diet and exercise, nine of ten patients with hepatitis C had reduced steatosis and five of ten had less fibrosis.[61] Weight loss was associated with improved insulin sensitivity. Although sampling variability of liver biopsy is a significant concern with such a small sample size, the demonstration that cellular markers of stellate cell activation were also turned off in patients with reduced weight and less fibrosis further strengthens the hypothesis of a deleterious impact of obesity in chronic hepatitis C. Similarly, it has been observed that surgical treatment of obesity decreased fibrosis.[62]

### *Interaction between genotype and metabolic factors*

It was observed that fibrosis was associated with steatosis only in genotype 3-infected individuals, and with past alcohol abuse and (marginally) diabetes only in patients infected with genotypes other than genotype 3.[37] Another study confirmed that HCV may induce insulin resistance and accelerate fibrosis progression, and this effect seems to be genotype 3-specific.[63]

### *Other factors*

There are very few studies for the following factors and more studies with a high sample size are needed: fluctuations of HCV RNA, intrahepatic cytokine profiles, HLA class genotype, C282Y heterozygote haemochromatosis gene mutation and cigarette consumption.

## Impact of treatment: regression of liver fibrosis

Many studies have now demonstrated that treatment of hepatitis C with IFN alone or in combination with ribavirin can stop the progression of liver fibrosis or even induce a significant regression of fibrosis.[3,11,21,33,64–73]

We pooled individual data from 3010 naïve patients with pretreatment and post-treatment biopsies from four randomized trials.[69] Ten different regimens combining standard IFN, pegylated IFN (PEG-IFN) and ribavirin were compared. The impact of each regimen was estimated by the percentage of patients with at least one grade improvement in the necrosis and inflammation (METAVIR score), the percentage of patients with at least one stage worsening in fibrosis METAVIR score and by the fibrosis progression rate per year. Necrosis and inflammation improvement ranged from 39% (IFN 24 weeks) to 73% (PEG-IFN 1.5 μg/kg + ribavirin >10.6 mg/kg/day). Fibrosis worsening ranged from 23% (IFN 24 weeks) to 8% (PEG-IFN 1.5 μg/kg + ribavirin >10.6 mg/kg/day). All regimens significantly reduced the fibrosis progression rates in comparison with rates before treatment. This effect can be observed even in patients without sustained virological response.

The reversal of cirrhosis was observed in 75 (49%) of 153 patients with baseline cirrhosis.[69] Six factors were independently and significantly associated with the absence of significant fibrosis after treatment: baseline fibrosis stage (odds ratio, OR = 0.12), sustained viral response (OR = 0.36), age <40 years (OR = 0.51), BMI <27 kg/m$^2$ (OR = 0.65), no or minimal baseline activity (OR = 0.70) and viral load <3.5 million copies per mL (OR = 0.79). Other studies have also documented reversal of cirrhosis in patients treated with PEG-IFN.[74]

## Conclusion

Tremendous progress has been achieved in the comprehension of fibrosis progression in patients with chronic hepatitis C. The roles of ageing and metabolic factors are particularly important for therapeutic decisions. The treatment of hepatitis C with IFN and ribavirin in combination is very effective for blocking fibrosis progression and can even induce reversal of cirrhosis, a concept that would have been unbelievable 10 years ago.

Unfortunately, even in developed countries, death due to hepatitis C is increasing because of inadequate detection and treatment.

# Chapter 32
# The natural history of hepatitis C and hepatocellular carcinoma

Edward Tabor

The disease caused by hepatitis C virus (HCV) infection is a continuum that extends over a period of decades. It ranges from acute infection early in the course to chronic infection in the majority of patients, and in some patients leads to hepatocellular carcinoma (HCC) near the end. It is estimated that 3.9 million Americans have antibody to HCV (anti-HCV), indicating current or prior infection with HCV, and 2.7 million of them have detectable HCV RNA in their serum, indicating a current infection (most of which are chronic infections). Most of these individuals are unaware that they have chronic HCV infections. Some will come to medical attention during the next two decades when HCV infections in the peak prevalence age group begin to cause life-altering symptoms, and a small but definable percentage will eventually develop HCV-associated HCC.

HCV infection is an important factor in the aetiology of HCC throughout the world. In Japan, the incidence of HCC, mostly associated with HCV infection, ranges from 11 to 32/100 000 among males (and from four to 8/100 000 in females).[1] In contrast, the incidence of HCC among males in the general population of the United States and Canada is 2/100 000 and 3/100 000, respectively (1/100 000 for females in both countries),[1] and only about 14–32% are associated with HCV infection.[2,3]

In all of these areas, cases of HCC associated with hepatitis B virus (HBV) infection also continue to occur. In Japan, HBV-associated HCC remains at a background level that is relatively constant from year to year, 24–27% of HCC patients.[4–6] In Africa and in some parts of Asia, such as China, HBV-associated HCC remains the predominant form of HCC.[1] In southern China, 70% of HCCs are associated with chronic HBV infections and only 5% with HCV infections.[7]

## The natural history of HCV infection

### Acute HCV infection

Acute HCV infection is characterized by the appearance of HCV RNA in the blood beginning 1–3 weeks after exposure. Symptoms can include jaundice, malaise, weakness and anorexia. However, symptoms are not observed in many individuals, even if liver enzymes in serum (e.g. alanine aminotransferase, ALT) are elevated. In most patients, symptoms resolve, but only about 23% truly recover, as defined by HCV RNA becoming undetectable in their serum.[8]

### Chronic HCV infection

HCV infections evolve into chronic hepatitis in 60–85% of acutely infected patients. The definition of 'chronic hepatitis C' is generally accepted as the detection of HCV RNA in serum for a period of at least 6 months. Most chronic HCV infections are life-long in duration without effective therapy. Spontaneous clearance of HCV occurs in patients with chronic HCV infections at a rate of 0.5% per year.[9]

The existence of chronic HCV infection may first be noted when elevated ALT levels are found on routine screening. As a result, many chronic HCV infections are not recognized until very late in the course. Many patients with chronic HCV infection will develop fibrosis of the liver and some will progress to cirrhosis. The task of predicting who among them will develop cirrhosis is daunting and new approaches are still being developed.

About 70% of individuals with chronic HCV infection are asymptomatic. ALT levels can also be normal

in some asymptomatic patients. Among all individuals with chronic HCV infection, 30% have persistently normal ALT levels, and another 40% have minimal or intermittent minimal elevations of ALT levels. Most of these individuals with normal or minimally elevated ALT levels are believed not to be at risk for progression to cirrhosis or HCC. However, careful observation is advisable because of the theoretical possibility that some could progress to cirrhosis or HCC.[10] Most patients with HCV RNA in their serum for a period of years and normal ALT levels have been shown to have persistently normal liver histology in liver biopsies obtained 2–5 years later.[11]

Life-long immunity to HCV appears to develop in almost all patients in whom spontaneous resolution occurs (i.e. loss of detectable HCV RNA). This combination of resolution and lasting immunity apparently requires the presence of an effective CD4 T-helper cell response. Conversely, the absence of an effective CD4 response has been shown to be associated with persistent viraemia and the emergence of escape mutants (based on studies in chimpanzees with chronic HCV infections in which the CD4 response was experimentally blocked).[12] If the CD4 response is adequate but is not accompanied by adequate interferon (IFN)-γ production, chronicity of HCV infection and development of HCC may be more likely to occur.[13]

## Development of cirrhosis

From 4% to 24% of persons with chronic HCV infection develop cirrhosis. The rate depends on the population, with lower rates (4–7%) being found in community-based and blood donor cohorts, and higher rates (>20%) being found in populations of HCV-infected patients followed in liver clinics.[14,15] Risk factors for development of cirrhosis include acquisition of HCV infection after age 30 years[15] and heavy ingestion of alcohol.[14]

As many as 70–80% of HCC patients have cirrhosis in the adjacent non-tumorous liver. The high rate of co-existing cirrhosis in HCC patients and the emergence of HCC in prospectively followed cirrhosis patients have led to the assumption that pre-existing cirrhosis is an important prerequisite for hepatocarcinogenesis, although some HCCs do arise in the absence of cirrhosis. It is generally believed that the majority of HCCs develop in a progression from acute hepatitis through various stages of chronic hepatitis, to cirrhosis, to HCC. In HCV-associated cirrhosis, the cumulative development of HCC increases steadily with time, reaching as high as 75% at 15 years in one study.[16] In contrast, in HBV-associated cirrhosis,[2] the cumulative prevalence increases with time but levels off (in one study, at 27% of patients after 8 years of follow-up[16]). Higher rates of HCC have been reported in cirrhosis inpatient studies.[17] There is an even greater risk of a patient with cirrhosis developing HCV-associated[18] but not HBV-associated[16] HCC if alcoholism is present in addition.

## Development of HCC

The incidence of HCC developing in patients with HCV-associated cirrhosis has been reported to be 2% per year (5-year cumulative incidence of 10%).[19] Others have reported an incidence of 5% per year, although this is generally considered to be unusual (cumulative incidence of 75% after 15 years).[16] In a study of haemophiliac patients with HCV cirrhosis, the incidence of HCC was 2% per year (12% during a 6-year study; most did not have co-infection with human immunodeficiency virus).[20] HCC is most likely to develop in those haemophiliacs who became infected with HCV as adults, particularly after age 40 years.[21,22]

It has been estimated that the mean interval from infection to diagnosis of cirrhosis is 20–24 years, and from infection to diagnosis of HCC is 27–29 years, based on a variety of studies.[8] Heavy ingestion of alcohol accompanying chronic HCV infection with cirrhosis results in a greater incidence of HCC, compared with cirrhosis patients with HCV and no alcohol use, or compared with those with heavy alcohol use alone (with no serological evidence of HCV).[18] (The same has not been found with regard to HBV-associated cirrhosis and alcohol.[16]) This could be due to additive damage to the liver from the two toxic agents (HCV and alcohol), or it could be due to a potentiation of HCV expression by alcohol by means of activating the transcription factor NF-κB, which has been demonstrated to occur in *in vitro* studies.[23]

Notwithstanding that HCV infection is believed to have a substantial negative effect on the quality of life and life expectancy of the patient, it is important to mention two reports that did not find increased mortality due to HCV, even though they may not be generalizable to other populations. In one study, a 67% all-cause mortality was observed in patients with HCV-associated ALT elevations acquired by transfusions after approximately 25 years. However, this mortality rate was no greater than that (65%) in a population of transfused controls who had not developed post-transfusion elevation of ALT (but who also were anti-HCV positive).[8] In this study, there was also a relatively low (3.3%) liver-related mortality in cases, compared with 0.3% in controls.[8] In another study, a 25-year follow-up of community-acquired HCV infection in Australia, excess mortality was observed in HCV-infected persons but was not due to liver disease.[24] It is not clear why these observations are so much at variance with the findings in other studies.

The possibility that mutations in HCV could play a role in the course of chronic HCV infection leading to HCC has not been fully investigated. No unique muta-

tions have been identified in HCV obtained from HCC patients.[25] An association between a greater number of HCV quasi-species in patients and the development of HCC has been suggested.[26] This could be consistent with a role for HCV mutations in carcinogenesis, but there are no data to support such a role at present.

## The rising incidence of HCC

During the past half-century, the incidence of HCC has doubled approximately every 20 years in Japan;[27–30] an increase that has been shown to be due primarily to cases associated with HCV infection.[27,30] Today, the prevalence of of HCV infection (anti-HCV without concomitant HBsAg) among HCCs in Japan is 54–70%.[4–6]

Essentially, the rise in HCC incidence is a direct reflection of the rise in HCV incidence in Japan. The high incidence of HCV in Japan is felt to be a post-World War II phenomenon, due to the reuse of medical syringes with inadequate sterilization, in an era before the availability of disposable plastic syringes. However, this widely held explanation is not based on systematic scientific or historical analyses, and the possibility that other societal changes in that era may be responsible for the high incidence of HCV should not be ruled out. Nevertheless, studies conducted among persons of Japanese ancestry living in Hawaii support the concept that the HCV incidence in Japan is at least a 20th Century phenomenon.[31]

It is perhaps consistent with this theory that areas in Japan with high endemicity of HCV appear to be very focal. Although the prevalence of HCV infection in the general population in Japan is high compared with the United States (about 1–2% of potential blood donors in large cities in Japan),[29,32,33] the prevalence of HCV is significantly higher in some towns and villages in Japan. Three such pockets have been reported: 'Village A' in Miyazaki prefecture, in which 23% of the population have anti-HCV,[34,35] 'Town H' in Fukuoka prefecture, in which 23% of the population have anti-HCV,[36] and 'K Town' in Saga prefecture, in which 22% of the population have anti-HCV.[37]

Preliminary evidence suggests that the incidence of HCC also may be increasing in the United States and other Western countries. Although none of those studies has so far included virological test results that could be used to determine whether HCV is an aetiological factor (most were retrospective analyses of large databases), many authorities have assumed that the increase in HCC incidence in Western countries also might be associated with HCV infection because of the epidemic increases in HCV incidence in recent years in the countries involved. An analysis of the SEER database revealed that the incidence of HCC in the United States increased from 1.4/100 000 in the period 1976–1980 to 2.4/100 000 in the period 1991–1995, a 41% increase.[38] Others reported a 140% increase in HCC incidence in the 47 years between 1950–1996 in the USA, also based on the SEER database.[39] A doubling of the incidence of HCC in the US state of Colorado between 1988 and 1997 has been reported.[40] Similarly, a nearly fourfold increase in HCC incidence (1.9 to 7.6/100 000) was reported in Göteborg, Sweden between 1958 and 1979.[41] A nearly fourfold increase in HCC incidence in men was reported in France between 1979 and 1994 (an increase from 3.2 to 11.1/100 000), along with a doubling in women (an increase from 1.2 to 2.5/100 000).[42]

Infection with both HBV and HCV (presence of both HBsAg and anti-HCV) has been reported in 3–13% of HCC patients.[2–7] In addition to these patients, a few additional patients with HCV infection may also have so-called 'silent HBV' infections, in which HBV DNA can be detected in serum and/or liver despite the absence of detectable serological markers of HBV infection.[43–46] These should also be considered to be co-infections with HBV and HCV, in considering the aetiology of their HCCs.

Nevertheless, it is not clear whether simultaneous infection with HBV and HCV truly increases the risk of developing HCC. The findings of both viruses in HCC patients could reflect the existence of common risk factors for exposure to both viruses, for instance because both viruses are blood-borne. Recent work has not answered the question. Some studies have supported an additive role and others have not. For instance, in one retrospective cohort study of 459 HCV-infected patients for an average of 6.6 ± 3.3 years, 23% of patients with anti-HBc developed HCC compared with only 9% of those without anti-HBc,[47] although no testing of HBsAg was reported. Another study, however, reported that the prevalence of anti-HBc in HCV-infected HCC patients was similar to that among HCV-infected candidate blood donors (i.e. without HCC) in Japan (54–56%).[48] In addition, simultaneous infections with HBV and HCV appear not to affect the severity or aggressiveness of HCC.[49]

## The effect of therapy for HCV: 'chemoprevention' for HCC

Treatment of HCV infection, particularly early in the course of infection, theoretically could prevent the development of HCC as an outcome of HCV infection. At present, the only data on prevention of HCC by treating the HCV infection involve IFN-α. Even though the combination of IFN-α and ribavirin has been shown to be far more effective in treating chronic HCV infection than IFN-α alone, the combination has not been evaluated for its impact on preventing HCC.

A reduction in HCC incidence in HCV-infected persons treated with IFN-α has been reported by many investigators[50–53] (reviewed by Tabor[54]). Nevertheless, most of the published studies have had defects in study design such as pooling of patients who received a variety of IFN-α treatment regimens, short periods of follow-up (relative to the incubation time for HCC), large numbers of drop-outs, and retrospective study design with historical controls. As a result, one must be cautious in evaluating chemoprevention of HCC with IFN-α until further studies are available. Preferably, future studies should evaluate the combination of IFN-α and ribavirin.

In many of these studies, it has appeared that more HCCs developed among non-responders to HCV treatment with IFN-α (i.e. patients in whom ALT or HCV RNA did not decrease or whose ALT or HCV RNA levels fluctuated after IFN treatment) than among responders. For example, in one study, HCC developed in 10/30 (33%) non-responders to IFN-α compared with 2/15 (13%) with a complete or partial response.[55–57] (In addition, the reduction in risk of HCC was greatest in patients without ALT elevations.[57]) In another similar study, HCC developed in 16% of 38 non-responders to IFN-α compared with none of 25 sustained responders, among patients with chronic active hepatitis due to HCV, all initially without cirrhosis (five of the six who developed HCC also eventually developed cirrhosis).[58] In another study, IFN-α treatment of HCV-infected patients with cirrhosis was reported to result in a sixfold reduction in developing HCC.[59]

## Projections for the future

We can expect a substantial increase in the incidence of HCV-associated HCC throughout the world, and probably also in the United States. The high prevalence of chronic HCV infections in many countries, combined with aging of those cohorts, is expected to lead to a greater prevalence of HCC. At present, the prevalence of HCC is directly proportional to the incidence of HCC, as the vast majority of HCC cases are fatal within 6 months of diagnosis.

It has been projected that the prevalence of HCV infections in the USA will peak (and begin to decline) by 2040.[60] By 2020, the prevalence of cirrhosis among HCV-infected persons will increase to a level of 32%. By 2020, the prevalence of HCC will nearly double (nearly 81% over current levels).[60] This consists of an increase in HCV-associated HCC from 7271 cases in 2000 to 13 183 in 2020. This model takes into account the aging of the cohort currently infected with HCV and the increased efficacy of antiviral therapy for HCV infection.

# Chapter 33
# Treatment of chronic hepatitis C

Jenny Heathcote, Janice Main

## Introduction

Acute infection with hepatitis C virus (HCV) is followed by chronic infection in 50–80% of those infected.[1,2] Individuals with chronic hepatitis C without treatment rarely spontaneously clear virus unless there is a change in their immune status.[3] Chronic infection is associated with multiple morbidities, not all due to liver disease. Data from post-transfusion studies indicate that the mortality from hepatitis C appears to be no more than 10–15%.[4]

It has been estimated that 2.2% of the world's population, i.e. 130 million individuals, are infected with hepatitis C. The majority have been infected via parenteral exposure with contaminated injections, either related to injection drug use (illegal) or contaminated injections or transfusion with blood products received as part of an individual's health care (iatrogenic). The majority of infected individuals are hard to access, thus, were primary prevention possible, it would be difficult to achieve in these particularly hard to reach populations. Secondary prevention, i.e. preventing an acute infection from becoming chronic, is effective but again is hard to achieve unless the individual is being closely monitored and the infection resulted from occupational exposure.

The current standard of care for hepatitis C is pegylated interferon-alpha (PEG-IFN-α) (given once weekly) in combination with oral ribavirin (given daily).[5] When interpreting the results of phase III studies, it must be realized that the participants included were a select patient population without significant co-morbidities, who were agreeable to regular follow-up in tertiary referral centres, and for the most part had only mild chronic hepatitis, i.e. probably not representative of the population at large chronically infected with hepatitis C.

## Treatment of acute hepatitis C infection

Because the majority of individuals infected acutely with hepatitis C are either asymptomatic or, if symptomatic, have other more serious life issues to contend with, it is rare outside the context of occupational exposure or close monitoring of injection drug users (IDUs) for an acute infection with hepatitis C to be identified. Recent data indicate that these two particular populations who are repeatedly exposed to small doses of hepatitis C may have evidence of cell-mediated immunity in the absence of viraemia and/or antibody (about a third), indicating that far more people than have been realized in the past have in fact been infected with hepatitis C and have spontaneously cleared the virus.[6–8] However, on re-exposure they may become transiently reinfected or chronically infected.[9]

Those who have been identified as being acutely infected need to be monitored closely for the first 12 weeks to establish whether or not they will undergo spontaneous viral clearance. Serum HCV RNA (qualitative, i.e. very sensitive) needs to be measured as close to baseline as possible, and this test should be repeated at least before 12 weeks have passed.[10] Rapid viral decline in titre after the initial identification of viraemia may predict those who will spontaneously clear virus, although this is not 100% reliable.[11] In those who remain viraemic at 12 weeks after initial seroconversion, antiviral therapy is recommended if there are no absolute contraindications to its use. The largest uncontrolled study which employed induction dosing with standard IFN-α-2b indicated that 95% of treated patients achieved a sustained virological response with only 6 months of therapy.[12] It is unlikely that the newer forms of IFN, namely PEG-IFN-α in combination with ribavirin, are going to be much more successful!

## Antiviral therapy for chronic hepatitis C

The standard of care as of 2002 is weekly subcutaneous PEG-IFN-α given in combination with daily oral ribavirin, but the optimal duration of treatment remains unclear.[5] Two large phase III studies, one employing PEG-IFN-α-2b plus ribavirin,[13] and the other PEG-IFN-α-2a plus ribavirin[14] – both given for 48 weeks – have demonstrated enhanced efficacy when compared with the earlier standard of care, i.e. standard IFN-α-2b given three times per week subcutaneously combined with

daily oral ribavirin. Sustained virologic response (SVR) rates, defined as undetectable HCV RNA (using a qualitative technique) in serum 6 months after cessation of therapy were 54% and 56%, respectively (Figs 33.1 and 33.2),[13,14] but there were some genotype-specific differences between the two forms of PEG-IFN-α. These differences may have resulted from what has now been clearly shown to be an inadequate dose of ribavarin (800 mg daily) when given to individuals infected with genotype 1, in the PEG-IFN-α-2b plus ribavirin study. So in the 48-week trial which involved PEG-IFN-α-2b plus ribavirin, antiviral efficacy in genotype 1 in the low dose and high dose IFN regimens was 34% and 42%, respectively, whereas for genotypes 2 or 3 it was 82% and 80% (SVR for genotypes 4/5/6 were 33% and 50%).

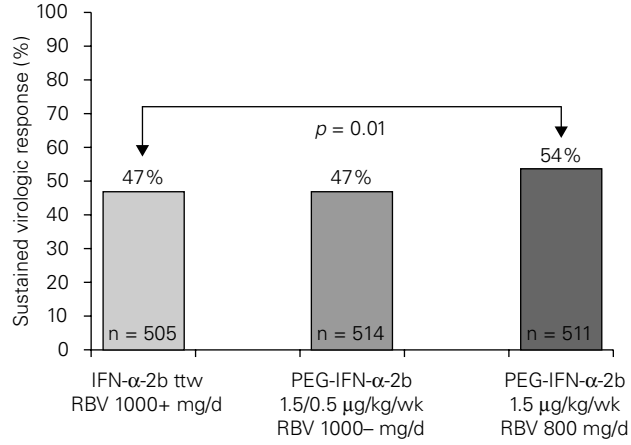

**Figure 33.1** PEG-IFN-α-2b (12 kDa) + ribavarin: 48 weeks sustained virologic response (SVR). RBV, ribavarin. (From Manns *et al*., *Lancet* 2001;**358**:958.[13])

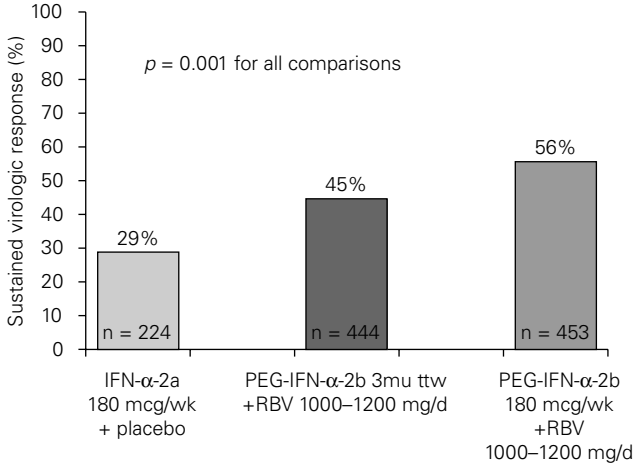

**Figure 33.2** PEG-IFN-α-2a (40 kDa) + ribavarin: 48 weeks sustained virologic response (SVR). RBV, ribavarin. (From Fried *et al*., *N Engl J Med* 2002;**347**:975.[14])

In the 48-week phase III trial of PEG-IFN-α-2a plus ribavirin, only one dose, 180 μg/wk of IFN and 1000–1200 mg ribavirin, was evaluated. In those with genotype 1, high viral load ($>2 \times 10^6$ c/mL) overall SVR was 41% (compared with 33% for standard IFN-α-2b plus ribavirin), whereas the SVR in those infected with either genotype 2 or 3 was 76% compared with 61% in those who received standard IFN-α-2b plus ribavirin.

It is likely that 24 weeks of treatment is sufficient for those infected with genotypes 2 and 3. Because of small numbers, the most appropriate duration of therapy for genotypes 4, 5 and 6 is unknown, whereas it is felt that for those infected with genotype 1 therapy for a full 48 weeks is required. Durability of SVR is excellent[15] and unless the patient is known to have cirrhosis pretreatment, long-term follow-up after achieving an SVR is probably unnecessary.

## Pharmacokinetics of PEG-IFNs

There are intrinsic differences between the two PEG-IFN-α preparations, causing the molecular weight and hence their pharmacokinetics to differ quite considerably[16] (Table 33.1). As the dose of PEG-IFN-α-2b, the 12-kDa molecule, needs to be weight-based (as does ribavirin), efficacy in part depends on the correct dose being given for a particular body weight. The larger size of the 40-kDa PEG-IFN-α-2a molecule means that it has a smaller volume of distribution, and thus it is unlikely that weight-based dosing is required.

## Who should be treated for chronic hepatitis C?

As treatment with PEG-IFN-α and ribavirin is curative in only about 50% of patients and this treatment regimen is associated with a wide spectrum of quite severe side-effects, treatment is not recommended for all infected individuals. In treatment-naïve individuals, those with a persistent hepatitis, as judged by elevated serum alanine aminotransferase (ALT) levels and a liver biopsy which shows some evidence of progressive disease in terms of hepatic fibrosis and who have no absolute contraindications to the standard of care, are thought to be the most appropriate to undergo antiviral therapy.[5]

There are many individuals who do not fulfil these criteria but who wish to be treated, e.g. those with persistently normal ALT levels, despite chronic infection. The response to treatment in those with normal ALT is no different from those who have persistently elevated ALT levels.[17] Others may have co-morbid complications of their hepatitis C, e.g. those with active vasculitus, secondary to an associated cryoglobulinaemia who require treatment for their vasculitus more than for their liver disease. In other situations, an infected

**Table 33.1** Pharmacokinetics standard and PEG-IFN-α

| | Standard PEG-IFN-α | IFN-α PEG-IFN-α–2b (12 kDa) | IFN-α PEG-IFN-α–2a (40 kDa) |
|---|---|---|---|
| Absorption half-life (h) | 2.3 | 4.6 | 50 |
| Elimination of half-life (h) | 2–5 | ≈ 40 | 77 |
| Volume of distribution (L) | 31–98 | 80 | 6–14 |
| Renal clearance (mL/h) | 11 800–16 170 | 1540 | 80 |

h, hours.

individual may be better off being treated sooner rather than later as it can be anticipated that they will be unsuitable candidates for treatment in the future. For example, individuals with minimally impaired renal function in whom subsequent development of end-stage renal failure can be anticipated, when effective antiviral therapy for hepatitis C will be much harder to institute.

The association of human immunodeficiency virus (HIV) infection and HCV is common, as both are acquired via similar routes. Since the advent of highly active antiretroviral therapy (HAART) for HIV, there has been a marked improvement in disease progression of HIV and with this, the relevance of the co-infection with hepatitis C has become more apparent. Disease progression in those with co-infection is much more rapid,[18,19] and death from liver failure in individuals with both controlled and uncontrolled HIV infection occurs.[20] Individuals co-infected with HIV and hepatitis C present a particularly urgent need for treatment, but the co-infection and the treatment for the same present very specific issues with regards to therapy and thus often the expertise from several disciplines, e.g. infectious diseases, hepatology and addiction medicine, is required[21] (see Chapter 50).

## Assessment of Individuals with chronic hepatitis C prior to antiviral therapy

There are some very definite contraindications to treatment with IFN and/or ribavirin that preclude certain individuals from receiving this therapy. In addition, there are other relative contraindications which, if they can be ameliorated, may allow antiviral therapy to be initiated. There are also a number of pretreatment conditions which affect treatment outcome in terms of antiviral responsiveness. Some of these – such as viral genotype – cannot be altered, but others may be modified, e.g. body weight, alcohol intake. Hence, it is important that the assessment of infected individuals includes not only screening for absolute contraindications, but also education of the patient so that their therapeutic outcome can be optimized.

## Absolute contraindications to PEG-IFN-α and/or ribavirin (Table 33.2)

### Hepatic decompensation

Any evidence of hepatic decompensation precludes treatment with IFN-α combined with ribavirin (except in rare circumstances just prior to a liver transplant).[22] It is important that the treating physician appreciates the sometimes subtle findings of hepatic failure, e.g. any elevation in serum bilirubin (in the absence of haemolysis or Gilberts' syndrome), an elevation of the international-alized ratio (INR) or a lowering below the lower limit of normal for serum albumin. The more obvious signs of liver failure such as jaundice, variceal haemorrhage, hepatic encephalopathy and ascites are not difficult to miss! If they are suitable candidates, it is better to refer such individuals to a liver transplant centre.

### Autoimmune disease

Both IFN and ribavirin modify the immune response, and it is likely that it is the combination of this stimulation of the immune response together with the antiviral activity of IFN (less so with ribavirin) that promotes viral clearance. Thus, in individuals who have an autoimmune disease, treatment with IFN and ribavirin could worsen their autoimmune condition,

**Table 33.2** Contraindications to antiviral therapy for hepatitis C

| |
|---|
| Interferon |
| Hepatic decompensation |
| Cardiac arrhythmia |
| Uncontrolled seizures / depression |
| Psychosis |
| Autoimmune disease (except thyroid) |
| Platelets < 70, ANC <1500 |
| Ribavirin |
| Renal failure |
| Ischaemic vascular / heart disease |
| Unwillingness to practise birth control |

so it is not recommended that individuals with active autoimmune disease undergo antiviral therapy, except in situations where simple drug therapy, e.g. thyroid replacement, is all that is required to control the effects of the autoimmune disease. Additionally, the need for immunosuppressive therapy to control autoimmune disease causes HCV RNA titres to be very high, which may reduce the chance of an SVR. Hence, the management of hepatitis C in individuals with autoimmune liver disease requires careful assessment of the risk: benefit ratio.

## Cardiac arrhythmias

Although rare, IFN therapy may induce a reversible cardiac arrhythmia[23] or cardiomyopathy,[24] and it is inadvisable to use IFN in individuals with ventricular arrhythmias or any other form of significant cardiac disease. It is rare for such individuals to be contemplated for antiviral therapy, as their cardiac disease usually presents a much greater risk of death than their hepatitis C.

## Anaemia/ischaemic vascular disease

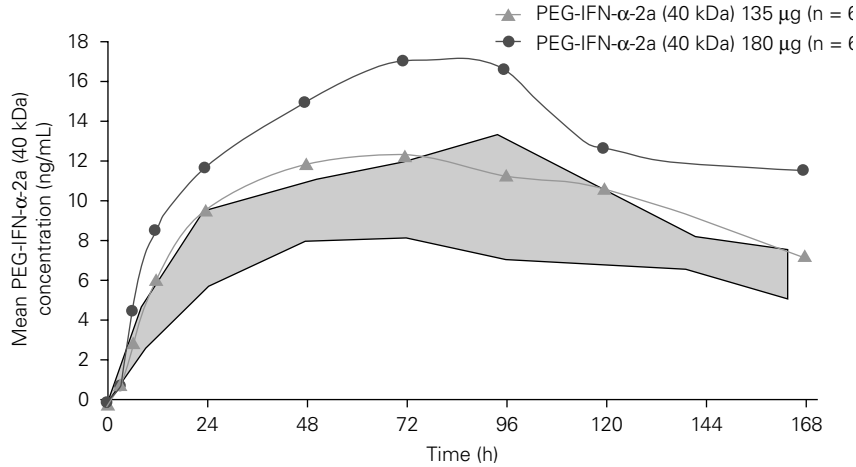
Ribavirin therapy is complicated by varying degrees of haemolysis in at least one-third of individuals undergoing combination therapy,[25] which may induce a sudden fall in haemoglobin. As it is a bone marrow suppressant, IFN monotherapy is also associated with a more gradual fall in haemoglobin. Thus, individuals who are anaemic at baseline need correction of their anaemia prior to the initiation of therapy. The risk incurred by a sudden fall in haemoglobin upon introduction of ribavirin means that individuals with ischaemic vascular disease (cardiac in particular) are unwise to undergo therapy for their chronic hepatitis C, if it involves the use of ribavirin.

## Renal failure

Ribavirin is excreted via the kidney, and so any renal impairment will promote high blood levels (particularly within erythrocytes) and as the usual half-life of ribavirin is 120 days, the presence of renal failure promotes severe ongoing haemolysis, and thus its use is contraindicated in renal failure. Very low-dose ribavirin has been utilized in end-stage renal disease in a few studies.[26] PEG-IFN, because its molecular size is much larger than that of standard IFN, has less renal excretion and may be better tolerated in patients with end-stage renal failure. Pharmacokinetic studies conducted in patients with varying degrees of impairment indicate that when the creatinine clearance is <30 mL/min blood levels of IFN when given as PEG-IFN-α-2a become markedly elevated,[27] not so with PEG-IFN-α-2a (the larger molecular weight form of PEG-IFN-α) (Fig. 33.3).

## Pregnancy

Ribavirin is teratogenic, whether it is taken by the male or the female in a partnership, and thus it is essential that all treated patients and their sexual partners practise safe sex, not only during the entire course of therapy, but for at least 6 months after the cessation of therapy because of the prolonged half-life of ribavirin.



*Shaded area denotes concentration of PEG-IFN-α-2a (40 kDa) for both doses in patients with normal creatinine clearance

**Figure 33.3** Pharmacokinetics of PEG-IFN-α-2a (40 kDa) in end-stage renal disease. The shaded area denotes concentration of PEG-IFN-α-2a (40 kDa) for both doses in patients with normal creatinine clearance. (From Lamb *et al.*, *Hepatology* 2001;**34**(Pt 2):266A.)

## Relative contraindications to antiviral therapy with PEG-IFN-α and ribavirin

### Pancytopenia

IFN is a bone marrow depressant, and it causes a dose-related neutropenia, thrombocytopenia and anaemia.[25] Adjunctive therapy to support blood components and high dose IFN therapy is efficacious in individuals with either a low absolute neutrophil count and/or haemoglobin at baseline.[28] However, there are no data yet that indicate that this very expensive therapy enhances antiviral responsiveness! The need for adjunctive therapy to support blood components is common in patients with HIV/HCV co-infection and/or in those with cirrhosis complicated by hypersplenism. Although the administration of granulocyte colony stimulating factor (G-CSF) will induce a marked rise in the peripheral neutrophil count, it remains to be seen whether this therapy reduces the chance of a bacterial infection. In the published phase III trials, in the few patients who had their PEG-IFN-α and ribavirin therapy complicated by an episode of sepsis, none developed sepsis at a time when their absolute neutrophil count was below $1.5 \times 10^9$ cells/mm$^3$.[13,14] Erythropoietin will increase the haemoglobin in anaemic patients suffering from chronic renal failure or those on HAART for their HIV infection. Another patient population frequently infected with HCV comprises those with congenital haemoglobinopathy, e.g. thalassaemia. Such individuals may be supported by blood transfusions during the course of antiviral therapy very successfully.[29]

### Psychiatric disorders

IFN, a cytokine, causes flu-like symptoms, malaise and mood changes and frank depression,[30] and thus individuals who already suffer from mood instability before treatment can be made much worse by antiviral therapy for their hepatitis C. In the past, depression has been considered a contraindication to treatment with IFN. In a large study of patients with melanoma undergoing IFN therapy, a randomized control trial of paroxetine (a selective serotonin-reuptake inhibitor, SSRI) clearly indicated that this drug was able to prevent IFN-associated depression.[31] The use of SSRIs in any individual who has a past history of depression has allowed many such individuals to undergo successful antiviral therapy without dire consequences. There are early reports suggesting that individuals with other psychiatric conditions may also undergo antiviral therapy for their hepatitis C safely[32] – individuals with schizophrenia or bipolar disorder were excluded from this study.

**Table 33.3** Factors influencing response to antiviral therapy – hepatitis C

| Viral | Host |
|---|---|
| Viral genotype | Race |
| HIV co-infection | Age |
| Viral load | Body weight |
| Early evolution of quasi-species | Alcohol |
| | Fibrosis |

### Seizure disorders

Whereas epilepsy may be exacerbated by the use of IFN therapy, those individuals whose seizure disorder is well controlled with drug therapy can safely be treated for their hepatitis C if this is felt to be necessary.

## Factors influencing response to antiviral therapy for hepatitis C (Table 33.3)

### Non-adjustable factors

#### *Viral genotype*

Viral genotype is the major viral factor which determines the likelihood of achieving an SVR following a complete course of antiviral therapy for hepatitis C. All studies, whether employing standard or pegylated IFN, given with or without ribavirin, indicate that the patients most likely to respond to therapy are those infected with genotype 2 and slightly less so, those with genotype 3. Unfortunately, the majority of individuals worldwide are infected with less responsive genotypes, namely genotypes 1 and 4.

#### *Viral load*

When antiviral therapies were less effective than they are now, viral load played an important role in determining whether the outcome of therapy was successful. However, the maintenance of high IFN levels week-long with PEG-IFNs has reduced the influence of viral load on antiviral responsiveness. But in immunosuppressed individuals, the viral load can be very high (as is found in HIV co-infected or post-liver transplant patients) and in these circumstances, the high viral titre combined with poor tolerance to antiviral therapy for hepatitis C reduces the likelihood of an SVR. Studies indicate that the pattern of quasi-species development following introduction of therapy also correlates with virological outcome.[33]

### *Ethnicity*

For reasons that still remain unclear, African-Americans respond poorly to antiviral therapy, regardless of infecting genotype.[34] This may or may not relate to specific genetic polymorphisms of IFN-associated proteins.

### *Degree of hepatic fibrosis*

Consistently across all published trials, the greater the degree of hepatic fibrosis the lower the response to antiviral therapy. When standard IFN monotherapy was used, there was a negligible response seen in patients with cirrhosis,[35] but upon the introduction of the long-acting PEG-IFN, a marked improvement was observed, such that 30% of patients with bridging fibrosis or cirrhosis achieved SVR with PEG-IFN-α-2a monotherapy.[36] Combination of ribavirin with PEG-IFN has improved the chance of SVR to just over 40%.[13,14] However, this figure still remains less than may be achieved in individuals without background cirrhosis.

## Adjustable factors

### *Hepatic steatosis and/or body mass index*

Recent data indicate that both the degree of fat within hepatocytes[37] and overall body weight, better still, body mass index (BMI), appear to influence treatment response.[38] An aggressive weight loss programme induced by a combination of dietary modification and exercise has been associated with a reduction in hepatic fat and a reduction in hepatic fibrosis in a small sample of individuals with hepatitis C.[39] It is logical to assume that this may lead to enhanced responsiveness to antiviral therapy, but this will be hard to prove.

It remains unclear whether all PEG-IFN doses should be weight-based. Weight-based dosing is recommended for the 12-kDa PEG-IFN-α-2b, but because of the much smaller volume of distribution of the larger molecule (limited to the vascular space) of the 40-kDa PEG-IFN-α-2a, theoretically this agent should not have to be weight-based.[40]

### *Alcohol consumption*

Retrospective analyses have shown that alcohol consumption both prior to and during treatment may influence the outcome of therapy, above and beyond the effects of alcohol in causing more rapid disease progression and influencing adherence.[41] Thus, it is recommended that patients abstain from alcohol prior to and during antiviral therapy for hepatitis C.

### *Age*

The likelihood of achieving SVR diminishes by about 5% per decade.[42] Thus, it has been suggested, particularly in those who are difficult to treat because they are infected with genotype 1, that treatment should be considered sooner rather than later, so as to not reduce the chance of achieving an SVR any more than is possible. There is no pharmacologic explanation for this age effect.[43]

# Adherence

## The effect of adherence on response to antiviral therapy for hepatitis C

### *Achieving an early virologic response (EVR)*

The factor that has the greatest effect on the outcome of antiviral therapy remains the ability of the patient to maintain full dose or close to full dose therapy for the prescribed duration. Trials of standard IFN and ribavirin indicated that a figure of ≥80% maintenance of therapy was critical. In the more recent studies of PEG-IFN and ribavirin, it has been calculated that individuals who are able to maintain at least 80% of the PEG-IFN dose required and 80% of the ribavirin dose required have an 80% chance of achieving an EVR,[44] defined as a ≥2 log drop in HCV RNA between baseline and 12 weeks of treatment. EVR determines the subsequent likelihood of an SVR. In patients who can maintain 80% of their prescribed PEG-IFN dose, but who take <80% of the ribavirin dose, the EVR rate falls to 60%. Alternatively, if 80% of the PEG-IFN dose cannot be achieved, but 80% of the ribavirin is achieved, the EVR rate is 70%. The worst outcome is when <80% of both PEG-IFN and the prescribed dose of ribavirin are taken; then the EVR rate falls to 30%!

## Enhancing adherence to therapy for hepatitis C

There are many factors which play a role in facilitating adherence to treatment with PEG-IFN and ribavirin.

### *Time of initiation of therapy*

This needs to be optimal for the patient. Thus, for students it is important to avoid examination time. For others, it is important to avoid the time of a major life event such as marriage, new job, moving home, etc.

### *Pre-emptive treatment of side-effects*

Predictable side-effects may be minimized. Of greatest benefit to the patient is for their ongoing treatment

to be closely monitored by an individual who has the time to interact and support them throughout treatment. Physicians are rarely able to achieve this, and this role is best performed by a specially trained nurse. Under their tutelage, the patient can learn to control the fevers associated with IFN by taking prophylactic acetaminophen. The irritating cough and dry skin associated with ribavirin therapy can be considerably reduced by encouraging the patient to maintain a high fluid intake. The troublesome depression that particularly affects individuals whose pretreatment history indicates past depressive illness, can be greatly helped by prophylactic use of antidepressant medications.

#### *Appropriate dose reduction of IFN and/or ribavirin*

Dose reduction is most often required because of adverse laboratory events, particularly a fall in haemoglobin and/or absolute neutrophil count. Sometimes symptoms, particularly overwhelming fatigue and shortness of breath, may occur when the haemoglobin is not very low but the haemolysis caused by ribavirin has been particularly rapid. Under these circumstances, it may be necessary to reduce ribavirin dosage for a short period of time.

#### *Addiction medicine counselling*

A recent study of antiviral therapy given to patients with hepatitis C who fell into various psychiatric risk groups indicated that adherence rates could be easily maintained in individuals with well controlled psychiatric illnesses or in those with prior addiction habits that were controlled on methadone. But in those who were former injecting drug users (IDUs), but not on methadone, the drop-out rate was higher and hence SVR rates were much lower.[32] Unfortunately, methadone is only useful in injecting drug users who are addicted to opioids, and at present there is no medication which helps curb addiction to other compounds such as cocaine. In some centres, antiviral treatment given to current IDUs is said to be successful,[45] although few current IDUs are motivated to seek and maintain medical help.

## Predicting response to antiviral therapy for hepatitis C

Retrospective analysis of outcomes following treatment with standard IFN and ribavirin suggested that it was possible early on in treatment to predict who may not attain an SVR by examining the fall in viral load from baseline to 4 weeks.[46] It was shown that 50–60% of subsequent non-responders could have been predicted early into treatment.[47] Prospective analysis of PEG-IFNα-2a plus ribavirin has shown that the likelihood of achieving an SVR can also be reliably predicted at 12 weeks into therapy.[14]

### Clinical implications of improved predictability of antiviral treatment in hepatitis C

Our ability to reliably predict outcome at 12 weeks into treatment means that the burden of therapy to patients can be limited to those who are most likely to respond. In those who do attain an EVR, this information may help to sustain them through the ongoing unpleasant side-effects of treatment required for a further 36 weeks, i.e. it acts as an incentive for patient counselling and education. An improvement in cost-benefit ratio will also be achieved if therapy is stopped at 12 weeks in those who do not achieve an EVR. However, as all those infected with genotype 2 or 3 achieve an EVR, testing at 12 weeks into treatment is not recommended, rather 6 months of treatment is given to all.

## Barriers to antiviral therapy for hepatitis C

### Accessibility

The major pool of infected individuals worldwide live in situations which are either hard to access, e.g. homeless individuals, impoverished individuals in the developing world, those living in isolated areas such as on reservations, and individuals not isolated, but in a social situation where the need for therapy is often ignored, i.e. individuals incarcerated in prisons. An equally disturbing situation is the inability of an individual to afford the cost of antiviral therapy in any part of the world because their insurance system fails to cover their costs.

The complex requirements of both repeated injections and serial blood monitoring, with the need to access patients immediately if the drug dose needs to be reduced or stopped, really precludes employing the current therapies in many individuals. But unless this large source of potential transmission for virus is controlled, there is no hope that we will significantly impact the burden of hepatitis C. Thus, clean needle exchange programmes have been initiated in many countries. Many governments have recognized the inadvisability of withholding antiviral therapy from the prison population. In such a controlled environment, there is no reason why antiviral therapy should not be successful.[48,49]

### Contraindications to current therapies

There remain many infected individuals who either have co-morbidities that preclude current antiviral therapies, e.g. severe seizure disorder which cannot be

adequately controlled, or who are unable to tolerate the treatment-associated side-effects. It is hoped that such individuals will be able to be successfully treated with the second generation of antiviral therapy for hepatitis C, namely enzyme inhibitors. There are others who cannot tolerate current therapies because their liver disease is too advanced, in which case if there are no other contraindications, liver transplantation may be the optimal route.

### Need for adjunctive therapy

With appropriate adjunctive and supportive therapy, the number of patients in whom treatment is recommended, but in whom co-morbid conditions have in the past precluded therapy, may be significantly reduced with the use of agents to control depression and support blood components.

## Special populations of patients with hepatitis C requiring antiviral therapy

### Patients with cirrhosis

Potentially, individuals with cirrhosis due to hepatitis C have the most to gain in the short and possibly the long term, were they to be successfully treated for their hepatitis C. Whereas therapy with standard IFN monotherapy was very disappointing, particularly in cirrhotic patients, the chance of achieving an SVR with PEG-IFN-α and ribavirin is markedly better, i.e. 40–50%. Those most likely to die from their hepatitis C are those with cirrhosis. Both early[50] and long-term[51] follow-up liver biopsy data indicate that regression of hepatic fibrosis may be observed following antiviral therapy most often when an SVR is achieved. If liver transplantation is still required, recurrence of hepatitis C post-transplant is much less in those who have undetectable HCV RNA.[22]

Analysis of very large numbers of patients with hepatitis C treated with all forms of antiviral therapy do suggest that the rate of subsequent hepatocellular carcinoma (HCC) is significantly less in those who at the time of therapy had a hepatic fibrosis score of 3 out of 4.[52] However, the benefit seems to be mainly in Japanese patients, in whom the risk of HCC in chronic hepatitis C is so much higher. A significant benefit in terms of reduction in HCC in Caucasians is disputed.[53,54] There are reports that following successful antiviral therapy the rate of hepatic decompensation is reduced in both Japanese and Caucasians – but all these data are from observational studies, where the less severe patients tend to be those treated.[55,56] It is logical to assume that if the inciting agent is removed, there will be a long-term benefit – just as there is when appropriate reduction in copper or iron overload is achieved in individuals with Wilson's disease or haemochromatosis.

### HIV/HCV co-infection

Liver-related mortality in individuals with HIV/HCV co-infection has become more overt since the introduction of effective therapy for HIV infection. Although the mortality from liver disease remains highest in co-infected individuals *not* treated for their HIV infection, liver disease remains a significant problem in those whose HIV infection is well controlled.[20] There is an urgent need to introduce effective antiviral therapy for hepatitis C in the co-infected individual, because the rate of liver disease progression in co-infected individuals is almost double that seen with HCV infection alone.

However, there are many problems encountered during treatment for hepatitis C in those who also are infected with HIV. Because of the background immune suppression, HCV RNA titres tend to be high. There are reports of untoward drug interactions between ribavirin and various components of HAART therapy, particularly with the 'd' drugs, which are probably related to competition for intracellular metabolism.[57,58] Such drug interactions may cause severe mitochondrial injury, hepatic steatosis and even liver failure, but less overt drug interactions may just destabilize the HAART. As many co-infected individuals either have been or currently remain IDUs, the issue of adherence to both HIV and HCV antiviral therapy is problematic.

Co-infected individuals generally have as their primary physician an individual who is not trained in the management of liver disease or skilled in the practice of liver biopsy. Without a liver biopsy, patients with cirrhosis will be missed, as compensated cirrhosis cannot be reliably assessed with non-invasive techniques. Antiviral therapy in HCV/HIV co-infection in an individual with cirrhosis who has even only mild evidence of hepatic impairment in terms of minimal elevation of serum bilirubin and/or low serum albumin, may lead to rapid hepatic decompensation and death.[59] Thus, it is advised that co-infected patients be managed in a multidisciplinary clinic which includes experts in HIV and liver disease as well as addiction medicine.[60]

#### *Timing of treatment for hepatitis C in individuals co-infected with HIV*

Management guidelines suggest that in individuals co-infected with HCV and HIV, it is generally best to consider the need for treatment of the HIV first and if anti-retroviral therapy is not required, then this is the ideal time for introducing treatment for hepatitis C. If anti-retroviral treatment is required, then this should be started before any antiviral therapy for hepatitis C is

given, and the HIV infection should be stabilized before introducing treatment with IFN and ribavirin (this is discussed in more detail in Chapter 50).

## Those with normal ALT with or without other non-hepatic, hepatitis C-related co-morbidities

At least 25% of individuals infected with hepatitis C have consistently or intermittently normal ALT levels, over a period of several years. Some may have significant hepatic fibrosis on liver biopsy, indicating that they are at risk for further disease progression and thus may warrant therapy.[61] Efficacy of PEG IFN-α-2a 180 μg/week plus ribavirin (800 mg/day) for 48 weeks indicates that SVR rates are not dissimilar to those observed in individuals with elevated ALT.[17]

There are other individuals who have significant co-morbidity caused by hepatitis C which may improve were the virus to be eradicated. Serum ALT values may well be normal, and liver biopsy may show only mild liver disease, but nevertheless treatment is warranted, particularly if the patient suffers from symptomatic vasculitus caused by cryoglobulinaemia with or without a complicating non-Hodgkin's lymphoma (NHL). A recent meta-analysis suggests that the association between hepatitis C and NHL appears real.[62]

Symptoms of cryoglobulinaemia caused by a vasculitus affecting most often the skin, kidneys or peripheral nerves are well controlled in 70% of those undergoing antiviral therapy, even when viraemia persists.[63] Relapse after cessation of therapy occurs if viral clearance has not been achieved, but symptoms may remain controlled even in the presence of persistent viraemia in many[64] without the need for immunosuppressive therapy and/or plasmapheresis. This particular co-morbidity may be one of the few indications for prolonged antiviral therapy in the face of persistent viraemia.

Complete resolution of splenic lymphoma associated with a chronic hepatitis C infection may be observed following a sustained viral response, not so if SVR is not achieved.[65]

The seroprevalence of hepatitis C in patients with end-stage renal disease is high.[66] As IFN is generally not recommended in patients with a kidney transplant because this drug may promote rejection of this small organ,[67] antiviral therapy needs to be given as early into the course of an individual's chronic renal disease as possible, as antiviral therapy is poorly tolerated in end-stage renal disease. However, the pharmacokinetics of the PEG-IFN-α-2a is such that these drugs may be better tolerated than standard IFN-α (Fig. 33.3)

## Liver transplant patients

End-stage liver disease caused by chronic hepatitis C is now the major indication for liver transplantation in Europe and North America. With no active intervention, graft reinfection is inevitable and, in the setting of the anti-rejection therapy, rapidly progressive disease can occur – threatening graft and patient survival.

### *Pre-transplant*

Ideally, the physician should aim for a sustained viral clearance before transplant, but this is rarely feasible as the patients frequently have decompensated disease and, in patients with HCC, the urgent need for transplant limits the use of effective antiviral therapy prior to the procedure.

With careful supervision and dose modification some patients can benefit from pre-transplant treatment.[22]

### *Post-transplant*

Despite the immunostimulatory effects of IFN-α and the theoretical risks of graft rejection, IFN is successfully used in many recipients of liver transplants. Most of the published studies have featured trials of standard IFN and ribavirin, and there is increasing use of PEG-IFN with ribavirin. Overall, the success rates are lower in the post-transplant patients and discontinuation rates are much higher than those seen in the non-transplant setting.

In one French study,[68] 52 liver transplant recipients were randomized to receive standard IFN in combination with ribavarin or placebo. The SVR was 21% in those who received the combination and 0% in those who received placebo. Significant side-effects, particularly severe anaemia, led to treatment discontinuation in 43%.

Another study compared treatment with IFN and ribavirin for 6 months versus 12 months.[69] Fifty-seven patients (68% genotype 1b) were treated, and the SVR was 22% in those who received therapy for 6 months and 17% in those who received therapy for 1 year, suggesting that a subgroup of patients may benefit from a relatively short course of treatment. This study also demonstrated that in the virological non-responders with a biochemical response there was also histological improvement, and there may be a role for 'maintenance therapy' in this group of patients.

In view of the poor tolerance of antiviral regimens and the low antiviral response in this group, other approaches have been tried such as ribavirin monotherapy. Short-term use of ribavirin monotherapy[70] has been shown to lead to a biochemical response and a decrease in the inflammatory score on liver histology, but longer-term follow-up will be required to ascertain whether this is also associated with a reduction in fibrosis development.

Most studies now feature PEG-IFN and ribavirin. One pilot study[71] described high levels of discontinuation

because of side-effects (43.6%) but an SVR of 66.7% in those who completed therapy.

For those patients unable to tolerate IFN and ribavirin, there are prospects of future therapy with protease and helicase inhibitors or alternative approaches with anti-fibrotic rather than antiviral agents.

## Ongoing drug use

The patient who continues to inject drugs can vary from the stable patient on a supervised (oral or injected) methadone or heroin programme to the erratic patient who injects from time to time and who continues to share needles and syringes with others. Delivery of care to the more chaotic patient is a considerable challenge and requires substantial resources. In the more erratic patient, there are risks of missing doses and monitoring visits and also the risk of reinfection at any time during the treatment course. A multidisciplinary approach is vital. Most would advise that the priority with such a patient is to work closely with the drug treatment centres and to encourage the patient to follow their prescribed drug stabilization programme before embarking on a treatment course for hepatitis C. Alcohol consumption, polydrug use, nutritional problems, anxiety and depression are common in this group and psychiatric input is therefore valuable. Many of the studies reporting beneficial effects of IFN and ribavirin in drug users exclude those with active drug or alcohol use.[72] In a Norwegian study[73] 27 ex-intravenous drug users who had been successfully treated for hepatitis C were followed up. Although 33% of the group had returned to injecting drugs, only one had evidence of reinfection, suggesting that at least some behaviour modification had occurred. It is also argued that treating drug users may have some benefits beyond the individual patient, and that reducing the viral load in a drug user reduces the chance of infection spreading to others.

Early treatment guidelines counselled against treating active drug users, and the wisdom and ethics of this have been questioned by Edlin and others.[74] They emphasize that adherence to treatment regimens is reduced in many chronic illnesses and that the risk versus benefit of side-effects, risk of reinfection and timing of treatment must be assessed for each individual.

Supervised drug treatment programmes may involve daily visits and can be combined with directly observed hepatitis C treatment programmes. This approach could also be adapted to the prison environment. The longer half-lives of PEG-IFNs lend themselves to the concept of once-weekly supervised therapy.

## African-American patients

African-American patients are more likely to have genotype 1 infection, lower ALT values and less rapid disease progression.[75] African-Americans also have lower neutrophil counts, which may lead to exclusion from therapy or to inappropriate dose reductions.[76] They are also less likely to have an elevated alpha-fetoprotein with HCC development.[77] The chance of responding to antiviral therapy is reduced and this is not fully understood, although the prevalence of 'hard-to-treat genotypes' tends to be high. Two clinical trials[78] were pooled to analyze this further. There were 53 black patients among the total of 1744 patients, and 96% of them had genotype 1 infection compared with 65% of the white patients. The overall response rate was 27% in the white patients and only 11% in the black patients. The SVR rates in the black patients were 20% with 24 weeks of standard IFN and ribavirin, 23% with 48 weeks of this therapy, and no patients responded to IFN monotherapy. For genotype 1 infection, the sustained response rates of 23% in the black patients and 22% in the white patients suggest that in this study the genotype was a major factor in the overall responses. Increased iron stores have been reported in African-Americans,[79] which may influence immune response.

One study compared the virological kinetics in 19 African-American and 16 white patients with genotype 1 infection and reported a decreased viral load reduction in the African-American group.[80] Similarly, intensification of the IFN dosing with daily administration also demonstrated a decreased response in this group.[81]

## Children

Earlier experiences with higher doses of IFN in children with chronic hepatitis B have shown that children tolerate such therapy surprisingly well. There are limited clinical trial data for children, and many of the children treated have underlying conditions such as haemophilia, thalassaemia or malignancy, which may impair their response and reduce their chance of tolerating antiviral therapy. In one study of 41 children, an SVR of 61% was reported following 1 year of standard IFN and ribavirin.[82] As yet, there are limited data on the use of PEG-IFN regimens in this group.

## Thalassaemia and iron overload

Thalassaemia patients with hepatitis C are challenging to treat as they may be unable to tolerate the haemolysis associated with ribavirin and may have advanced liver disease and a substantial iron overload at baseline – factors which generally reduce the chance of responding to treatment.

In one IFN monotherapy study,[83] six of thirteen children responded and a favourable response was more likely in those with less severe liver disease and lower

baseline ferritin levels. An Australian study,[84] however, found that the baseline hepatic iron concentration did not affect the chance of a sustained response.

In a pilot study,[85] 11 patients with thalassaemia were treated with a combination of standard IFN and ribavirin. Five patients had a sustained response although, probably as a result of the ribavirin, transfusion and iron chelation requirements were increased during the treatment period. In another study,[86] 18 patients (14 with genotype 1b) received 12 months of combination of standard IFN and ribavirin and the SVR was 72.2% with a 30% increase in supportive blood transfusion.

Studies are underway with PEG-IFN and ribavirin, and PEG-IFN monotherapy may be an option for those who are unable to tolerate ribavirin.

### Non-responders and relapsers to standard IFN monotherapy or combination regimens with ribavirin

Several studies have shown that for those who have previously failed to respond to IFN monotherapy there is a reasonable chance of responding to combination therapy.

The benefit is particularly seen in those who initially responded and then relapsed. In one study[87] of 345 patients who had relapsed following IFN monotherapy, the sustained response rate was 49% in those who received IFN and ribavirin combination therapy and only 5% in those who were retreated with IFN monotherapy.

Response rates in previous non-responders are much lower at 15–20%.[88–92] Other studies have tried other approaches such as an induction period with high dose IFN.

Another approach has been the addition of amantadine to the regimen. In a large study of 225 non-responders,[93] IFN and ribavirin was compared with IFN, ribavirin and amantadine. There was a trend towards a higher response rate in the group who received triple therapy (25% versus 18%).

The use of other types of IFNs has also been tried in this group of patients. A pilot study of treatment with consensus IFN and ribavirin[94] in patients who had failed to respond to standard IFN and ribavirin reported SVRs of 33% in the previous non-responders and 42% in the previous relapsers.

There are limited data on PEG-IFN ribavirin regimens as retreatment, but preliminary results suggest significant benefits for those who have received IFN monotherapy and more modest gains for those who have already received IFN and ribavirin. The early virological response will hopefully also prove useful in determining the chance of an SVR in these patients, but more data are required to ascertain whether the predictors in previously treated patients undergoing retreatment remain valid.

Overall, the factors associated with a higher chance of responding to retreatment are previous relapse (rather than non-response), genotypes 2 and 3, lower levels of HCV RNA and an early virological response to treatment. Negative factors include being African-American and/or cirrhotic.

Those with only mild liver damage can afford to wait for the development of new antiviral agents, but for those with more severe disease a more realistic priority may be to inhibit fibrosis and maintain liver function. Long-term maintenance regimens may need to be considered.

# Chapter 34
# New drugs for the management of hepatitis C

John G McHutchison, Jennifer M King, Amany Zekry

## Introduction

Approximately 170 million people worldwide are infected with hepatitis C virus (HCV).[1] Current therapies for chronic HCV infection (Table 34.1) are only effective in approximately 50% of patients. In addition, therapies are costly, prolonged, associated with significant side-effects, and not suitable for all patients.

Fortunately, many new treatments for HCV infection are currently being designed and evaluated in preclinical, animal and human studies. For patients with chronic hepatitis C infection, the ideal therapy would be highly effective, orally bioavailable, without major side-effects and affordable. While such a drug is unlikely to be developed in the near future, a number of novel and promising compounds may significantly improve current options for therapy. Many were designed on the basis of insights into the mechanics of HCV replication, entry into cells and host cellular immune responses. Others may slow the progression of liver disease. In this chapter, we highlight and summarize many of these ongoing developments and research.

**Table 34.1** Hepatitis C drugs in various phases of development

| Drug type | Compound | Phase of development | Comments |
|---|---|---|---|
| Small molecules and viral enzyme inhibitors | | | |
| NS3 helicase inhibitors | | Preclinical and phase 1 | Numerous agents in preclinical stages. Development of one compound halted in early dose-ranging studies |
| NS5B polymerase inhibitors | JTK-003 | Phase 1 and 2 | Inhibits HCV RNA replication in cell culture |
| | JTK-109 | Preclinical | Inhibits HCV RNA replication in cell culture |
| | NM-283 | Phase 1 and 2 | Inhibits HCV RNA replication in cell culture. Up to 1 log reduction preliminarily reported in early short-term clinical trials |
| p7 inhibitors | Long-alkyl-chain iminosugar derivatives | Phase 2 | Have antiviral activity against bovine viral diarrhoea virus. Clinical data pending in HCV-infected patients |
| Ribozymes | Directed at IRES | Phase 1 and 2 | Further development halted because of animal toxicology findings |
| Antisense oligonucleotides | ISIS-14803 | Phase 2 | >1 log reductions observed in some HCV non-responder patients, associated with transient asymptomatic ALT elevations |
| siRNA and eiRNA | | Preclinical | Uses double-stranded RNA to downregulate post-translational gene expression |
| NS3 serine protease inhibitors | | Preclinical and phase 1 | A multitude of agents from different classes are in preclinical development. One agent, BILN-2061, has entered a phase 1 trial and is associated with profound viral inhibition, but further development has been halted |

(*Continued*.)

**Table 34.1** (*Continued*)

| Drug type | Compound | Phase of development | Comments |
|---|---|---|---|
| Non-specific immune activators | | | |
| Interferons | IFN-α-2a | Approved | Roferon-A (Roche), 3 MU three times/week, SC |
| | IFN-α-2b | Approved | Intron A (Schering-Plough), 3 MU three times/week, SC |
| | IFN-alfacon-I | Approved | Infergen (InterMune), 9 μg three times/week, SC |
| | PEG-IFN-α-2a | Approved | Pegasys (Roche), 180 μg once/week, SC |
| | PEG-IFN-α-2b | Approved | Peg-Intron (Schering Plough), 1.0–1.5 μg/kg once/week, SC |
| | Albuferon | Phase 2 | Fusion of interferon with albumin to increase half-life. Preliminary data suggest prolonged half-life and similar antiviral efficacy |
| | Omega-interferon (IFN-ω) | Phase 2 | Alternate type 1 IFN. Early studies suggest similar antiviral effects to type 1 IFNs and similar side-effect profile |
| | Gamma-interferon (IFN-γ) | Phase 2 | Combination studies with type 1 IFNs for non-responder patients in progress |
| | Oral IFNs | Phase 1 | Absorption of IFN via oral route |
| Oral interferon inducers | Imiquimod | Preclinical | Approved for use as a topical agent in dermatology |
| | Resiquimod | Phase 2 | Studies show no antiviral effects or cytokine induction, but doses may have been inadequate |
| | ANA 245 | Phase 1 | Low molecular weight nucleoside analogue |
| | ANA 971 | Phase 1 | Delivers ANA 245 to plasma of various animals |
| Nucleoside analogues | Ribavirin* | Approved | Copegus (Roche), 0.8–1.4 g/day, orally† Rebetol (Schering-Plough), 0.8–1.4 g/day, orally† |
| | Levovirin | | Development is halted because of absorption and delivery issues |
| | Viramidine | Phase 3 | Ribavirin 'prodrug' with preferential liver uptake. Large-scale international multicentre trials in combination with PEG-IFNs in progress |
| | ANA 246 | Preclinical | Oral compound that enhances the type 1 cytokine response |
| IMPDH inhibitors | VX-497 | Phase 2 | Specific IMPDH inhibitor, no haemolysis, further trials with IFNs and ribavirin in progress |
| | Mycophenylate mofetil | Phase 2 | Evaluation of efficacy combined with IFN-α in non-responders in progress |
| Broad-spectrum antivirals | Amantadine | Phase 2 | Numerous clinical trials evaluating efficacy with IFN or IFN and ribavirin in naïve and non-responder populations |
| | Rimantadine | Phase 2 | Similar trials to those for amantadine |
| Other immunomodulators | Histamine dihydrochloride | Phase 2 | NK cell activator. Combined with PEG-IFN and ribavirin in clinical trials in non-responder patients |
| | Thymosin α-1 | Phase 2 and 3 | Two large-scale trials comparing PEG-IFN alone or with thymosin α-1 in non-responders |
| | IL-10 | Phase 2 and 3 | Anti-inflammatory cytokine. Randomized controlled trial failed to show benefit in terms of fibrosis; IL-10 was associated with decreased ALT values and hepatic inflammation, but increased viral concentrations |
| | IL-12 | Phase 2 and 3 | Proinflammatory cytokine. Phase 2 trial indicated lack of efficacy and significant toxicity |
| Passive immunization | | | |
| | HCIg | Phase 1 and 2 | Inactivated pooled high-titre HCV RNA-negative immunoglobulin. Initial trial to evaluate recurrence of HCV post-liver transplantation |
| Therapeutic vaccination | | | |
| | E1 therapeutic vaccine | Phase 2 | Administration of E1 vaccine in HCV patients after 28 weeks produced detectable levels of E1 antibody and specific T-cell responses |

(*Continued*.)

**Table 34.1** (*Continued*)

| Drug type | Compound | Phase of development | Comments |
|---|---|---|---|
| | E1/E2 therapeutic vaccine | Preclinical and phase 1 | Recombinant E1/E2 vaccine has been effective in preventing infection or chronic illness in chimpanzees |
| | NS3–NS4–NS5–core fusion protein | Phase 1 | Combined with an adjuvant, primed broad CD4+ and CD8+ T-cell responses in chimpanzees |
| Antifibrotics | | | |
| | IFN-γ-1b | Phase 2 | Large-scale antifibrotic trial did not reach its end-points in terms of antifibrotic effects |

ALT, alanine aminotransferase; HCIg, hyperimmune anti-HCV immunoglobulins; HCV, hepatitis C virus; IMPDH, inosine monophosphate dehydrogenase; IRES, internal ribosome entry site; MU, million units; NK, natural killer; PEG-IFN, pegylated interferon; SC, subcutaneously.
*Ribavirin is not approved as a monotherapy, but as part of a combination therapy with IFN-α.
†According to HCV genotype and body weight.

## The HCV life-cycle and potential inhibitors

HCV is an enveloped positive-sense RNA virus (Fig. 34.1). The genome (Fig. 34.2) has a single open reading frame (ORF) of approximately 9.6 kb flanked by 5′ and 3′ untranslated regions (UTRs) that are required for replication and protein synthesis. The 5′ UTR of the HCV genome contains an internal ribosome entry site (IRES) for the initiation of translation.[2,3] Translation of the HCV ORF leads to synthesis of a polyprotein that varies in length between 3010 and 3033 amino acids depending on the strain. The polyprotein is processed into 10 mature structural (core, E1, E2 and p7) and non-structural (NS2, NS3, NS4, NS5A and NS5B) proteins.

A number of macromolecules involved in viral replication, protein translation and post-translational modification are potential inhibitory targets for drug development. Exogenous macromolecules may in theory also be effective inhibitors of such functions.

### RNA replication

#### *NS3 helicase*

The primary function of the HCV NS3 helicase is to unwind viral genomic RNA during replication. Recent insights into the mechanics of polynucleotide unwinding have led to new strategies for drug discovery.[4] In addition, three-dimensional helicase structure determinations have helped to pinpoint the functionally important regions of NS3 helicase and domain motions that accompany the progressive unwinding of nucleic acid duplexes.[5,6] A few small molecules inhibit NS3 helicase *in vitro*. Also in this setting, recombinant antibody fragments at nanomolar concentrations can inhibit NS3 helicase enymatic activity.[7] Their specificity and potential efficacy in the clinical setting remain unclear.[8]

#### *NS5B*

NS5B, or the HCV RNA-dependent RNA polymerase (RdRp), is a 68-kDa protein with a hydrophobic tail that anchors to internal cellular membranes and catalyzes RNA synthesis during replication. The three-dimensional structure of the active RdRp[9–11] has revealed several inhibitory targets. The RdRp has the classical 'finger/palm/thumb' motif of many other single-chain nucleic acid polymerases. However, it has a unique, fully encircled, preformed active site where nucleotides can bind in the absence of the template. The active site is a target for nucleoside/nucleotide analogue inhibitors.[6] In addition, on the surface of the enzyme there is a specific guanosine triphosphate (GTP) binding site that is more than 30 Å away from the active site.[12] Non-nucleoside inhibitors of HCV RNA-dependent RNA polymerase (RdRp) can bind very close to the surface GTP site, suggesting that these drugs may inhibit a conformational change needed for RNA elongation.[13]

Inhibitors of viral polymerases can be classified into three categories: nucleoside (substrate) analogues, non-nucleoside inhibitors and pyrophosphate (product) analogues. In the cytoplasm of infected cells, nucleoside analogues (cyclic or acyclic) become triphosphorylated nucleotides. Nucleotides are then incorporated by the viral polymerase during processive nucleic acid synthesis, causing premature termination of replication. Nucleoside inhibitors of viral polymerases are used therapeutically for HIV (human immunodeficiency virus), hepatitis B (HBV) and herpes viruses. The only non-nucleoside inhibitors of clinical interest act against HIV-1 reverse transcriptase. These compounds bind to an allosteric site on the enzyme surface away from the active site, possibly distorting the precise geometry of the active site. Phosphonoformic acid (Foscarnet) is the only pyrophosphate analogue approved for treatment of herpes viruses. Pyrophosphate analogues are believed

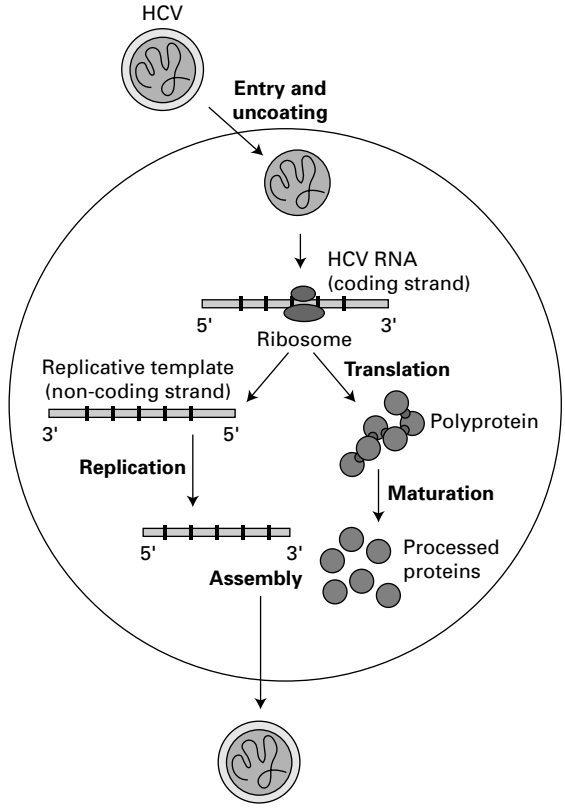

**Figure 34.1** Life-cycle of the hepatitis C virus (HCV). The virus selectively fuses with liver cell plasma membranes. This interaction probably involves the HCV envelope glycoproteins E1 and E2, making them potential targets of inhibitory drugs. Once fusion of the viral lipid coat and host plasma membrane is complete, the viral core enters the host cell. The HCV genome is a sense strand of RNA, which can be directly read by the host's ribosomes. During translation, the ribosomes produce a polyprotein that is processed into 10 proteins (four structural and six non-structural – NS). Potential specific inhibitors of HCV translation include antisense oligonucleotides and RNA interference. The enzymes NS3 serine protease and NS2/NS3 protease cleave the polyprotein and are thus targets for inhibitors. When adequate RNA transcriptase is produced, an antisense version of HCV RNA is made to serve as a template for RNA replication. The enzyme NS3 helicase unwinds the RNA during replication, and NS5B, or the HCV RNA-dependent RNA polymerase, catalyzes RNA synthesis. Both are also targets for inhibitors. The newly produced RNA and processed proteins assemble to form viruses that travel to the inside portion of the plasma membrane and then exit the host cell.

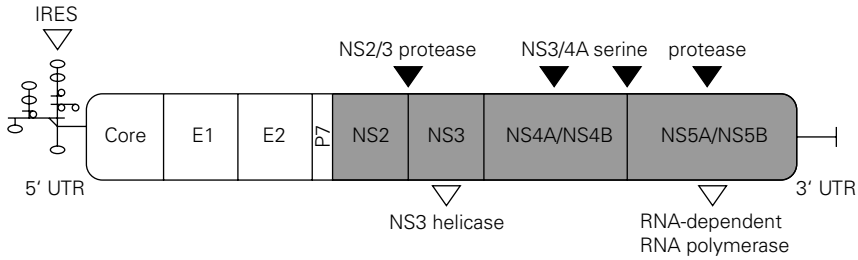

**Figure 34.2** Schematic representation of the hepatitis C genome. Unshaded region indicates the major structural proteins: core, envelope (E1 and E2) and p7. The shaded region indicates the non-structural proteins NS2, NS3, NS4A/NS4B, NS5A/NS5B. At the 5′ untranslated region (UTR) resides the internal ribosome entry site (IRES), which is a potential target of translation inhibitors such as antisense oligonucleotides and ribozymes. NS3 encodes a specific helicase, and the NS5A region encodes RNA-dependent RNA polymerase, both important in viral replication. Other potential enzyme targets include the HCV-specific proteases (NS2/3 and NS3/4), which are involved in processing the viral polyprotein at specific sites (closed arrows).

to interact directly with the pyrophosphate-binding site of the viral polymerases.

Use of high throughput screening and rational drug design has led to the identification of HCV RdRp inhibitors that belong to each of the above classes.[14] Several compounds inhibit HCV RNA replication in cell culture. Moreover, a few orally bioavailable inhibitors of HCV RdRp, such as JTK-003, JTK-109 and NM-283, are being studied in early clinical trials. However, their mechanism(s) of action remain unclear, and preliminary *in vitro* results suggest that resistance to RdRp inhibitors might occur in the clinical setting.

### *p7*

Although its function is partly unknown, p7 has ion channel activity,[15,16] and there is preliminary evidence that p7 localizes to plasma and endoplasmic reticulum membranes[17] and is necessary for HCV replication.[18] Long-alkyl-chain iminosugar derivatives, which have antiviral activity against bovine viral diarrhoea virus,[19] can inhibit HCV p7 ion channels.[16] Therefore, such iminosugar derivatives that have low toxicity profiles in animals might in theory be used in treating chronic hepatitis C. One such compound is currently being tested in a phase 2 trial.

### *Ribozymes*

Ribozymes, catalytic RNA molecules that cleave specific RNA sequences, represent another potential mechanism to interrupt HCV genomic replication. Ribozymes contain a catalytic core region flanked by binding arms with nucleotide sequences complementary to the target RNA. An HCV-specific ribozyme was developed to treat chronic hepatitis C: Heptazyme™, a synthetic, stabilized 33-mer that is chemically modified for resistance to enzymatic and chemical degradation. In cell culture, Heptazyme selectively cleaves hepatitis C RNA within the IRES, significantly inhibiting viral replication.[20] In a phase 2 clinical trial, Heptazyme given alone led to reduced serum HCV RNA concentrations in 10% of patients.[21] Unfortunately, further development has been halted because of an observation in toxicology studies in animals. Instead, a product with an improved therapeutic index for stability and targeting to specific tissues is being developed.

## Protein translation

### *Antisense oligonucleotides*

Viral genomes contain numerous unique nucleic acid sequences that are drug targets because they are not present in the human genome. Because of the high affinity and selectivity of nucleic acid hybridization, antisense oligonucleotides can be used to develop highly specific drugs. Several antisense oligonucleotides inhibit the translation of HCV RNA in cell-free systems and cell culture models.[22,23] Among them is ISIS 14803, a 20-nucleotide antisense oligodeoxynucleotide that is complementary to the IRES surrounding the translation initiation codon. ISIS 14803, which is in clinical development, decreases HCV RNA and protein levels in various *in vitro* and *in vivo* models through RNase H cleavage of HCV in heteroduplexed regions of oligonucleotide and genomic RNA. In two clinical studies of ISIS 14803 monotherapy, plasma HCV RNA concentrations were reduced in three of ten patients treated at 2 mg/kg (–1.3 to –2.2 $\log_{10}$) and in six of twenty patients dosed twice weekly at 6 mg/kg (–1.0 to –3.8 $\log_{10}$).[24,25] However, patients with and without plasma HCV RNA reductions had transient asymptomatic alanine aminotransferase (ALT) flares 1–30 times the upper limit of normal range. The mechanism(s) by which HCV RNA reductions and the ALT elevations occurred is unclear, and further studies are required.

### *RNA interference*

Another potential therapy involves using RNA interference (RNAi). RNAi is a process in which cells downregulate gene expression through destruction of a specifically targeted mRNA.[26] The RNAi process is mediated inside the cell by a naturally occurring protein complex that uses double-stranded RNA as a molecular guide to downregulate expression post-translationally. In human cells, small interfering RNA (siRNA) are biologically active short fragments of 20–23 residues. Stabilized siRNA and eiRNA (expressed interfering RNA) compounds are currently being evaluated in the preclinical setting for their potential inhibitory activity of HCV genes. In a human hepatoma (HepG2) cell line, iRNAs targeted against specific sites in the HCV genome dramatically reduced virus-specific protein expression and RNA synthesis.[27,28] Similarly, recent data indicate that viral vectors can be used successfully for transducing HCV-specific siRNA. The latter approach effectively inhibits HCV replication in Huh-7 cells.[29,30]

### *Small molecules*

The increased understanding of the atomic structures of the 5′ and 3′ non-coding RNA segments[31–33] should aid rational design of small molecules that bind specifically to structures within these regions and that could serve as inhibitors of translation or of translation initiation and/or HCV RdRp recognition. In both cases, the target would be a relatively large RNA structure that most probably has multiple contacts with macromolecular protein assemblies, such as the 40S ribosome

subunit or the replication complex.[31,33] For example, small RNA molecules corresponding to the different stem-loop domains of the HCV IRES efficiently inhibit HCV IRES-mediated translation.[34] Whether small molecules could effectively disrupt the resulting high affinity RNA–protein interaction remains under investigation.

## Post-translational modification

### *NS3 serine protease*

The non-structural (NS) viral protein 3 encodes a multifunctional protein that contains a serine protease (NS3 protease) in the N-terminus. The NS3 protease requires the relatively small NS4A sequence as a co-factor for proteolytic activity and mediates essential polyprotein processing through cleavage of junctions NS3–NS4A, NS4A–NS4B, NS4B–NS5A and NS5A–NS5B. NS3 cleaves an initially synthesized viral polyprotein into functional proteins. The NS3 protease structure has been recently determined by X-ray crystallography.[6]

A number of peptide-based or peptidomimetic inhibitors of NS3 serine protease have been developed and tested *in vitro*. Most fall into one of three classes: (1) substrate analogues, (2) serine-trap inhibitors (or transition-state analogues), or (3) product analogues.

Efforts to discover non-peptide inhibitors have also been made.[8] BILN 2061 is a small, selective and potent inhibitor of the NS3 serine protease.[35] Inhibitor constant values of 0.30 nM and 0.66 nM with a non-covalent, competitive mode of inhibition were obtained for genotypes 1a and 1b, respectively. BILN 2061 retains its inhibitory efficacy in human cells and showed low nanomolar inhibition of HCV RNA replication through blockade of the NS3 protease-dependent polyprotein processing. In early clinical development studies, BILN 2061 was administered for 48 hours to HCV-infected patients. Administration resulted in a rapid, dose-dependent HCV RNA decrease up to 4 $\log_{10}$ that happened within 2 days for the highest doses. Within a week after treatment withdrawal, HCV RNA concentrations progressively returned to baseline.[36,37]

### *NS2/NS3 protease*

The NS2/NS3 protease is a zinc-dependent metalloprotease that cleaves the non-structural proteins between the NS2 and NS3 polypeptides. This region overlaps with the NS3 serine protease. The search for inhibitors of the NS2/NS3 cleavage reaction has been hampered by the hydrophobic nature of the protein and by the autocatalytic nature of the cleavage.

## Virus attachment and entry into cells

The mechanism by which HCV enters target cells is currently unknown. The envelope glycoproteins E1 and E2 probably determine selective interaction of HCV with specific cell-surface receptors. E1 and E2 are released from the viral polyprotein by signal peptidase cleavages and expressed as non-covalent heterodimers at the surface of viral particles. E2 is thought to initiate virus attachment, and E1 has been hypothesized to be responsible for viral and cellular membrane fusion.[38] An early interaction of envelope glycoproteins with glycosaminoglycans has been suggested to play a role in cell recognition and tropism.

Truncated soluble versions of E2 can bind specifically to human cells. The truncated versions have been used to identify interactions with tetraspanin CD81,[39] with scavenger receptor class B type I,[40] and with dendritic cell-specific intercellular adhesion molecule 3-grabbing non-integrin (DC-SIGN) and liver/lymph node-specific intercellular adhesion molecule 3-grabbing integrin (L-SIGN).[41] The low-density lipoprotein (LDL) receptor is also an entry point for HCV *in vitro*.[42] Whether these ligands are receptors for HCV infection *in vivo* and could be targets for future therapies is currently unknown. A recently described *in vitro* interaction between cholesterol metabolism and HCV replication that was inhibited by 3-hydroxy-3-methyglutaryl (HMG) CoA reductase inhibitors highlights the potential importance of these interactions and the potential of future metabolic pathways to help in designing drugs effective against HCV.[43]

Testing inhibitors of cell entry has been limited by a lack of conventional cell culture systems for HCV. A recent effective approach is to generate infectious HCV pseudoparticles expressing HCV glycoproteins on the surface of another virus.[44,45] This system should help dissect the early events of HCV infection, identify novel HCV receptors or co-receptors, and test alternative therapeutic approaches based on inhibiting viral entry. The system could also be used to assess neutralizing responses *in vitro* and to test therapies based on viral neutralization, such as specific anti-HCV immunoglobulins.

# Host immune responses and immune therapies

The cellular immune response plays a major role in HCV infection. Vigorous and multi-specific CD4+ and CD8+ T-cell responses during acute hepatitis C are associated with viral clearance and recovery.[46] Memory T-cell responses specific to HCV are detectable in the peripheral blood for decades[47] and can mediate rapid viral clearance upon re-exposure.[48,49] In contrast, insufficient T-cell

response, particularly in combination with viral mutations, is associated with persistent infection and chronic hepatitis.[50] Once infection is persistent, typically the number of HCV-specific T cells is low and their proliferative, cytokine and cytotoxic effector functions appear to be impaired.[51] Whether antiviral therapy can lead to reconstitution of cellular immune responses is unclear.[52] Nonetheless, the cellular immune response remains an attractive target for therapeutic intervention.

## Non-specific immune responses

### *Interferons*

Human interferons (IFNs) are classified based on the cell surface receptor that they bind. Type 1 IFNs bind to the IFN-α heterodimeric receptor IFNAR1/IFNAR2 and include the 21 non-allelic subtypes of IFN-α, IFN-β, IFN-ω and IFN-τ.[53] IFN-γ, a type 2 IFN, binds a unique cell surface receptor and has antiviral, antifibrotic and immunomodulating activity that stimulates the T-helper (Th) 1 response.[54] Three novel cytokines share sequence identity with type 1 IFNs and bind to a novel cell surface receptor. These putative type 3 IFN molecules, called interleukin (IL)-28A, IL-28B and IL-29, are induced by viral infections and have marked antiviral activity *in vitro*.[55]

α-IFNs have been used for more than a decade to treat patients with hepatitis C. Yet IFNs can have poor pharmacokinetic profiles, limited biological activity and suboptimal therapeutic indices. And knowledge is limited as to the efficacy of non-α, non-β IFNs. Several groups have modified naturally occurring IFNs to improve their performance. Modifications include altering the primary amino acid sequences, adding polyethylene glycol (PEG; i.e. pegylated IFNs), altering glycosylation patterns and making fusion proteins. Consensus IFN-α (IFN-alfacon1) is an engineered second-generation cytokine that contains the most frequently occurring amino acids of the non-allelic IFN-α subtypes. IFN-alfacon1 is more effective than naturally occurring type 1 IFNs in cell culture models and equally effective in clinical trials.[56,57] Other novel α-IFNs have been produced by shuffling the family of 20 human IFN-α DNA encoding sequences.[58] Gene shuffling has led to the production of a novel non-naturally occurring type 1 IFN with a 285 000-fold increase in antiviral activity compared with IFN-α-2b. Whether this highly active IFN can be used to treat chronic hepatitis C is unknown.

Adding PEG to therapeutic IFN-α proteins can dramatically increase plasma exposure following dosing and lead to increased response rates.[59,60] An IFN-β molecule conjugated to a linear 20-kDa PEG molecule[61] is entering clinical trials for treating chronic hepatitis C. A pegylated IFN-alfacon1 will also be clinically evaluated. A fusion protein of IFN-α-2 and human serum albumin, Albuferon, has entered clinical trials.[62] Albuferon has similar *in vitro* antiviral and antiproliferative activity to unmodified IFN-α-2, but with markedly improved pharmacokinetics. Several new techniques for selecting second-generation IFNs have produced molecules that are even more potent. Clinical trials of these molecules are either underway or planned. Lastly, additional naturally occurring IFN species, such as IFN-γ and IFN-ω, are being studied in clinical trials.

### *Oral IFN inducers*

Oral IFN inducers have the potential to generate an effective immune response by inducing or modulating cytokine responses at the site of infection, or by supplementing or replacing parenteral administration of IFN. Many have attempted to identify inducers of both IFN and other innate immune responses, but the central challenge in using such agents as oral therapy against chronic HCV infection has been delivery of effective doses to the liver. Agents known to induce IFN-α and other cytokines include (among many) relatively high molecular weight agents such as double-stranded RNA (poly I:C) and CpG oligonucleotide derivatives. Low molecular weight molecules may have useful immunomodulating properties but with a reasonable probability of oral absorption. Of the multiple candidate compounds, few have progressed to clinical trials for chronic viral hepatitis. Two chemical classes that are more advanced include the imidazoquinolones imiquimod and resiquimod[63] and the nucleoside analogues ANA245 and ANA971.

Imiquimod is approved for use as a topical agent in dermatology. Toxicity, probably resulting from cytokine induction, was reported in humans.[64,65] Resiquimod is currently in phase 2 studies for chronic viral hepatitis. ANA245 is a low molecular weight nucleoside analogue. There is preliminary evidence that ANA245 induces multiple cytokines, including IFN-α, and has immunologically mediated antiviral activity in a range of viral infection models. However, ANA245's oral bioavailability is limited at high doses. Preliminary evidence also indicates that ANA971, a novel molecule, efficiently delivers ANA245 to the plasma of various animals at concentrations associated with antiviral effects. As a component of the development programme for ANA971, studies in humans are underway to characterize the safety and pharmacokinetics of ANA245 after intravenous administration. If efficient, these drugs could be used in combination with other antiviral drugs to maximize durable responses.

### *Ribavirin-like molecules*

Ribavirin is a synthetic nucleoside resembling guano-

sine. As a monotherapy, ribavirin is ineffective in inducing sustained viral clearance, but it significantly enhances the sustained viral clearance rate after IFN therapy. The mechanism by which ribavirin enhances IFN efficacy is unknown, but four mechanisms have been proposed: immune-mediated activity on the host Th1/Th2 balance, inhibition of the inosine monophosphate dehydrogenase (IMPDH) activity, weak inhibition of the viral RdRp and induction of RNA mutagenesis.[66] Haemolytic anaemia is a frequent side-effect that limits ribavirin dosing and underscores the need for alternative molecules with similar mechanisms and efficacy but reduced toxicity.

Levovirin is the L-sugar analogue of ribavirin and has similar Th1/Th2 immunomodulatory activity. However, as an L-isomer, it does not inhibit IMPDH or accumulate in erythrocytes, the mechanism responsible for haemolytic anaemia.[67] In preclinical studies, levovirin was well tolerated by animals and did not have mutagenic effects in conventional short-term *in vitro* and *in vivo* assays. In humans, the drug is orally absorbed and well tolerated. Further development of this drug has been curtailed because of issues related to absorption and delivery of sufficient intracellular drug to hepatocytes.

Viramidine, a liver-targeted prodrug of ribavirin, is the amidine version of ribavirin, which is converted by adenosine deaminase (ADA) to ribavirin.[68] Oral dosing leads to preferential viramidine delivery to the liver because the liver is rich in deaminases. Viramidine is thus converted to ribavirin and its phosphorylated metabolites and preferentially retained in the liver rather than other tissues, including erythrocytes.[67] Rodent and chimpanzee experiments confirmed that viramidine targets the liver, and early studies suggest acceptable safety, pharmacology and toxicology profiles. In phase 1 studies, viramidine's profile of adverse events was similar to ribavirin's.[69] However, the extent of haemoglobin decline with the highest dose was lower than the haemoglobin drop with conventional combination therapy. A phase 2 proof-of-concept study of viramidine in combination with pegylated IFN-α (PEG-IFN-α) is underway. Preliminary results from this study in 180 patients indicate similar antiviral efficacy at week 24 of therapy compared with the PEG-IFN/ribavirin combination, and significantly less anaemia. Final results of this trial are now awaited, and a phase 3 programme is underway to evaluate this strategy.

IMPDH inhibitors (one of the putative mechanisms of action of ribavirin), such as mycophenolic acid (Cellcept) and VX-497,[70] are also currently being studied in patients with chronic hepatitis C. As with ribavirin, preliminary results with these agents have shown no direct antiviral efficacy in short-term studies. Recent results from a small European study suggest a higher on-treatment response rate with a triple therapy strategy including VX497, which was not associated with an enhanced sustained response rate.[71] Further combination therapy studies with PEG-IFN and ribavirin in combination with VX 497 therapy in non-responder populations are now planned.

### *Other immunomodulatory drugs*

Several parenterally administered immunomodulatory drugs are currently being used in combination with IFN or PEG-IFN in clinical trials. They include (1) histamine dihydrochloride,[72] which inhibits phagocyte-derived oxidative stress and inflammation and is currently being studied in phase 2 trials in combination with PEG-IFN and ribavirin and (2) thymosin α-1, which promotes T-cell maturation and natural killer (NK) cells and differentiation of pluripotent stem cells. Preliminary results with thymosin α-1 and IFN-α were inconclusive. Thymosin α-1 is currently being evaluated in large phase 2 and 3 trials in combination with PEG-IFN-α.[73]

In a randomized controlled trial, IL-10, an anti-inflammatory cytokine, did show an improvement in histologic inflammation and ALT levels that was associated with a proviral effect, despite a positive antifibrotic effect in an initial pilot study.[74,75] In a phase 2 study of IL-12, a different and proinflammatory drug, the results suggested that IL-12 was associated with additional toxicity and lacked efficacy.[76,77]

## Hyperimmune anti-HCV immunoglobulins

It has been hypothesized that multiple infusions of hyperimmune anti-HCV immunoglobulins (HCIg) may modify viral replication and the clinical course of HCV infection. Experiments with chimpanzees have provided compelling evidence that infection of susceptible animals can be prevented by neutralizing the epitopes located in the hypervariable region 1 of the HCV envelope gene.[78,79] Therapeutic HCIg could also be particularly valuable in preventing recurrent hepatitis C in HCV-infected liver transplant recipients. A polyclonal HCIg has been prepared from virus-inactivated, HCV RNA-negative, 5% IgG from 460 anti–HCV-positive plasma donors (Civacir™). In three experimentally and chronically infected chimpanzees, passive transfer of the HCIg decreased ALT concentrations. In two of the three it decreased HCV RNA concentrations once the level of passively transferred anti-HCV E2 reached a plateau. When HCIg infusions were stopped, both markers returned to baseline.[80] In three other HCV-inoculated chimpanzees, multiple infusions of HCIg prevented acute hepatitis and significantly shortened the length of HCV viraemia compared with animals treated with immunoglobulin preparations without anti-HCV. In two animals in the HCIg group, HCV RNA disappeared from serum after

a significantly shortened period of viraemia, but it recurred in one of the two when the level of anti-HCV E2 declined. Enzymatic and histopathological evidence of either acute or chronic hepatitis followed recurrent HCV viraemia.[80,81] The mechanisms by which HCIg may potentially affect the rate of HCV replication remain unclear.

### Therapeutic vaccines

A therapeutic vaccine capable of stimulating functional CD4+ and CD8+ T-cell responses in chronic carriers may also be beneficial. CD4+ and CD8+ T-cell responses are quantitatively weaker in the chronic phase of infection.[82] Recent qualitative data also suggest that HCV-specific CD8+ T cells lack effector function (secretion of antiviral cytokines and killing activity).[51,83] Various HCV recombinant polypeptide and plasmid DNA vaccines that have been tested in non-human primates can prime broad, functional CD4+ and CD8+ T-cell responses.

In a significant number of chimpanzees, a recombinant E1/E2 vaccine primed viral neutralizing antibodies and CD4+ T-cell responses and was more effective than a control in preventing infection or chronic illness.[84] Another vaccine, based on a yeast-derived fusion polyprotein comprising HCV genotype 1 NS3–NS4–NS5–core sequences combined with an immunostimulating complexes (ISCOMs) adjuvant, primed broad CD4+ and CD8+ T-cell responses in chimpanzees. This vaccine is now being tested for optimal formulations in early phase trials in chronic hepatitis C patients.

The cellular immune responses to the E1 envelope protein are frequently suppressed or absent in patients with chronic hepatitis C, but long-term responders to IFN-α therapy have on average higher levels of E1 antibodies.[85,86] A clinical grade HCV E1 protein produced and purified from mammalian cells has been evaluated in initial trials. In a phase 2a study, the vast majority of patients converted from a negative to a strong E1-specific T-helper response.[87] After the second course of E1 injections, levels of anti-E1 antibodies increased three- to fourfold, and the proportion of patients with a significant T-cell response to E1 increased from 9% to 91%. E1-treated patients also exhibited a decline in ALT relative to baseline, and in 38% of the patients liver fibrosis improved by one point or more. These changes were observed without any observed reduction in serum HCV RNA. Further clinical studies are now required to evaluate the long-term efficacy of this strategy.

## Progression of liver disease

If HCV cannot be eradicated, an alternative approach is to slow the progression of liver disease. Hepatic fibrosis is the major histological complication of chronic HCV infection, leading to cirrhosis within 10–50 years. During fibrosis progression, resident hepatic stellate cells are transformed from a quiescent to an activated state. This process is characterized by increased production of extracellular matrix, fibrogenesis and *de novo* expression of smooth muscle α-actin consistent with cellular transformation to myofibroblasts.[88–90]

Fibrogenesis after injury to the liver is characterized by significant increases in collagen (type I>III>IV) and other extracellular matrix constituents such as laminin, fibronectin and proteoglycans (dermatan sulfate, chondroitin sulfate, heparan sulfate).[88–90] This 'wounding' process involves matrix synthesis, deposition and degradation. Cross-talk between stellate cells and the extracellular matrix appears to play a critical role in fibrogenesis, as do a number of cytokines and small peptides, including transforming growth factor (TGF)-β, platelet-derived growth factor (PDGF), endothelin and angiotensin II.

Thus far, no drugs have been proven effective as hepatic antifibrotic agents in humans. The liver does, however, offer a unique advantage as a target for orally administered agents: those with efficient hepatic first-pass extraction will have inherent liver targeting, minimizing systemic distribution and non-liver adverse effects. It is uncertain whether antifibrotic therapies will require intermittent or continuous administration.

New antifibrotic therapies may be derived from at least three sources: (1) drugs indicated for other diseases; (2) drugs under development to treat other diseases; and (3) agents specifically developed for use in liver fibrosis. Unlike antiviral drugs, the efficacy of antifibrotics cannot be simply assessed. A clinical benefit may only appear after a prolonged treatment period. In addition, there are no established serum fibrosis markers that can substitute for percutaneous liver biopsies.

Nonetheless, several antifibrotic approaches are theoretically possible.

**Reduce** inflammation or the host response to avoid stellate cell activation. Ursodeoxycholic acid and antagonists to TNF-α may have some use in treating inflammatory liver disease.[91]

**Directly** downregulate stellate cell activation. The most practical approach is to reduce oxidative stress. Possible targets include anti-oxidants such as α-tocopherol (vitamin E);[92] the cytokines IFN-α and hepatocyte growth factor (HGF);[93,94] peroxisome proliferator activated nuclear receptors (PPAR), including PPARγ, through ligands (thiazolidinediones) that downregulate stellate cell activation.[95]

**Neutralize** proliferative, fibrogenic, contractile and/or proinflammatory responses of stellate cells. Many inhibitors of proliferative cytokines, including PDGF, FGF and TGF-α signalling through tyrosine kinase receptors, are undergoing clinical trials in other diseases. TGF-β

antagonists could have the dual effect of inhibiting matrix production and accelerating its degradation. Endothelin-1 antagonists have been tested as both antifibrotic and portal hypotensive agents.[96,97] Finally, halofuginone, an anticoccidial compound, has antifibrotic activity.[98]

**Stimulate** apoptosis of stellate cells. A recent study using gliotoxin reduced fibrosis in rats with liver injury due to $CCl_4$.[99] Additional targets may include TRAIL (tumour necrosis factor-related apoptosis-inducing ligand) receptors.

**Increase** scar matrix degredation, either by stimulating cells that produce matrix proteases, downregulating their inhibitors, or directly administering matrix proteases. In addition to preventing new scarring, antifibrotic therapy will need to provoke resorption of existing matrix. Direct administration of metalloproteinase mRNA via gene therapy in animal models of hepatic fibrosis has confirmed that, in principle, matrix can be resorbed.[100]

## Conclusion

The World Health Organization has estimated that 3 to 4 million people worldwide are newly infected with HCV each year.[1] High quality, patient-centred research is necessary to develop improved therapeutics to treat the majority of hepatitis C patients effectively and economically, and to eventually develop preventative vaccines. To that end, many recent advances and insights into the molecular biology of HCV and the host immunopathogenesis of this disease will continue to help us understand the process of infection and to identify potential new targets for drug development. Such knowledge provides many opportunities to provide patients who have chronic HCV infection with newer, more effective and more individually targeted therapies.

# Chapter 35
# Prevention

Sergio Abrignani, Grazia Galli, Michael Houghton

## Introduction

Although the transmission of hepatitis C virus (HCV) has declined substantially,[1] there is still a pressing need to develop an efficacious HCV vaccine. In fact, given that about 200 million persons worldwide harbour infection[2] and that certain modes of HCV transmission, such as injection drug use, will continue for the foreseeable future, the pool of asymptomatic chronic HCV carriers, who represent an infectious reservoir, will remain substantial. Furthermore, because of the high rate of chronic infection following acute HCV infection and the limited efficacy of the therapies currently available, prevention of new infections would be a cost-effective strategy for control of the disease.

An efficacious HCV vaccine would be of potential benefit to all persons at risk of coming in contact with contaminated blood. This includes health-care workers, haemodialysis patients, those with diseases requiring frequent blood products and intravenous drug users (IDUs). Considering intravenous drug use, an HCV vaccine might be broadly given to adolescents considered at risk for later drug use. Although the risk of sexual transmission of HCV is low, it may be reasonable to recommend vaccination to the sexual partners of infected individuals. Eventually, a safe and efficacious HCV vaccine could be recommended for widespread general use.

## What should an HCV vaccine protect against?

An HCV vaccine should be capable of either preventing infection altogether or preventing the development of chronic infection following acute infection. Although preventing initial infection by providing 'sterilizing immunity' would be ideal, this may be difficult to achieve. As the great majority of acute infections are asymptomatic and without clinical consequences, and the clinically relevant disease is due to the ensuing chronic HCV infection, a vaccine that allowed only a 'transient infection' (either subclinical or of limited acuity) while preventing the development of chronic HCV infection could be as beneficial as one that provided sterilizing immunity. Theoretically, a vaccine that did not accomplish either effect could still be beneficial if it prevented or delayed the development of progressive liver disease, such as cirrhosis.

An essential requirement for an HCV vaccine is that it must protect against the major circulating genotypes. An HCV vaccine that demonstrated narrow genotype-specific efficacy might require geography-specific limitations in its use and would be difficult to use in practice. Eventually, an efficacious HCV vaccine might exhibit a gradation of efficacy such that it might prevent infection by heterologous subtypes at a lower but still clinically significant level compared with more closely related subtypes.

## How difficult will it be to develop an HCV vaccine?

To frame and estimate problems in developing an HCV vaccine, it is interesting to compare the similarities and differences faced in developing an HIV (human immunodeficiency virus) vaccine. Both HCV and HIV infections exhibit a propensity towards chronic infection. However, while spontaneous resolution of HIV infection has not been found to occur, about 25% of HCV infections spontaneously resolve,[3] presumably due in part to activation of host immune defence mechanisms capable of clearing infection. Thus, it may be easier to protect against HCV if the types of immune responses occurring in natural infection that lead to clearance can be stimulated. Both viruses exhibit marked genetic and phenotypic heterogeneity with regions that are relatively conserved or hypervariable. Our current limited understanding of the critical correlates of protection for both HCV and HIV infection is a major challenge in vaccine development for both diseases. However, an HCV vaccine does not have to overcome additional problems faced in developing an HIV vaccine. Mucosal transmission via sexual activity predominates in HIV infection but is uncommon in HCV infection. HCV does not exist

in a latent integrated proviral state as is the case with HIV.

The problems that arise in designing an HCV vaccine because of the peculiarity of HCV are as follows. Firstly, HCV is a relatively low viraemic virus *in vivo*, and is only readily detected as RNA by polymerase chain reaction (PCR). Secondly, the only species that can be infected by HCV are humans and chimpanzees. Finally, the virus does not replicate efficiently *in vitro* and, therefore, little is known about the appearance of HCV.

## Virology of the hepatitis C virus

Hepatitis C virus (HCV) is classified as a member of the Hepacivirus genus within the Flaviviridae family[4] and is a positive-stranded RNA virus with a genome of approximately 10 000 nucleotides.[5] The genome encodes a polyprotein precursor of about 3000 amino acids (aa) that is cleaved co-translationally and post-translationally to yield a variety of structural and non-structural (NS) proteins (Fig. 35.1).[6]

Translation is mediated through an internal ribosome entry site (IRES) situated within the 5′ untranslated region (UTR) of the RNA genome.[7] Recently, a –2/+1 ribosomal frame shift has been observed to occur around aa 11 of the C protein, resulting in the synthesis of the F protein. The sequence of the F protein is partially conserved within the genus but its function is unknown.[8,9] However, the basic charged character of the F protein may also imply a nucleocapsid-like function.

As large-scale purification of the virus is not feasible, the information on the structure of the virion is largely derived from expression studies with cloned cDNAs. Such studies have revealed co-translational processing of the polyprotein precursor via host signalase to yield the presumptive structural proteins (the nucleocapsid (C) and envelope glycoproteins gpE1 and gpE2).[10–12]

The two structural proteins gpE1 and gpE2 have been shown to translocate into the lumen of the endoplasmic reticulum (ER), where they remain tightly anchored in the form of a non-covalently bound heterodimer.[13–15] Deletion of the C-terminal transmembrane anchor regions (TMR) of either gpE1 or gpE2 results in secretion of the respective ectodomain from cDNA-transfected cells via the Golgi apparatus, although this is an inefficient process in the case of gpE1.[11,16] The nucleocapsid is also cleaved by host signal peptide peptidase to yield a smaller species (p19 or p21), which appears to be the form found within virions circulating in the bloodstream.[17,18] The C protein has the ability to self-associate into core particles[19] and is phosphorylated.[20]

A large variety of NS proteins are thought to be processed downstream of the structural protein region (Fig. 35.1).[6] p7 is processed through the action of host signalase,[21] and in the related pestiviruses it has been shown to be required for virion assembly and/or secretion.[22] Further downstream proteins are processed from the precursor polyprotein through the action of viral-encoded proteases encoded by NS genes 2, 3 and 4a.[23–25] The NS proteins associate together on the ER, to form a viral replication complex, and various individual functions have been assigned (Fig. 35.1). The 3′ UTR region comprises a 3′ terminal 98 nt region that is highly conserved, which is located immediately downstream from a short pyrimidine-rich tract. This pyrimidine-rich tract is preceded by a more variable region, immediately downstream of the polyprotein precursor terminator codon.[26,27]

As RNA viruses encode error-prone RNA replicases that lack the proofreading abilities of host DNA polymerase, the HCV genomes and encoded proteins are highly

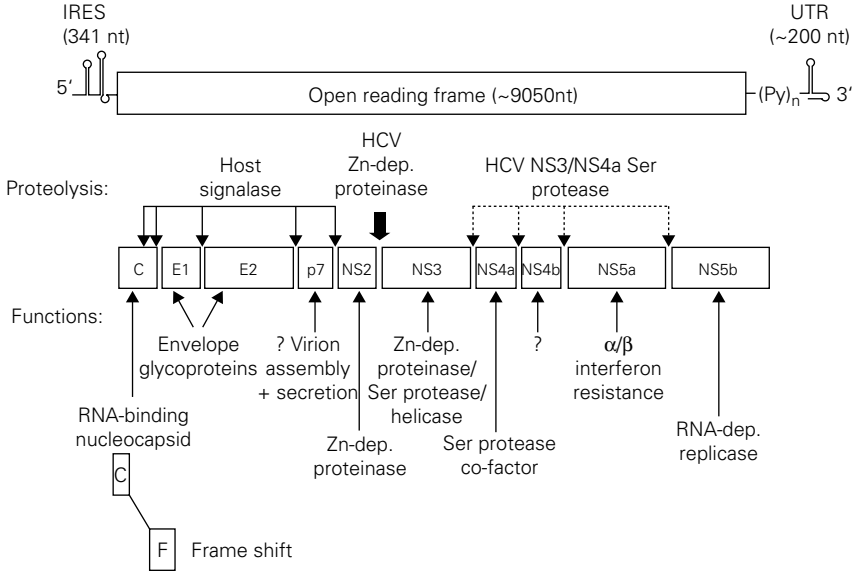

**Figure 35.1** Organization of the HCV genome and encoded proteins.

variable. The 5′ and 3′ UTRs are highly conserved, as is the C gene and encoded nucleocapsid protein, but the rest of the viral genes/proteins exhibit considerable heterogeneity.[28] In addition, the N-terminal 30 aa of gpE2 (E2HVR1) is hypervariable and, using the chimpanzee infection model, it has been shown to contain epitopes binding viral-neutralizing antibodies that are under considerable selective pressure.[29–34]

At least six different basic HCV genotypes have been distinguished phylogenetically along with numerous subtypes (Fig. 35.2),[35] with type 1 being the most common genotype in the United States, China, Japan and Europe (Fig. 35.3).[36] Unfortunately, due to the lack of an *in vitro* virus-neutralizing antibody assay, the number of serotypes is unknown. Recent progress in developing mouse infection models may facilitate further studies in this important area.[37]

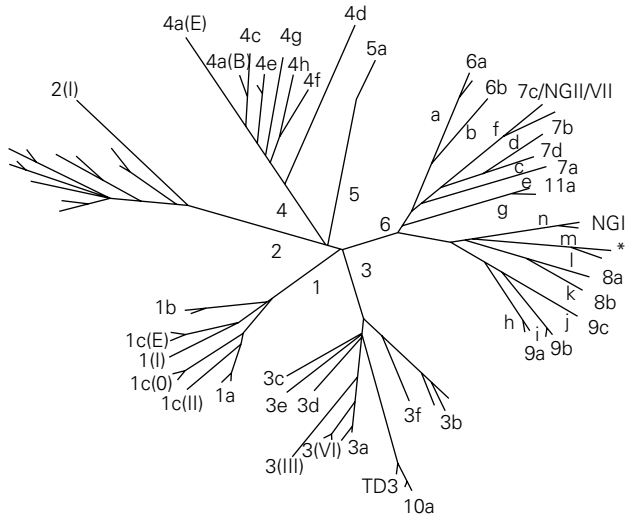

**Figure 35.2** Phylogenetic analysis of nucleotide sequences from part of the HCV NS5b region amplified from HCV-infected blood donors and patients from several countries (from Simmonds[35]).

## Immune correlates of protection

Recent studies in the chimpanzee challenge model and of multiply exposed humans have demonstrated that there is significant natural immunity against HCV. In one chimpanzee study,[30] an animal was infected by intrahepatic administration of an infectious RNA derived from HCV strain HCV-1 (of the 1a subtype). This subtype is the most common clade in the United States (Fig. 35.3). Following resolution of the ensuing acute infection and disappearance of viraemia, the animal was shown to be resistant to an intravenous rechallenge with homologous virus. No viraemia was observed following rechallenge, indicating that sterilizing immunity was generated by the original infection. When rechallenged subsequently with a heterologous 1a strain, the animal experienced very transient, minimal viraemia, while control naïve animals showed substantial viraemia. Resolution of the infection in the rechallenged animal was confirmed by showing the absence of viral RNA from the blood and liver. Furthermore, when rechallenged again with a heterologous 1b strain, the most common clade worldwide (Fig. 35.3), only a transient viraemia was observed prior to disappearance of the virus from plasma and the liver.[30] Very similar results were obtained in separate chimpanzee studies in which animals were challenged and then rechallenged intravenously with different infectious viral inocula. Only transient viraemia occurred when animals that recovered from a first 1a strain infection were rechallenged with either a heterologous 1a strain or a heterologous 1b strain.[38,39] Additional chimpanzee studies indicate the existence of cross-protective immunity between HCV types 1 and 3 (A.J. Weiner, unpublished

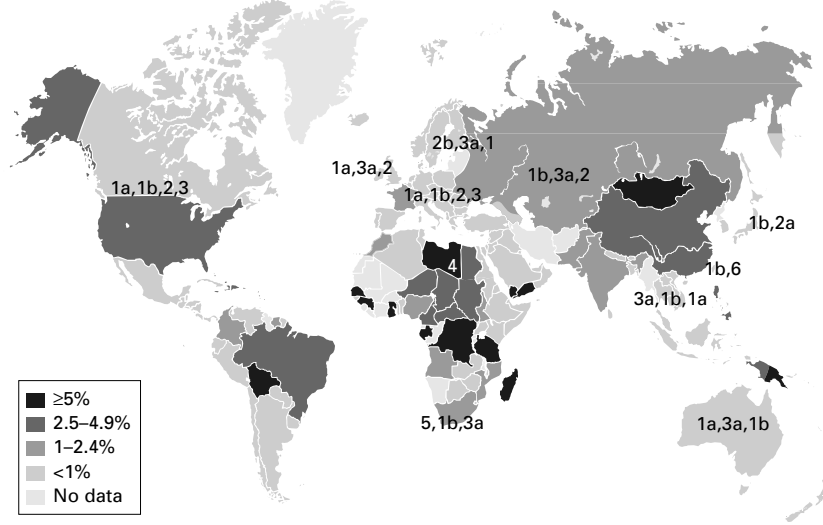

**Figure 35.3** Approximate HCV prevalence and genotype distribution (from Ebeling[36]).

observations, 2001). The latter HCV type is commonly found in IDUs.

Similar findings have also been reported in a prospective study of IDUs from the United States. Strikingly, the incidence of persistent viraemia in IDUs who had recovered from a previous infection was 12 times lower than that in IDUs who had not experienced a previous infection.[40] As seen in the chimpanzee studies, peak viral loads were substantially higher (by almost 2 logs) in the first-time infections as compared with the reinfections.[40] Also, HIV co-infection produced persistent HCV infection in all cases, indicating the role of the immune response in HCV recovery.[40] Intriguingly, it has now been shown that HIV patients co-infected with HCV have lowered peripheral immune responses to HCV as compared with patients with HCV mono-infections, even in the absence of severe CD4+ T-cell depletion.[41]

Collectively, these chimpanzee and human data provide evidence for the existence of significant immunity to HCV and, importantly, for the existence of cross-protective immunity within and between commonly occurring HCV clades. It is important to note, however, that not all reinfections in chimpanzees were resolved without progressing to chronicity (three of nine became chronically infected),[40] indicating that natural immunity to HCV is not complete and not as effective as for the hepatitis A and B viruses. It should also be mentioned that earlier studies in the chimpanzee model have concluded a lack of protective immunity to HCV.[42] This apparent contradiction may be due to the earlier studies measuring immunity more in terms of sterilizing immunity, rather than the ability to prevent the development of chronic infection, as in the more recent studies.

## Role of cell-mediated responses

It was first noted that early and broad major histocompatibility complex (MHC) class II-restricted CD4+ T-helper responses to HCV are associated with recovery from acute, symptomatic infections of man.[43,44] Subsequently, using the valuable chimpanzee model again, it was shown that recovery could occur in the absence of any antibody to the HCV envelope glycoproteins, but in the presence of an early and broad MHC I-restricted CD8+ cytotoxic T-lymphocyte (CTL) response to the virus.[45] This association of HCV-specific CD4+ T-helper and CD8+ CTL responses with resolution of acute infection has been confirmed in many human studies,[46–51] although the relative importance of each type of cellular immune response is unknown at present.

A recent study sheds further light on the potential mechanism of recovery from clinically asymptomatic, acute infections in man. Shortly after infection, activated HCV-specific CD8+ T cells appeared in the peripheral blood that were associated with an increase in serum alanine aminotransferease (ALT) levels (signifying liver damage), and with a small decrease in viral RNA levels. These activated CD8+ cells did not secrete gamma-interferon (IFN)-γ. Shortly afterwards, a 5 log reduction in viral load occurred commensurate with the appearance of HCV-specific, IFN-γ-secreting CD8+ cells with a non-activated phenotype (CD38-negative). This large reduction in viral load was not accompanied by an increase in serum ALT levels, suggesting that a non-cytolytic viral clearance mechanism mediated by IFN-γ might be operative (Fig. 35.4).[50,52] This conclusion is consistent with the demonstrated anti-HCV activity of IFN-γ in cell cultures containing HCV replicons.[53]

In contrast, individuals who develop chronic, persistent infection show weaker cellular immune responses to the viruses that are not maintained over time[46–50,54] and that have dysfunctional CD8+ T-cell effector functions.[55–57] The association of HCV-specific cellular immune responses with recovery is further reinforced by data from several studies showing that memory T-cell responses to the virus can be detected in long-term convalescent individuals,[54] in non-viraemic and HCV antibody-negative, healthy family members of HCV patients,[58] and in other individuals who lack HCV antibody and RNA but who may have been exposed to the virus earlier.[59]

The kinetics of induction of HCV-specific T-cell responses to multiple epitopes may be crucial in determining the outcome of infection, because the ability of the virus to mutate and thus evade CD8+ T-cell responses has been demonstrated convincingly in the chimpanzee model.[60] The latter study suggests that if a multi-specific T-cell response is made early in infection, then it is harder for the virus to mutate several epitopes simultaneously and, therefore, more likely to result in resolution of infection. Host and viral factors have been found to be involved in determining the breadth, strength, kinetics and decline[55,56] of HCV-specific cellular immune responses. In this regard, certain MHC class I and II alleles are associated with recovery in humans.[61–63]

## Role of the antibody response

The role of anti-envelope antibody in resolution of HCV infection is unclear at present. Initially, it was found that nearly all chronically infected humans have significant antibodies to gpE1 and gpE2, as measured in ELISA assays, and that there was not a clear relationship between the induction of these antibodies and resolution of acute infection.[64] These findings were extended in other studies showing that in man and chimpanzees, finding of anti-envelope antibody (as measured in ELISA assays) was more likely in chronically infected individuals than in those resolving the acute infection.[65–67] This lack of correlation between anti-envelope antibodies and immunity apparently contrasts with the situation found for many

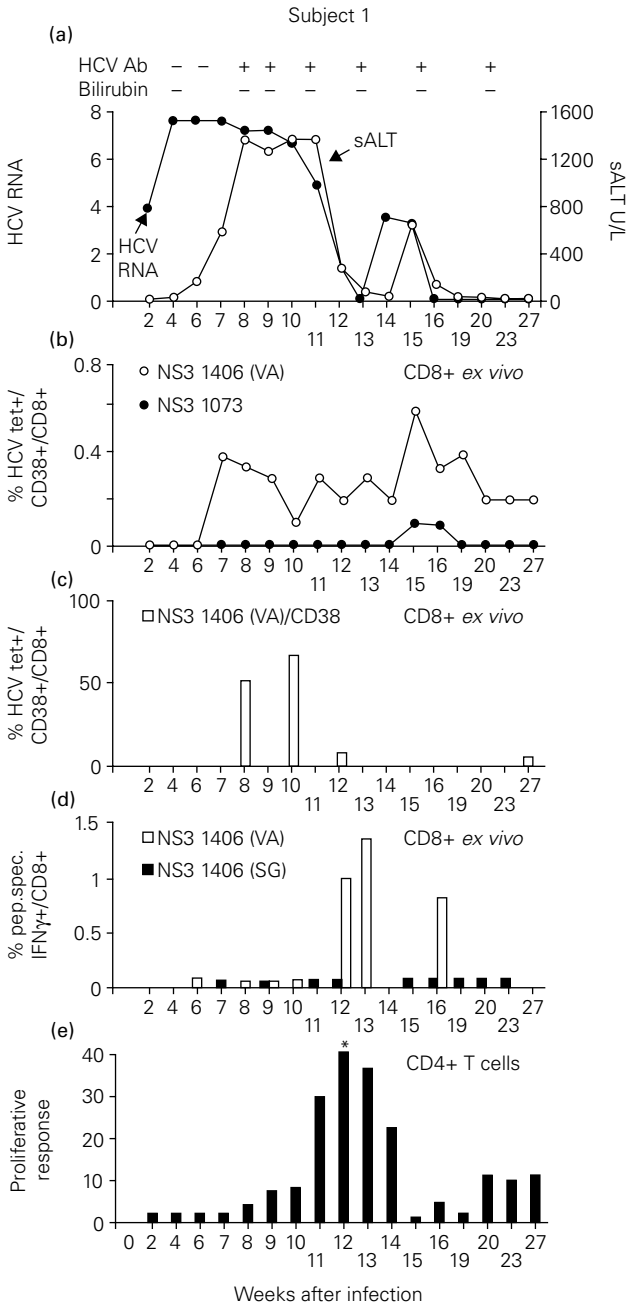

**Figure 35.4** HCV-specific T-cell responses in subject I during asymptomatic, resolving acute HCV infection. (a) Course of infection. (b) Percentage of CD8+ lymphocytes that were tetramer-positive at each time-point. CD8+ T-cell responses were tested directly *ex vivo* using HLA-A2 tetramers complexed with five different HLA-A2 restricted epitopes. CD8+ T-cell responses against two epitopes (NS3 1073 and NS3 1406 [VA]) were detectable. (c) Percentage of NS3 1406 (VA)-specific CD8+ T cells expressing the activation marker CD38. (d) Percentage of CD8+ T cells that produced IFN-γ in response to HCV NS3 1406 (VA) (black bars) and NS3 1406 (SG) (white bars). (e) Proliferative CD4+ T-cell responses against core, NS3, NS4 and NS5 are shown as the sum of all positive stimulation indices. *Sum of all specific stimulation indices is 56 (from Choo *et al*.[52]).

infectious agents, e.g. the hepatitis B virus (HBV).

It should be noted, however, that a true *in vitro*, viral-neutralizing antibody assay has not been developed due to the lack of a reliable cell culture system for HCV, and so the presence, level and affinity of neutralizing antibody cannot be easily monitored. However, the presence of neutralizing antibody has been demonstrated using the chimpanzee model. Serum derived from a patient was shown to be capable of neutralizing the infectivity of the virus taken from the same patient, 2 years earlier. Interestingly, the same viral inoculum could not be neutralized using serum from the patient obtained many years later.[68]

Additional evidence for the generation of neutralizing antibody comes from several studies showing the efficacy of human immunoglobulin preparations, derived from numerous donors, in preventing the transmission of HCV following blood transfusion[69] and liver transplantation,[70] and between sexual partners.[71] Chimpanzees that received human immunoglobulin prior to experimental viral challenge also showed a clear inhibition of acute hepatitis and viraemia throughout the lifetime of the antibodies.[72] Also, preliminary studies in humans have reported that the early induction of anti-E2HVR1 antibodies may correlate with resolution of acute infection.[73,74] Finally, it has been shown that antisera raised against the E2HVR1 can neutralize the infectivity of homologous virus in chimpanzees.[33] When combined with clinical evidence for worse HCV-associated disease in hypogammaglobulinaemic patients,[75,76] these data clearly suggest that HCV infection does induce neutralizing antibody.

Why, then, is there a lack of correlation between anti-envelope antibody and the outcome of infection? Several possibilities exist. Many studies have suggested that the E2HVR1 region mutates readily under the pressure of the specific humoral immune response, thus evading the binding of anti-E2HVR1 antibodies.[32,34,77] This might also explain the apparent protective efficacies of complex human immunoglobulin preparations, if they contain highly plural anti-E2HVR1 antibodies.

Another mechanism through which the HCV virus can escape the antibody response can result from its ability to bind low-density lipoproteins that can mask neutralizing epitopes.[78–80]

A third possibility is that HCV may be transmitted between adjacent hepatocytes because giant multinucleate hepatocytes are observed in the HCV-infected liver.

In conclusion, the role of anti-envelope antibody in the protective immune response is poorly defined at present, although it is most likely a complex situation. While it is well established that humans and experimentally infected chimpanzees can resolve acute infections in the absence of detectable anti-envelope antibodies, but in the presence of early and broad T-cell responses,

this does not rule out a role for neutralizing antibodies in the protective immune response in all individuals.

## Strategies for an HCV vaccine

An ideal HCV vaccine should prime cross-neutralizing anti-envelope antibodies and provide broad HCV-specific helper and inflammatory CD4+ T-cell responses, as well as HCV-specific CD8+ T-cell responses. Conventionally, it has proven difficult to achieve the latter through the use of soluble proteins combined with adjuvants, although there has been recent progress in this area using recombinant HCV proteins combined with the ISCOM adjuvant (a particulate adjuvant comprising cholesterol, phospholipid and naturally occurring saponins). Therefore, most activities designed to achieve the priming of CD8+ T cells to the virus have focused around the use of DNA vaccines, using either bacterial plasmids or various viral vectors. In this way, HCV proteins are synthesized endogenously within the cytosol, where they can then be processed within the proteosome and the resulting peptides are transported to the cell surface in association with MHC class I antigens, where they can stimulate CD8+ T-cell responses. In addition, some groups have also aimed at priming anti-envelope antibody responses via protein or DNA immunization involving either the gpE1/gpE2 heterodimer or either envelope glycoprotein alone. Other strategies have pursued the creation of a consensus E2HVR1 peptide that can prime broadly cross-reactive neutralizing antibody.

Due to the lack of a system for propagating HCV *in vitro*, the prospect of using a killed or attenuated HCV viral vaccine is not feasible at present.

### Vaccines based on adjuvanted, recombinant HCV proteins

A vaccine comprising the recombinant gpE1/gpE2 heterodimer combined with an oil/water microemulsified adjuvant has been tested for efficacy in the chimpanzee model.[5,52,81] The heterodimer was derived from HeLa cells infected with a recombinant vaccinia virus expressing a C–gpE1–gpE2–p7–NS2 gene cassette derived from the HCV-1 strain (1a clade). Generally, 30–40 μg of the subunits were administered intramuscularly (i.m.) in approximately months 0, 1 and 6, and a homologous viral challenge was given intravenously (i.v.) 2–3 weeks after the third immunization. Encouragingly, of seven animals receiving the vaccine, five were completely protected against the challenge, with no signs of viral infection in any of the assays, including sensitive RT-PCR assays for viral RNA (Fig. 35.5, middle panel).[52] In addition, the two chimpanzees that became infected following challenge eventually resolved the acute infection without becoming chronic carriers (Fig. 35.5, bottom panel).[52,81,82] In contrast, most control animals became chronically infected following viral challenge (Fig. 35.5, top panel).[52,81,82] The five apparently sterilized animals were the highest responders to the vaccine in terms of elicited titres of anti-gpE1/gpE2.[52] Sterilization did not correlate with antibody titres to E2HVR1 but did correlate with the titre of antibodies that block the binding of recombinant E2 to the CD81 ligand,[83] a tetraspanin that has been shown to act as *bona fide* HCV receptor.[84]

Given that the prime, practical goal of an HCV vaccine would be to prevent the development of chronic infection following exposure to the virus, this study provided much encouragement for the development of an effective vaccine.[52,81,82] This work has now been extended to address the key question of whether the vaccine protects against experimental challenge with a heterologous 1a viral strain. Initial data were derived from three vaccinees, previously protected against homologous viral challenge, that were then re-boosted with vaccine prior to rechallenge with the HCV-H strain (another member of the 1a clade common in the United States). While sterilization was not achieved, two of the three animals exhibited an amelioration of the acute infection followed by resolution.[81,82] Using additional chimpanzees, including five naïve animals that had not been challenged with HCV previously, it has now been shown that out of a cumulative total of 10 vaccinees challenged with the heterologous HCV-H strain, while all 10 animals experienced acute infections, only one developed chronic, persistent infection. In contrast, most control animals challenged with HCV-H became chronic carriers (seven of nine animals; $p = 0.005$; S. Abrignani and M. Houghton, unpublished observations, 2001).

Another group has also immunized a chimpanzee with insect cell-derived recombinant gpE1 and gpE2 (from HCV strain N2), in addition to a peptide spanning the E2HVR1 (from HCV strain 6). The two envelope proteins were each expressed and purified separately and lacked the C-terminal transmembrane anchors. The E2HVR1 peptide was conjugated to keyhole limpet haemocyanin and Freund's adjuvant was employed to augment immune responses. Their conclusion, from a series of immunizations and challenges with HCV strain 6 in the same animal, was that sterilization was dependent on high anti-E2HVR1 titres rather than anti-gpE2 or anti-gpE1 titres.[85,86] However, the outcome of challenging with other viral strains was not reported. It should also be noted that insect-derived gpE2 (truncated at the C-terminus) has been shown to bind poorly to a putative HCV receptor, CD81, as compared with gpE2 derived from mammalian cells.[83] However, the gpE1/gpE2 heterodimer is generally considered to be a more native reflection of the HCV virion than either ectodomain alone and, as mentioned above, has demonstrable prophylactic efficacy in

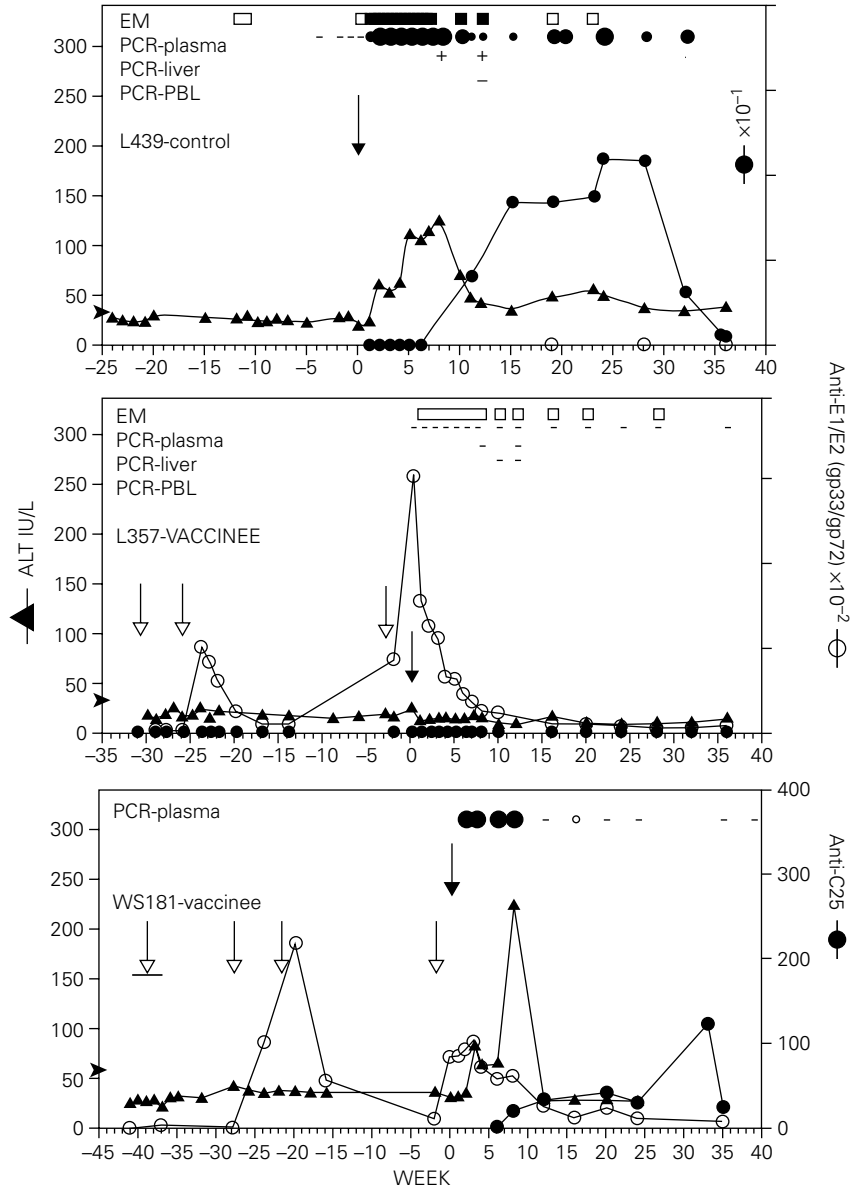

**Figure 35.5** HCV-1 challenge of vaccinated and control chimpanzees. Control and immunized chimpanzees (L, Laboratory for Experimental Medicine and Surgery in Primates; WS, White Sands) were challenged with about 10 $CID_{50}$ of HCV-1. The presence (solid boxes) or absence (open boxes) of hepatocyte ultrastructural changes observed with electron microscopy (EM) are indicated. The approximate relative levels of HCV-1 RNA detected in plasma using reverse transcriptase (RT)-PCR assays are reflected by the sizes of the shaded circles (open circles denote borderline positives; minus signs denote undetectable levels). The results of RT-PCR assays of liver and PBL (peripheral blood lymphocytes) extracts are recorded as either + or –. The arrows in the ALT axes indicate the mean + 3.75 SD of prechallenge values; open vertical arrows denote time of subunit vaccine administration, and the solid vertical arrow denotes viral challenge on week 0. IU/L, international units per litre (from Choo *et al*.[52]).

the chimpanzee. Therefore, recombinant gpE1/gpE2 remains an encouraging human vaccine candidate.

Some work has been directed to the synthesis of virus-like particles (VLPs) by expressing the structural genes in different cells. In insect cells, expression of the C–gpE1–gpE2 gene cassette has been reported to result in the generation of 40–60-nm VLPs within cytoplasmic cysternae.[87] Following partial purification, these VLPs appear to be immunogenic in small animals and, as such, represent a potential vaccine candidate for humans.[88] Similar-sized VLPs have been observed in the process of budding into the lumen of the ER, following expression of the same gene cassette in mammalian cells using a Semliki Forest viral vector.[89] HCV gene expression was observed to induce convoluted membranes or membranes similar to those seen in infected livers.[89] However, some viral or host factor is limiting the release of the VLPs into the lumen and from its secretion into the cell media.[89]

Because the E2HVR1 region of gpE2 has been shown to possess viral neutralizing epitopes and to be highly mutable, attempts have been made to select a cross-reacting version using phage display of mimotopes. Rabbit antiserum raised against one mimotype was highly cross-reactive with the E2HVR1 of many viral isolates and reacted to discontinuous epitopes.[90] Such mimotypes or consensus E2HVR1 peptides may be valuable components of an HCV vaccine. In this regard, a consensus E2HVR1 peptide sequence has been fused to the B subunit of cholera toxin and expressed in plants through the use of a tobacco mosaic viral vector. Crude extracts were administered intranasally to mice, which

then generated cross-reactive E2HVR1 antibodies that were capable of capturing virions.[91]

Recombinant C protein is also being studied as a potential component of an HCV vaccine for several reasons. Firstly, broad HCV-specific CD4+ and CD8+ T-cell responses, including those against the C protein, are associated with recovery from HCV infection.[45–48,50] Secondly, the C protein is the most conserved HCV polypeptide and contains CD4+ and CD8+ epitopes that are highly conserved among the different HCV genotypes, which should therefore facilitate the generation of cross-protective immunity.[92,93] Thirdly, recombinant C protein has been shown to self-assemble into particles[19] with concomitant high immunogenicity in animal models. Substantial CD4+ T-cell priming and high anti-C antibody titres have been obtained in mice and sheep.[93,94] Furthermore, through the use of the ISCOM adjuvant, it has been possible to prime strong CD8+ CTL activity (and CD4+ T-cell activity) in rhesus macaques, using a recombinant C antigen derived from *Escherichia coli* (Fig. 35.6).[95] Cytotoxic T-lymphocytes to at least two epitopes were identified. This approach is a promising and practical option for the development of an HCV vaccine capable of priming cross-reactive HCV-specific T-cell responses associated with protection.

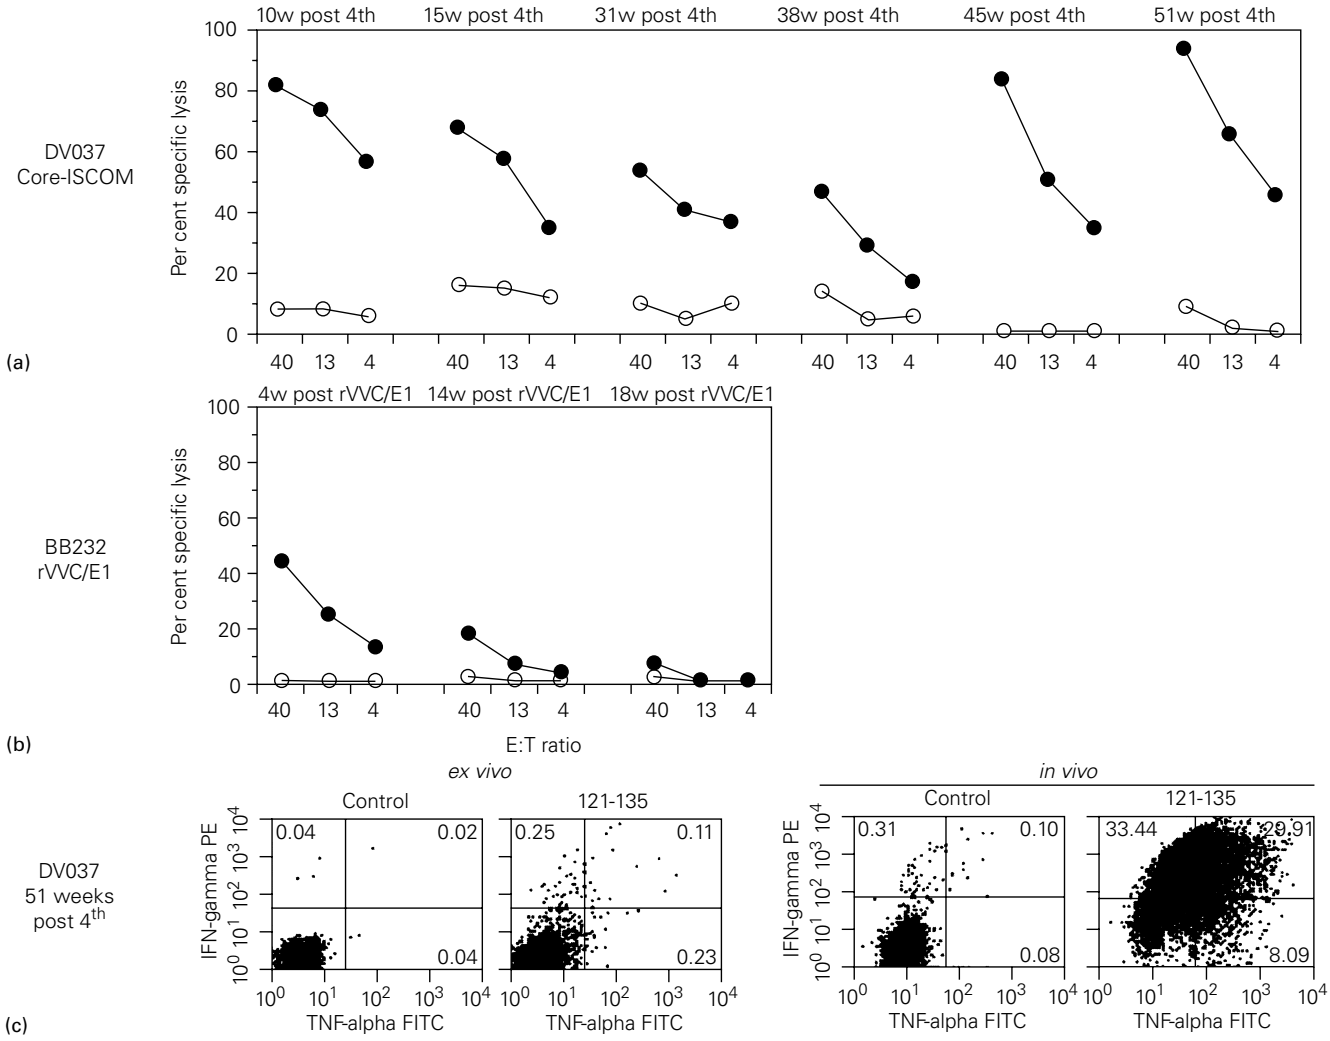

**Figure 35.6** Longevity of the CTL responses primed by vaccination with recombinant HCV core in ISCOMs adjuvant. Peripheral blood mononuclear cells (PBMCs) from rhesus macaques DV037 (a) and BB232 (b) were restimulated *in vitro* with the epitopic peptide 121–135. After CD8+ enrichment, cells were tested for cytotoxic activity against autologous B-LCLs (B-lymphoblastoid cell lines) sensitized with the epitopic peptide 121–135 (black circles) or an irrelevant peptide (open circles). (c) Freshly isolated PBMCs from DV037 51 weeks after its last immunization (two left panels) or *in vitro* restimulated PBMCs from the same time-point (two right panels) were restimulated for 12 hours with peptide 121–135 or a control peptide and stained for surface CD8 and intracellular IFN-γ and TNF-α. Lymphocytes were gated by side versus forward scatter light and then for CD8-PerCP. Plots show log fluorescence intensity for TNF-α-FITC and IFN-γ-PE (from Polakos *et al*.[95]).

There are numerous CD4+ and CD8+ epitopes that are conserved among the different HCV genotypes. These reside within the various HCV-encoded virion and non-structural proteins.[92,96,97] The inclusion of a multiplicity of these epitopes will facilitate the vaccine-mediated generation of broad cellular immune responses to the virus, which could then result in the elicitation of cross-protective immunity against different HCV genotypes. One such approach involves the assembly of 'HCV polytope vaccines' consisting of a consecutive sequence of these conserved HCV T-cell epitopes, in the form of a recombinant polypeptide or DNA vaccine. Focusing the immune response on a collection of highly conserved epitopes that can be presented by diverse human MHC class I and class II antigens may optimize the generation of strong, cross-protective immunity and possibly avoid the 'dilution' of the immune response to variable, more mutable HCV epitopes.

Other approaches being explored to generate cellular immune responses include the fusion of recombinant HCV proteins with bacterial pore-forming toxoids. Certain detoxified bacterial toxoids have the ability to induce pore-mediated endocytosis in antigen-presenting cells (APCs), thus resulting in the generation of strong CD8+ and CD4+ T-cell responses to the toxoid and fused HCV moiety.[98] Electrically mediated uptake of synthetic HCV peptides has also been reported to result in priming of reactive CTLs in electroporated BALB/c mice.[99] Host heat-shock proteins are known to be good mediators of CD8+ MHC class I-restricted immune responses to associated foreign protein sequences.[100] As such, this approach may be applicable to the development of HCV vaccines, provided that harmful, autoimmune responses are not generated. Another intriguing avenue of research involves the use of influenza-based virosomes to deposit recombinant HCV proteins or synthetic HCV peptides on the MHC class I pathway, resulting in the generation of viral-specific CD8+ CTLs. Comprising liposomes with influenza haemagglutinin and neuraminidase on the surface, these VLPs allow fusion with the membrane of APCs and the subsequent deposition of the HCV moiety in the cytosol. This then facilitates association of peptides with MHC class I molecules and TAP-mediated transfer to the surface of the cell where priming of reactive CTLs occurs.[101]

## Vaccines based on HCV DNA

The advantages of using a DNA vaccine relate to the ease and cost of manufacture, the gene-mediated synthesis *in vivo* of native and often complex protein structures (that would otherwise be difficult to produce in the form of recombinant proteins), good stability (that renders the use of DNA vaccines particularly suitable to the needs of developing countries) and the ready ability to employ multiple genes, gene cassettes or plasmids to elicit broad immune responses. Another important feature relates to the ability of DNA vaccines to stimulate CD8+ MHC class I-restricted CTL responses via the endogenous synthesis of proteins *de novo* in the cytosol. Disadvantages, however, can include a weaker potency as compared with other vaccine formulations as well as safety issues revolving around their potential to integrate into the host genome, thereby increasing the risks of mutagenesis and carcinogenesis.

In the case of HCV, relatively long-term expression of the C gene has been reported to exert multiple pathogenic effects in transfected cells and animals. Its role in inducing steatosis and hepatocellular carcinoma in transgenic mice has been documented,[102,103] as has its ability to co-promote cellular transformation *in vitro*.[104] There have been numerous other reports demonstrating the ability of the C gene product to bind to a member of the tumour necrosis factor (TNF)-α superfamily,[105] modulate apoptosis,[106] induce oxidative stress,[107,108] activate cellular and viral promoters,[109] and affect other regulatory functions.[110] While the pathogenic significance of these findings in infected humans, if any, remains to be determined, it may be prudent in the meantime to omit the C gene from a potential HCV DNA vaccine (although the intermittent use of a recombinant C polypeptide subunit vaccine is unlikely to pose such a safety risk). Similarly, the 5′ terminal region of the NS3 gene (encoding the protease domain) has been linked with transformation of cells and carcinogenesis in nude mice.[111]

Many studies have immunized mice with plasmids expressing the envelope genes of HCV, generally using the immediate-early CMV promoter and intron to achieve high expression levels. Accordingly, the generation of humoral and cellular immune responses to gpE2 has been widely reported, including cross-reactive anti-gpE2 antibodies between subtypes 1a and 1b.[112–118] The use of a DNA vaccine encoding intracellular forms of gpE2, rather than secreted forms, has been emphasized in order to elicit anti-gpE2 antibodies capable of preventing the interaction between gpE2 and CD81, the latter being a candidate HCV receptor.[119] Boosting DNA-primed mice with recombinant gpE2 has been reported to elicit higher anti-gpE2 titres than repeated DNA or protein immunizations.[120]

Immunogenicity of gpE2 DNA vaccines has also been demonstrated in rhesus macaques.[117] However, it must be underlined that small animals and even rhesus macaques are questionable models for immunogenicity of DNA vaccines in humans. Only one small HCV DNA vaccine study in the chimpanzee model has been reported so far. In an attempt to optimize immunogenicity, the ectodomain of gpE2 (aa 384–715) was fused to the CD4 C-terminal, transmembrane region (TMR) that facilitated sequestration of the encoded gpE2 glycopro-

tein to the outer cell surface, rather than being anchored in the lumen of the ER via the use of the homologous TMR. Ten milligrams of DNA were administered using a bioinjector into the quadriceps of two animals at weeks 0, 9 and 23, followed by experimental challenge with homologous, monoclonal virus 3 weeks later. Humoral and cellular immune responses to the vaccine were observed in only one animal but, following challenge, viraemia was lowered as compared with a control animal, and hepatitis occurred earlier, as a result of the primed immunity. Importantly, both vaccinees resolved their acute infections quickly, whereas the control unvaccinated animal became chronically infected following viral challenge. This result is promising, but further studies are warranted due to the small number of animals and because one of the vaccinees had already experienced an experimental HCV infection, prior to vaccination, that would have conferred immunity.[121]

In order to recapitulate the broad T-cell responses associated with protective immunity against HCV infection, many groups are investigating DNA vaccines capable of priming HCV-specific CD4+ and CD8+ T-cell responses to many HCV gene products. A DNA vaccine encoding NS3, NS4 and NS5 not only primed broad and specific antibodies, CD4+ T-helper and CD8+ CTL responses, but also conferred protection to the immunized BALB/c mice against challenge with syngeneic SP2/0 myeloma cells expressing NS5.[122] Co-expression of the GM-CSF cytokine gene has also been shown to augment cellular immune responses to these NS gene products when administered as a bicistronic plasmid to Buffalo rats.[123] Many studies have been conducted with DNA vaccines containing the HCV C gene, as this encodes the most conserved viral protein and is known to contain important T-cell epitopes. Immunogenicity in mice has been reported[124–127] and, in addition, the co-administration of either interleukin (IL)-2 or granulocyte macrophage colony-stimulating factor (GM-CSF) has been shown to augment humoral and cellular immune responses to C in mice.[127] On the contrary, co-immunization with a plasmid expressing IL-4 resulted in the elicitation of a Th0 phenotype and a concomitant suppression of C-specific CTLs.[127] The use of transgenic mice expressing human HLA-A2.1 has also shown the ability of NS3 DNA vaccines to induce specific CTLs to the same immunodominant epitope observed in humans.[128]

As with DNA vaccines targeting other infectious agents, the mode of injection drastically alters the immune response. Administration of a gpE2 DNA vaccine by gene gun, in which DNA is physically administered intra-epithelially on gold microparticles, resulted in anti-gpE2 titres that were 100-fold higher than if delivered by needle i.m.[115] This increase in vaccine potency should translate to the use of lower doses in humans, thus lessening safety concerns. Other methods to improve the potency of DNA vaccines include the application of an electric field at the site of DNA injection (so-called 'electroporation'). In the case of a gpE2 DNA vaccine, electroporation led to 10-fold increases in expression levels and in concomitant anti-gpE2 responses. The latter also included cross-reactive anti-E2HVR1 antibodies that were not obtained without the use of electroporation, and in significant increases in gpE2-specific CD4+ T-helper and CD8+ CTL responses.[129] Other improvements include the formulation of DNA vaccines into particles, thereby increasing the uptake by antigen-presenting dendritic cells with corresponding increases in immunogenicity.[130] Lipid formulations of DNA that result in improved transfection efficiency *in vivo*, as well as better uptake by dendritic cells, have been shown to be part of an encouraging immunization regimen for rhesus macaques against SHIV challenge and have applications to HCV and other infectious diseases.[131]

Finally, it is also noteworthy that defective RNA vaccines have been shown to be very effective at protecting against flaviviral infections.[132] Conferring good protective immunity in the absence of integration into the host genome, this approach has great promise for HCV and other infectious diseases.

## HCV vaccines based on disabled microbial vectors

The use of a defective or attenuated viral or bacterial vector to deliver vaccines has several potential advantages. Firstly, a wide tropism of the host vector leads to the efficient delivery of the vaccine genes and encoded antigens. Preferably, this tropism includes APCs, leading to a very effective priming of the immune response and thereby requiring only one immunization for long-lasting immunity. The use of a vector already used as a vaccine itself offers further obvious advantages with respect to manufacturing, distribution and user acceptance. Finally, many vectors allow the insertion of multiple genes, thus facilitating the induction of a broad, cross-protective immune response, particularly useful against heterogeneous agents such as HCV. One such promising approach for HCV has been the use of an attenuated rabies viral vector into which either the HCV gpE1–gpE2–p7 gene cassette was inserted, or just the ectodomain of gpE2 linked to the CD4, C-terminal TMR, and cytoplasmic domain. In the case of the latter construction, recombinant rabies virions were produced that actually contained the hybrid gpE2. Virions expressing gpE1–gpE2–p7 were immunogenic in mice, eliciting CTL responses to gpE2.[133] Similarly, defective Semliki Forest virions containing the HCV NS3 gene produced long-lasting NS3-specific CTLs after one immunization in mice transgenic for human HLA-A2.1.[134] As observed in HCV-infected patients, the immune re-

sponse was directed to one immunodominant epitope within NS3. Defective recombinant adenoviruses expressing the HCV C–gpE1–gpE2 gene cassette have also been shown to prime HCV-specific CTLs in mice immunized i.m., although the induction of anti-gpE1/gpE2 antibodies required further immunization with purified gpE1/gpE2 glycoproteins.[135] Replication-defective adenoviruses expressing C and gpE1 also primed long-lasting specific CTL responses in mice.[136] Recombinant canary pox viruses, expressing an HCV gene cassette containing C–gpE1–gpE2–p7–NS2–NS3, elicited HCV-specific humoral and cellular immune responses in mice, although the optimum immunization regimen required first priming with a plasmid DNA expressing the HCV genes prior to boosting with the recombinant canary pox virus.[137] Attenuated *Salmonella typhimurium* transformed with a plasmid expressing the HCV NS3 gene has also been shown to elicit NS3-specific CTLs in mice transgenic for human HLA-A2.1. The bacterium was administered orally and the resulting CTL responses persisted for at least 10 months.[138]

## Conclusions

Recent studies in man and in the chimpanzee model provide evidence for significant natural immunity to HCV infection, encouraging the efforts to develop a vaccine against HCV. Chimpanzee challenge studies, using recombinant envelope glycoprotein vaccines, have demonstrated prophylactic efficacy and the feasibility of protecting against the development of chronic infection following experimental challenge with both homologous and heterologous viral strains. The application of broad technologies to HCV vaccination should result in effective vaccines, which should be very useful in substantially lowering the current incidence of HCV infection with its ensuing clinical sequelae, although they may not be 100% effective.

# Section VI
# Hepatitis D Virus

# Chapter 36
# Structure and molecular virology

Michael MC Lai

Hepatitis delta virus (HDV) was first detected as a new nuclear antigen in the hepatocytes of patients infected with hepatitis B virus (HBV) and was frequently associated with severe acute or chronic hepatitis.[1] The antigen, named delta antigen (HDAg), was initially thought to be a previously undescribed HBV-encoded antigen, but later was found to be associated with a new transmissible agent, an RNA-containing virus enveloped by the surface antigen of HBV, HBsAg.[2] HDAg was subsequently shown to be an internal component of the HDV virion particles, and antibodies against this viral structural protein were detected in patients during infection.[3]

HDV infection has been reported worldwide, with particularly high prevalence rates in the Mediterranean Basin, South America, Middle East, West Africa and certain South Pacific islands.[4,5] Transmission of HDV requires either co-infection with HBV or superinfection in individuals who are HBV carriers. Although HDV infection is closely associated with HBV, HDV clearly belongs to a distinct virus group. Currently, HDV is assigned a floating genus, Deltavirus.

## Virion structure

HDV is a small RNA virus consisting of spherical particles of about 36 nm in diameter and with a buoyant density of 1.25 g/cm$^3$ in caesium chloride.[3,6–8] The outer coat of HDV consists of hepatitis B surface antigen (HBsAg) and lipid, which envelopes the RNA genome and the delta antigen.[2,3] All three components (S, M, L) of HBsAg are present in the HDV virion particles. However, the ratio of the three (S:M:L = 95:5:1)[3] is different from that of the infectious HBV Dane particles, but more like that of the 22-nm non-infectious HBV particles. An internal, spherical nucleocapsid approximately 19 nm in diameter was released from the virus particle after HDV was treated with non-ionic detergents.[9] It consists of HDV RNA and the delta antigen, the latter of which consists of two protein species (27 and 24 kDa) of variable ratios. There are approximately 70 HDAg molecules per RNA molecule.[9] The precise structure of the nucleocapsid has not been determined.

## The genome

The RNA genome is approximately 1700 nucleotides long, single-stranded and circular, with a high (60%) G+C content and a high degree (up to 70%) of intramolecular base-pairing.[10–12] The last property was clearly demonstrated by electron microscopy, in which native HDV RNA molecules appear as compact rods, but convert to circular molecules under denaturing conditions.[13] Because of its double-strandedness under native conditions, HDV RNA is relatively stable under a variety of manipulations in the laboratory.

Many different HDV isolates have been sequenced. Based on sequence relationship, HDV isolates have been grouped into three genotypes.[14] Genotype I comprises most of the HDV isolates sequenced so far and includes isolates obtained from almost every part of the world. The pathogenic properties of this genotype also show great diversity. Genotype II represents isolates prevalent in some part of Asia, particularly Taiwan and Japan,[15–17] and may be associated with relatively milder diseases.[17] Genotype III represents several isolates from South America[14] and is associated with a particularly fulminant form of hepatitis.[18] These three genotypes can be differentiated based on the differences in the immunogenic properties of their delta antigen.[19] Recombination between different isolates has been reported.[20] HDV RNA in patients undergoes continuous evolution throughout the clinical course of disease, with an evolution rate as high as $3 \times 10^{-2}$ to $10^{-3}$ substitutions per nucleotide per year in some cases.[21,22] There are several highly conserved regions, which correspond to important functional domains of HDV RNA or its encoded protein, HDAg.[21,23]

For purposes of genomic sequence organization, a *Hin*dIII restriction site present in the cDNA of the prototype chimpanzee-passaged HDV RNA[12] was designated

nucleotide 0 (Fig. 36.1).[11] The region from approximately nucleotide 615 to 950 shows some sequence similarity with a group of plant pathogens, namely, viroids and virusoids,[24] and is called the viroid-like domain.[25] Similar to some virusoid RNAs, this domain exhibits ribozyme activities, i.e. autocatalytic cleavage activities, on both the genomic and its complementary antigenomic strand.[26–29] Cleavage occurs in the absence of protein and requires divalent cations such as $Mg^{2+}$. The cleavage site is located between the U and G at nucleotide 688/689 (in the Makino *et al*. 1987 sequence[11]).[26,29] RNA sequence required for the ribozyme activity resides in approximately 85 nucleotides at the 3′-side of the cleavage site. The sequence at its 5′-side is not critical but may affect the cleavage rate.[30–32] The HDV ribozyme can fold into five helical segments connected as a double pseudoknot.[33] The unique structural and sequence requirements of HDV RNA catalysis indicate that HDV RNA belongs to a novel class of ribozymes, distinct from other known ribozymes, such as the 'hammerhead' or 'hairpin' types.[34–36] Furthermore, the HDV ribozyme can undergo base catalysis in the absence of divalent ions, another novel property among ribozymes.[37] The catalytic activity on the antigenomic-sense RNA cleaves the HDV RNA at nucleotide 903/904,[26,38] which is complementary to the genomic cleavage site in the proposed HDV RNA rod structure. Both of the genomic and antigenomic ribozyme activities are required for HDV RNA replication.[39,40] The ribozyme activities *in vitro* can be inhibited by aminoglycoside, tetracycline or peptide antibiotics,[41,42] but the effects of these antibiotics on HDV ribozymes *in vivo* have not been demonstrated. HDV RNA also contains an autocatalytic ligation activity under an artificial condition, namely in the presence of a complementary cDNA fragment.[27] However, the functional role of this ligation activity has not been proven.

HDV RNA contains only one functional open reading frame (ORF), which is located on the antigenomic strand and encodes HDAg. This ORF exists in two sizes, a small and a large form, on different RNA molecules, with coding capacities for 195 and 214 amino acids, respectively. The difference between these two ORFs resides in a single base mutation at position 1015. This nucleotide on the antigenomic strand is either A, which leads to a termination codon UAG, or G, giving UGG (Trp), which allows for the read-through of 19 additional amino acids. Both forms of RNA exist in every delta hepatitis patient.[12,21,43] The generation of this mutation is the result of an RNA editing process and is closely associated with the replication process of HDV (see below). Based on these properties, HDV RNA can be divided into two structural domains.[25] One is the viroid-like domain, which contains the ribozyme activity on both genomic and antigenomic strands, and is evolutionarily related to viroids. The remaining RNA sequence contains a functional ORF that encodes the delta antigen.

## Hepatitis delta antigen (HDAg)

HDAg is the only known functional protein encoded by HDV RNA, and is an internal component of HDV virion particles.[2,3] HDAg is usually found in patients' serum or liver in two forms of 27 000 kDa and 24 000 kDa molecular weight,[6,44–46] designated large and small HDAg, respectively. These forms are not present in a fixed stoichiometric ratio as expected for structural proteins of a defined regular structure. As indicated above, these two HDAg forms are translated from two RNA species different by a single point mutation. The two protein forms are identical except that the large HDAg has 19 additional amino acids at the C-terminus. The N-terminal two-thirds of the protein are highly basic, while the C-

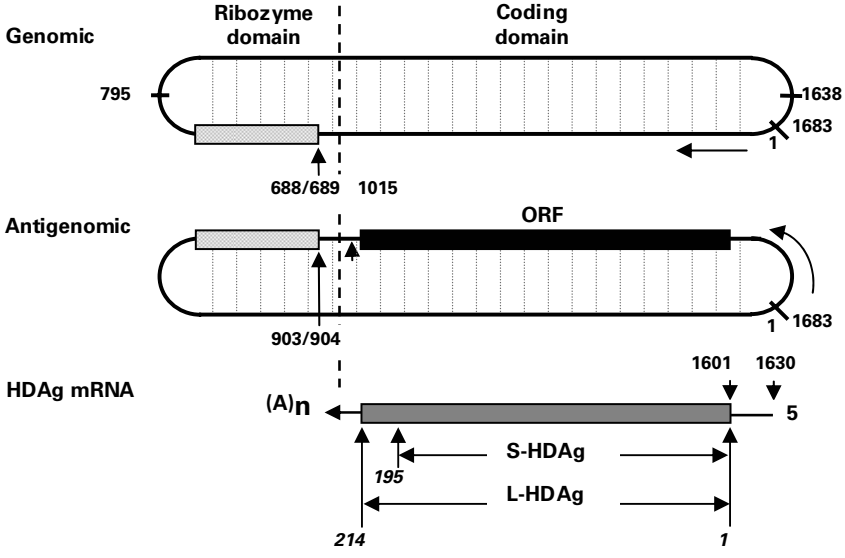

**Figure 36.1** Schematic diagrams of the structure of HDV RNA. The antigenomic (Ag) RNA and 0.8-kb mRNA are present only in the cells. The nucleotide numbers are according to Makino *et al*. (1987)[11] and represented in genomic orientation on both the genomic and antigenomic strands. The genomic RNA is represented in clockwise orientation, while antigenomic RNA is counterclockwise. Nucleotides 688/689 and 903/904 are ribozyme cleavage sites for genomic and antigenomic RNAs, respectively. The hatched boxes represent the ribozyme domain. Nucleotide 1015 denotes the RNA editing site. The amino acid residue numbers are in italics.

terminal one-third is relatively uncharged.[47] Both forms are phosphorylated, with phosphorylation occurring at serine residues.[47,48] Phosphorylation may be carried out by casein kinase II, protein kinase C or the double-stranded RNA-activated kinase PKR and is required for certain steps of HDV RNA replication.[49,50] In particular, phosphorylation at serine-177 appears to regulate the replication of different strands of HDV RNA.[51] HDAg is a general RNA-binding protein,[52–54] with particularly high binding affinity for HDV RNA. However, the binding specificity is not absolute. In the virion particles, HDAg is bound to HDV RNA.[54] This HDAg–RNA interaction probably plays a role not only in the structural organization of virion particles, but also in HDV RNA replication (see below). In virus-infected cells, HDAg appears to be localized exclusively in the nuclei, based on immunohistochemical staining.[1] However, it can be seen variably in the nucleoli, nucleoplasm or diffusely throughout the nuclei, depending on individual cells.[55] Recent biochemical fractionation and metabolic labelling studies showed that a substantial portion of HDAg is present in the cytoplasm[56,57] and that it can be shuttled between the cytoplasm and the nucleus.[58]

At least four functional domains have been identified in HDAg (Fig. 36.2). The first is the RNA-binding motif, which is located in the middle one-third of HDAg.[54] This domain consists of two stretches of arginine-rich motif (ARM),[59] which is characteristic of many RNA-binding proteins.[60] Both of the ARM sequences and a spacer sequence of appropriate length are required for RNA binding.[59] Another potential RNA-binding motif has been identified in the N-terminal region of the protein.[61] Curiously, an RNA chaperone activity, which requires RNA-binding activities, has been found in the N-terminal one-third of the protein.[62] This domain includes the N-terminal, but not the middle, RNA-binding motif. The second domain is a nuclear localization signal located in the N-terminal half of the protein.[55] This domain contains two stretches of basic amino acids, both of which are required for targeting HDAg to the nuclei. HDAg carries HDV RNA to the nucleus, where RNA replication occurs in the nucleus.[63] The third domain is a coiled-coil sequence, present in the N-terminal one-third of the protein.[55,64] This domain is responsible for oligomerization of the protein. The large and small HDAg can form either homo- or heterodimer.[55,65] The oligomerization of HDAg is required for the various functions of both the large and small HDAg (see below). The fourth domain is present only in the large HDAg, i.e. the C-terminal 19 amino acids of the large HDAg. This region is prenylated at cystine-211.[53,66–68] Prenylation alters the conformation of the HDAg, resulting in the masking of a C-terminal epitope (9E4),[69] so that it is shielded from being recognized by the humoral arm of the immune system.[70] It also enables the interaction between the large HDAg and HBsAg,[71,72] which is a critical step in HDV particle assembly. The 19 amino acids are necessary and sufficient as the signal for virion assembly.[73] Curiously, this 19 amino acid sequence is extremely divergent among different genotypes,[14] except for the last 4 amino acids, which is the prenylation motif (CXXC). Prenylation inhibitors inhibit the production of infectious virus particles.[74] Besides prenylation, HDAg is also modified by phosphorylation. The extent of phosphorylation is important for the regulation of the various functions of HDAg. In addition, it is also methylated at Arg-13 (Li and Lai, unpublished observations). Like phosphorylation, methylation is important for the functions of HDAg in HDV RNA replication.

Although the structure and biochemical properties of the large and small HDAgs are very similar, they have significantly different functions (Table 36.1). The small HDAg is absolutely required for HDV RNA replication *in vivo*.[75] It acts *in trans* and complements defects of the HDV RNA that do not synthesize a functional HDAg.[75] The ability of S-HDAg to promote HDV RNA replication appears to be genotype-specific, as S-HDAg of genotype I cannot support genotype III RNA replication and vice versa.[76] It has been suggested that S-HDAg can promote the elongation of RNA synthesis in DNA-dependent as well as RNA-dependent RNA synthesis carried out by RNA polymerase II *in vitro*.[77] Another possibility is that the small HDAg may merely serve as a carrier to transport HDV RNA into the nucleus, but may not participate in RNA replication directly.[78] In any case, the S-HDAg appears to be required for both the initiation and maintenance of continuing RNA synthesis. The large HDAg is required for the assembly and export of virion particles.[79–81] This function requires prenylation of the last 19 amino acids. Another function ascribed to L-HDAg

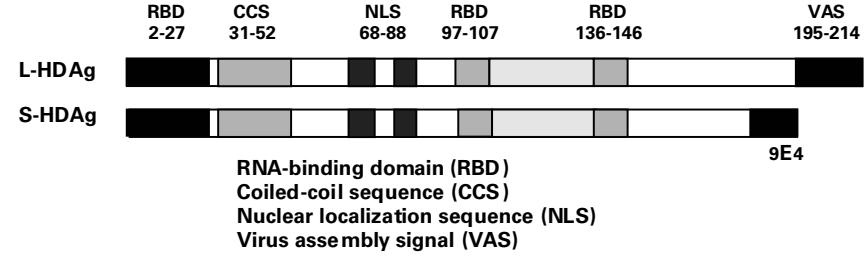

**Figure 36.2** Schematic diagram of the functional domains of the large and small hepatitis delta antigen.

**Table 36.1** Comparison of biochemical properties and biological activities of the large and small HDAg

| Biochemical properties and biological activities | Large HDAg | Small HDAg |
|---|---|---|
| Amino acid residues | 214 | 195 |
| Dimerization | + | + |
| RNA binding | + | + |
| Phosphorylation | + | + |
| Isoprenylation | + | – |
| C-terminus-specific epitope (9E4) | – | + |
| *Trans*-acting function for RNA synthesis | – | + |

| Interaction with HBsAg (virion assembly) | + | – |
| RNA chaperone | + | + |
| Stabilization of HDV RNA | + | + |
| Enhancement of ribozyme activity | + | + |

is the suppression of HDV RNA replication. Thus, L-HDAg was thought to be critical for modulating the amount of HDV RNA in the viral life-cycle.[82] However, recent studies indicate that this interpretation is not correct. The inhibitory activity was noted only when L-HDAg was expressed artificially early in the replication cycle of HDV.[57] Even under this condition, it interferes with the synthesis of only genomic RNA from the antigenomic RNA template, but not vice versa.[83] Furthermore, it has been shown that the presence or absence of L-HDAg does not affect the final level of HDV RNA.[57] Despite these obvious differences, the S- and L-HDAg did share some common functions, such as stabilization of HDV RNA,[84] enhancement of ribozyme activity[85] and RNA chaperone activity[62] (Table 36.1). They were reported to have other activities, such as suppression of polyadenylation of mRNA,[86] which is likely an artefact of the experimental systems.

HDAg can induce humoral antibodies as well as T-cell responses in infected patients or experimental animals.[70,87,88]

## Replication

In natural infections, HDV infects only hepatocytes. No extrahepatic infection has been detected. The mode of HDV entry into target cells is currently unknown. As the HDV envelope consists of all three protein species (L, M and S) of HBsAg,[3,6] HDV probably utilizes the same cellular receptor as HBV. Once inside cells, HDV can replicate in the absence of HBV.[89,90]

Several experimental approaches are available for studying HDV replication. Besides the chimpanzee model, woodchucks provide the most convenient small animal model. However, the majority of our knowledge on HDV replication came from cell culture studies using HDV cDNA or RNA transfection approaches. In these approaches, the production of S-HDAg is the first required step for the initiation of HDV RNA replication. S-HDAg can be made *in vivo* from HDV RNA transcripts (from the transfected cDNA) or from a co-transfected mRNA (that encodes S-HDAg) in the transfected cells, or provided as a recombinant protein. In natural infection, S-HDAg is present inside the virus particles, probably complexed with HDV RNA. The presence of S-HDAg allows the initiation of HDV RNA replication.

Although HDV infects only hepatocytes *in vivo*, HDV RNA can replicate in a wide range of cell types, including hepatocytes, fibroblasts and monkey kidney cell lines, upon transfection of HDV cDNA or RNA into those cells. One of the exceptions is avian cells, which appear to lack certain host factors for HDV RNA replication,[91] although a different study claimed that the failure of avian cells to support HDV replication is due to killing of the infected cells.[92] Replication of HDV RNA is thought to occur via a rolling circle mechanism similar to that described for the replication of viroids.[93] In this model, antigenomic RNA of multiple genomic lengths is first synthesized, followed by its processing into monomer-size RNAs. The monomer antigenomic RNA is ligated intramolecularly to form a circular RNA, which is then used as the template for a second round of rolling circle replication to generate the monomer genomic-sense RNA, thus completing the replication cycle (Fig. 36.3). This model, called the 'double rolling circle mechanism', is supported by the kinetic studies of the *in vivo* labelled HDV RNA in the cells transfected with HDV RNA. In these cells, the oligomeric HDV RNA was detected before the monomer RNA appeared.[57] The processing of the multimeric RNA into monomer is mediated by ribozyme activities, which are present in both genomic and antigenomic RNA. Abolition of the ribozyme activity of either genomic or antigenomic strand inhibited HDV RNA replication, indicating that both genomic and antigenomic strands need to be processed before replication can proceed,[39] further supporting the double rolling circle replication model. The cleavage site specificity and RNA sequence and structural requirements for the HDV ribozyme activity in the cells are the same as those *in vitro*.[39,40] However, the HDV ribozyme activity

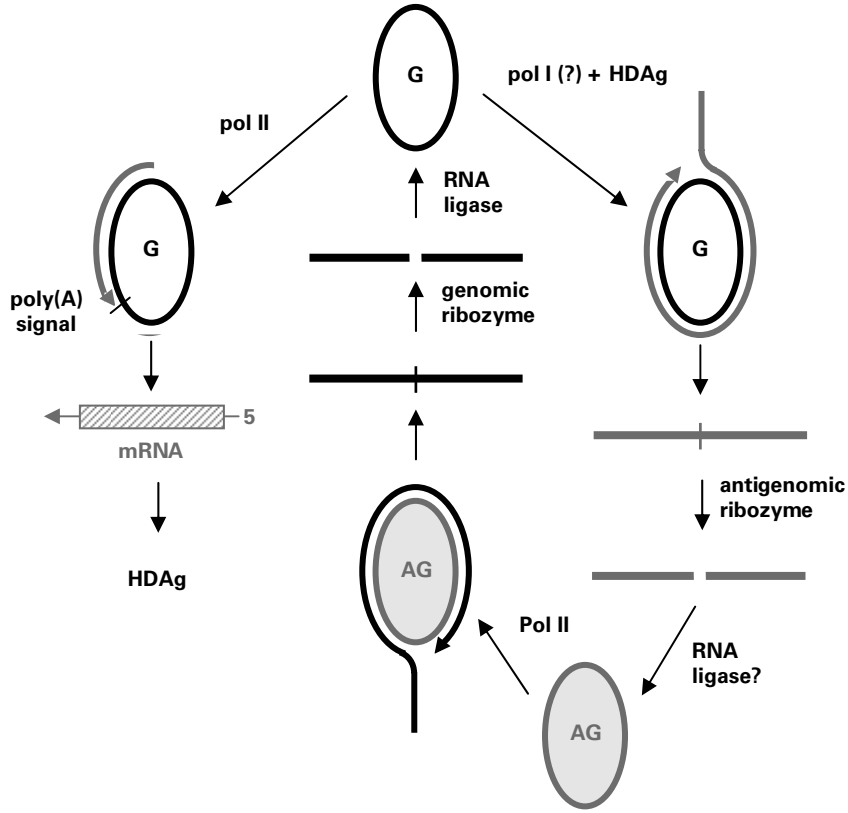

**Figure 36.3** The proposed replication and transcription models of HDV RNA. The incoming genomic RNA is transcribed into an antigenomic mRNA encoding the small HDAg, which together with pol I (or another cellular polymerase), is involved in the replication of the genomic RNA into the antigenomic RNA strand. The remaining chain of the replication is the 'double rolling circle' model, involving the cleavage of the RNA intermediates by antigenomic and genomic ribozymes and ligation by RNA ligases. The enzymes involved in all these processes have not been established.

requires a complex tertiary structure,[94–96] whereas HDV RNA naturally assumes a rod-like structure. Therefore, the conformation of HDV RNA is probably dynamic, and the conformational changes may be facilitated by cellular or viral factors. Indeed, RNA chaperone activity of HDAg can facilitate the HDV RNA ribozyme activity *in vitro* and *in vivo*.[62,85] The intermediates of HDV RNA replication exist as dimer, trimer and higher oligomers, indicating that the newly synthesized RNA is processed soon after synthesis. These intermediates eventually are processed into monomers. Thus, the processing of these RNA products probably involves both a rapid and a slow phase. The monomeric RNA and some of the dimeric RNA are ligated intramolecularly into circular RNA. This process was initially thought to be carried out by a self-ligating activity of HDV RNA but now appears to be carried out by a cellular enzyme, such as RNA ligase.[97] It is not known whether the reported self-ligating activity of HDV RNA *in vitro*[27] has any functional significance. The origins of replication on both genomic and antigenomic RNAs have not been unequivocally determined. *In vitro* studies suggested that the antigenomic-sense RNA synthesis may initiate from one end of the rod-like structure of HDV RNA.[98]

Replication of HDV RNA occurs in the nuclei of the cells as both HDAg, detected by immunofluorescence, and HDV RNA, detected by *in situ* hybridization, are localized exclusively in the nuclei.[99,100] Metabolic labelling of newly synthesized HDV RNA with $^{32}$P-orthophosphate showed that the radiolabelled RNA first appeared as the multimer form in the nuclei.[101] As the replication proceeded, the monomer form gradually accumulated and became the predominant RNA species, suggesting that the multimer form is the precursor of HDV monomer RNA.[101] Recent data further showed that HDAg and HDV RNA (as ribonucleoprotein complex) shuttled in and out of the nuclei.[58,63] HDV RNA has also been shown to be rapidly transported to the cytoplasm soon after its synthesis in the nuclei, probably after the RNA intermediates have been cleaved into monomer and ligated to the circular form.[56] The role of the cytoplasmic phase in HDV RNA replication is still not certain. It appears that a substantial portion of the genomic RNA is transported to the cytoplasm after its synthesis, whereas antigenomic RNA is retained mostly in the nucleus. The biological functions and mechanism of the differential transport of the genomic and antigenomic RNA in the life-cycle of HDV is not known. It should be noted that the cytoplasmic export of HDV genomic RNA is not only required for the eventual assembly of virus particles, but may also be part of the RNA replication process.

An antigenomic-sense 0.8-kb RNA has also been detected in the HDV RNA-replicating cells.[102,103] This RNA species contains a poly(A) sequence.[102] The 5′ end of

this transcript starts at position 1630, which is near the initiation codon of the ORF for HDAg.[104] The 3′ end of the transcript is 76 nucleotides downstream from the termination codon of HDAg and is preceded (15 nucleotides upstream) by an AAUAAA polyadenylation signal.[103] Thus, this RNA covers the entire ORF for HDAg and serves as the mRNA for encoding HDAg. This is the only HDV RNA species capable of synthesizing HDAg,[105] even though the full-length antigenomic RNA also contains the coding sequence for HDAg. Thus, the transcription of this mRNA is important for continuous RNA replication. It was thought that this mRNA was present in very low abundance (roughly 60 molecules per cell as compared with 6000 molecules of the antigenomic RNA and 300 000 molecules of the genomic RNA) and was synthesized only at the beginning of the HDV life-cycle.[102,103] However, recent studies showed that these views were not correct.[106] The original hypothesis was that the generation of the 0.8-kb mRNA is part of the replication process of antigenomic RNA. When sufficient HDAg accumulates, the HDAg serves as an antiterminator protein, allowing the subsequent rounds of RNA synthesis to pass beyond the polyadenylation signal.[86,107] As a result, a multimeric HDV RNA is synthesized. However, recent studies showed that the transcription of 0.8-kb mRNA and replication of HDV RNA are independent processes, and that the mRNA is synthesized throughout the viral life-cycles. Furthermore, it can be as abundant as the HDV antigenomic RNA.[106] As discussed below, the transcription of this mRNA and replication of genomic RNA are most likely mediated by different polymerases. Thus, conceivably, they are carried out in different subcellular compartments.

During HDV RNA replication, a specific nucleotide conversion (U→C) occurs at nucleotide 1015 of the genomic sense RNA, changing the termination codon for small HDAg (on the antigenomic strand) to a tryptophan codon and extending the ORF for an additional 19 amino acids.[108] This mutation results in the synthesis of the large HDAg, which initiates virus particle assembly.[79,80] This specific mutation, termed RNA editing, requires a rod-like RNA structure and specific nucleotide sequences around the editing site and its complementary region.[109] It occurs on the antigenomic-sense RNA, causing an A→G mutation, resulting in a U→C conversion in the genomic-sense RNA.[110,111] (Earlier reports reaching opposite conclusions were most likely incorrect.[109,112]) This RNA editing appears to be carried out by a double-stranded RNA-adenosine deaminase (ADAR).[113] More recent studies have further identified ADAR I, but not ADAR II, as the enzyme responsible for HDV RNA editing.[114,115] ADAR I is a nuclear protein. The efficiency of RNA editing *in vitro* appears to be very high. However, the extent of RNA editing in the cells is regulated, so that L-HDAg is not over-produced. Such a feedback inhibition probably is caused by the enhanced deleterious mutations occurring in the genome triggered by the edited sequence[116] or L-HDAg *per se*.[117] In a woodchuck model, the amount of the L-HDAg in hepatocytes increased during the course of acute HDV infection, but it decreased during chronic infection.[118] However, in human delta hepatitis patients, the relative ratio of the large and small HDAg appears to be variable, irrespective of the clinical stage of infection.[119] In every delta hepatitis patient examined, both RNA species containing a large and a small HDAg ORF are present.[43] However, RNA editing did not occur in some experimental systems, such as transgenic mice expressing HDV RNA.[120]

The enzymology of HDV RNA replication is not yet entirely clear. Significant progress has recently been made in this regard. It has been shown that HDV RNA replication is suppressed by a low concentration (1–5 μg/mL) of α-amanitin, suggesting the involvement of DNA-dependent RNA polymerase II (pol II) from the host cells.[78] Pol II can elongate RNA-dependent RNA synthesis *in vitro* using HDV RNA as a template, although the RNA product is different from the natural RNA species.[121] More recent studies showed differential sensitivity of the synthesis of the two strands of HDV RNA to α-amanitin. The genomic RNA synthesis (from the antigenomic RNA template) is sensitive to α-amanitin, whereas antigenomic RNA synthesis (from the genomic RNA template) is resistant (up to 100 μg/mL of α-amanitin).[101,122] The mRNA transcription is also sensitive to the low concentration of α-amanitin. These findings suggest that a different polymerase, in addition to pol II, is also involved in HDV RNA replication. Most likely, pol I is involved in the antigenomic RNA synthesis from the genomic RNA template. The dichotomy of genomic and antigenomic RNA synthesis in their metabolic requirement is consistent with other known properties of these two RNA species. For example, antigenomic RNA cannot initiate RNA replication when it is transfected together with the recombinant HDAg derived from *Escherichia coli*, whereas genomic RNA can.[123] Certain phosphorylation (at serine-177) and methylation of HDAg is required for antigenomic but not genomic RNA synthesis[51] (Li and Lai, unpublished observations). Genomic but not antigenomic RNA synthesis is inhibited by L-HDAg, when the latter is expressed early in viral replication.[83] Finally, the genomic and antigenomic RNA have different distribution patterns within the nucleus.[124] HDAg also has been reported to complex with a nucleolar protein B23 and HDV RNA synthesis is enhanced when B23 is overexpressed,[125] another indication that HDV RNA may be located in the nucleolus at certain stages of the HDV life-cycle.

The question remains as to how RNA polymerase II or other cellular polymerases can utilize an RNA template rather than their normal DNA template. Possibly, HDAg

may complex with cellular transcription factors and then interact directly or indirectly with pol II, thereby altering its template specificity. As HDAg binds to HDV RNA,[47,54] a transcription complex consisting of HDAg, pol II and cellular transcription factors could conceivably complex with HDV RNA and carry out RNA replication. However, HDV RNA synthesis did occur in the absence of HDAg in cell-free lysates,[78,121,126] although some of these studies have so far failed to be reproduced. Another study showed that HDAg can promote the elongation, but not initiation, of HDV RNA-dependent RNA synthesis carried out by pol II in a reconstituted pol II transcription reaction.[77] It is noteworthy that the rod-shaped structure of HDV RNA resembles double-stranded DNA. Therefore, it is conceivable that cellular RNA polymerases and transcription factors may recognize double-stranded RNA. Indeed, the double-stranded DNA counterpart of the region encompassing the replication origin for the antigenomic-strand HDV RNA has a promoter activity for transcription.[127,128] These questions remain the most critical issues as regards the HDV replication cycle.

## Virus assembly

Co-transfection studies using different forms of HBsAg gene and plasmids coding for either L- or S-HDAg and HDV cDNAs have shown that the large form, but not the small form, of HDAg is required for the assembly of HDV particles.[79–81] A virus-like particle can be formed even in the absence of HDV RNA, the minimum requirement being the large HDAg and HBsAg. It has been shown that the large HDAg by itself can bind to HBsAg *in vitro*.[69] This interaction requires prenylation and specific amino acids within the C-terminal 19 amino acids.[66,67] The 19 amino acids are necessary and sufficient for virus assembly.[69,73] On the other hand, the small HBsAg alone, but not other forms of HBsAg, is sufficient for HDV particle assembly,[80,81] but the presence of the large HBsAg (pre-S1) polypeptides in the assembled particles is required for the infectivity of the assembled HDV particles in primary primate hepatocyte cultures.[81] Although the small HDAg is not required for HDV particle assembly, it can be packaged into virus particles,[64] probably because of its interaction with the large HDAg.[129] The relative ratio of the large and small HDAg in HDV virus particles obtained from infected serum[46,130] varies from 0.5 to 10 or higher, suggesting that there is no strict requirement for a fixed ratio between the large and small forms of HDAg in virus particles. Alternatively, there may be a population of virus particles containing exclusively the large form or the small form, respectively.

The intracellular site of interaction between HDAg and HBsAg is not certain, inasmuch as HDAg is present mainly in the nuclei, while HBsAg is localized exclusively in the cytoplasm. Recent studies showed that HDAg can shuttle in and out of the nuclei.[58] It has been shown that an HDAg mutant with a deletion in the nuclear localization signal could still be packaged into virus particles,[131] suggesting that the interaction takes place in the cytoplasm. The prenylates of the large HDAg may allow it to interact with a cellular membrane component that harbours HBsAg. This interaction may be the nucleation point of virus assembly. Other virion components, such as the small HDAg and HDV RNA, are incorporated into virus particles through their interaction with the large HDAg. HDV RNA is packaged most likely by binding to the large or small HDAg. However, although the large HDAg is sufficient for packaging of HDV RNA into virion, efficient RNA packaging requires the small HDAg as well, suggesting that HDV RNA may bind to both the large and small HDAg in the virion.[132] Only the genomic sense RNA is packaged into virion, although the antigenomic sense RNA binds equally well to HDAg *in vitro*.[52,54] The basis for the selectivity of RNA packaging is not clear. In the assembled virus particles, HDAg has been shown to complex with HDV RNA.[54] So far, no distinct nucleocapsid structure has been observed within virus particles.

## Molecular basis of viral pathogenesis

Current knowledge on the molecular biology of HDV provides clues toward the understanding of the viral pathogenesis and clinical manifestation of HDV infection. Both viral and host factors probably play significant roles in this process. It has been recognized that genotype III isolates, which are detected only in South America, are associated with more severe, frequently fulminant, hepatitis.[14,133] In contrast, genotype II isolates, which are found mainly in Asia, are associated with milder hepatitis.[17] The virulence of genotype I viruses is more variable. The genetic basis of HDV RNA for such variance is not clear. Interestingly, the most divergent region among the three genotypes is the region encoding the C-terminal 19 amino acids of L-HDAg, which shows genotype-specific variations.[14] This region is known to be essential for virus assembly and for inhibition of viral replication early in the viral life-cycle. HDV RNA with genotype II-specific 19 amino acids has a poorer efficiency of RNA editing and virus assembly than genotype I RNA. Correspondingly, genotype II viruses had lower virus yields and poorer virus spread.[134] Type II-derived HDV cDNA clones appear to replicate less efficiently than type I cDNA clones.[135]

Another potential mechanism of HDV pathogenesis is that HDV RNA replication may disturb cellular functions. It has been noted that a stretch of HDV RNA sequence bears homology to the cellular 7S RNA,[136,137] which is involved in protein translation and transport. However, no evidence is available to suggest that trans-

lation of cellular proteins is affected by HDV infection. Furthermore, HDV RNA replication utilizes cellular transcriptional machinery. As a consequence, transcription of cellular genes may be inhibited. This possibility has been evidenced in the inhibition of HBV replication and gene expression by HDV co-infection.[138–142] Both the small and large HDAg have been shown to affect cellular pol II-mediated transcription, although the precise effects (stimulatory or inhibitory) are contradictory in two different studies.[143,144] In addition, HDAg, particularly the small HDAg, was shown to be cytotoxic when it was expressed at high levels in the cells.[145–148] However, no significant pathology can be seen in the HDAg-expressing transgenic mice,[120,149] HDAg-expressing cell lines, and HDV infection of primary hepatocyte cultures.[150–152] Interestingly, HDV reinfections of transplanted livers in patients very often remain asymptomatic until HBV reactivates,[153] suggesting that HDV by itself may not be pathogenic and requires HBV for the manifestation of the disease. Still another possibility is that pathogenesis of HDV is due to immunopathic attack by cytotoxic T lymphocytes.[100,154] This possibility is supported by the finding that experimental vaccination of chimpanzees or woodchucks with HDAg exacerbated the illness of subsequent HDV infection.[155] These possibilities have still to be investigated.

Although a double-stranded, rod-like HDV RNA could be expected to act as a powerful interferon (IFN) inducer, the ability of HDV to replicate actively in infected cells indicates that HDV RNA either fails as an IFN inducer or evades a response to IFN. In fact, administration of IFN-α or IFN-γ to HDV cDNA-transfected cells failed to inhibit HDV replication in the presence of otherwise functionally preserved IFN-activated pathways, which include the dsRNA activation of protein kinase (PKR).[156] This was confirmed in another study where PKR activation by HDV RNA was not associated with inhibition of protein synthesis.[157] Obviously, many viral and cellular factors may contribute to HDV-induced pathogenicity. The elucidation of these factors will require further understanding of the molecular biology of the virus.

# Chapter 37
# Epidemiology and natural history

Floriano Rosina, Mario Rizzetto

## Epidemiology of delta hepatitis

The hepatitis delta virus (HDV) was identified in 1977 in Italy from a nuclear immunofluorescence staining in liver biopsies of patients infected with the hepatitis B virus (HBV).[1] The staining was recognized as an antigen (delta antigen, HDAg) of the new virus and antibodies directed against the HDAg (anti-HD) were identified in sera from HDV-infected patients. When an assay for anti-HD was developed, evidence of HDV infection was found all around the world.[2]

Although the use of an antibody test is not optimal for the correct interpretation of HDV epidemiology, direct markers of HDV replication have been rarely used in epidemiological studies. Radioimmunoassays and enzyme-linked immunoassays for detection of HDAg give positive results only in the early stages of acute HDV infection and molecular hybridization and PCR assays for the RNA genome of HDV (HDV RNA) were not available when most epidemiological studies were done or were deemed to be unreliable in frozen stored samples due the intrinsic frailty of RNA. Thus, epidemiological data rest primarily on indirect assays such as IgG and IgM anti-HD, both expressions of the host response to the virus.

In acute hepatitis D anti-HD appears late and may be missed if repeated testing is not performed.[3] Thus, the true incidence of acute hepatitis D may be underestimated. This is particularly true in immunodeficient individuals such as patients infected with human immunodeficiency virus (HIV), in whom the antibody response to HDV may be delayed or absent.[4,5] Furthermore, if HDV infection does not progress to chronicity, after resolution of acute hepatitis D anti-HD may disappear with time, making the diagnosis of past acute HDV infection impossible. In contrast, patients who develop chronic hepatitis D mount brisk antibody responses that persist in high titres throughout the course of HDV infections.[6] Data on HDV epidemiology have therefore mostly been gathered from chronic hepatitis B virus (HBV) carriers superinfected by HDV in whom HDV infection has progressed to chronicity.

Data collected in the 1980s indicated that no less than 5% of the HBsAg carriers in the world were infected by HDV. As the number of HBV carriers was then estimated to be around 300 000 000, no less than 15 000 000 persons were expected to be infected by HDV. The geographical distribution of HDV infection did not parallel that of HBV, as some endemic areas for HBV were almost HDV-free. Currently, HDV remains endemic in tropical and subtropical areas. In the 1970s to 1980s, HDV infection occurred sporadically in the general HBV population in the Western world, but was endemic in HBsAg subpopulations sharing risk factors predisposing to viral transmission.

Three epidemiological patterns of HDV infection have been described: the endemic and epidemic patterns and HDV infection of high-risk groups.

### Endemic HDV infection

HDV infection was endemic in populations living around the Mediterranean Sea up to the early 1990s. Infection tended to occur early in life, affecting mainly children and young adults. The main route of transmission was inapparent permucosal or percutaneous spread. Intrafamilial transmission was common and may have been aided by poor hygiene. A recent study conducted in Italy indicates that the prevalence of HDV infection diminished sharply in the country in the last two decades.[7] In 1997, anti-HD was detected in only 8.3% of 834 HBsAg-positive patients compared with a 23% and 14% prevalence reported in 1987 and 1992, respectively.

In areas that maintain endemicity, the diffusion of HDV is uneven at the regional level. In Brazil,[8] Kenya[9] and China[10,11] pockets of hyperendemic infection have been identified close to areas where the prevalence of HDV was negligible. In part, such discrepancies depend on the disparate sampling of the patients enrolled to extrapolate local rate of HDV infection. Because of

the association between HDV and liver disease, higher prevalences of HDV were reported when those tested were HBsAg carriers with abnormal liver function tests than when they were healthy carriers recruited at blood banks.

In endemic areas, HDV is a major cause of fulminant hepatitis, especially when an HBsAg carrier with ongoing liver disease is superinfected by HDV.[12–19]

### Epidemic HDV infection

HDV infection has been reported to occur in epidemics in some populations or in high-risk subjects. Separate epidemics have been described among the Yupca and the Yanomani Indians of Venezuela,[20,21] both associated with a high rate of fulminant hepatitis and with a peculiar liver histology characterized by foamy degeneration of hepatocytes due to microvesicular steatosis.[22] Small-scale outbreaks of HDV infections have been related to nosocomial transmission, either by haemodialysis[23] or cancer chemotherapy.[24]

### HDV infection in high-risk groups

In North America and northern Europe, HDV was largely confined to high-risk groups that share as predisposing factors the carriage of HBsAg and apparent or inapparent parenteral exposure to uncontrolled blood or promiscuity in non-hygienic and overcrowded conditions.

Intravenous drug addicts sharing needles have been reported as the major victims of HDV infection in the Western world, with prevalence in the 1980s varying from 17% to 98% and a consistent presence of anti-HDV also in anti-HBs-positive subjects.[25–30]

### Ongoing changes in HDV epidemiology

The epidemiology of HDV infection has changed in the last 10 years. Improvements in socio-economic conditions, increased awareness of the risk of transmitting infectious diseases fostered by AIDS prevention policies and vaccination campaigns against HBV have all contributed to a spectacular decline in the incidence of HBV and HDV infections, especially in areas such as Italy and Greece where HDV was endemic.[7,31,32] However, new migration patterns can be expected to further modify the epidemiology of HDV. People migrating from eastern countries such as Romania and Albania to Western European countries may bring with them HDV infection.[33] Southern Africa, where no HDV infection was identified,[34,35] has been relatively isolated from the rest of Africa until quite recently, but with increases in travelling and trade with other African countries the 15% of South African HBsAg-positive black individuals may now be at risk of becoming infected with HDV.

### Molecular epidemiology of HDV

Genetic analysis of HDV isolates from around the world has shown that there are at least three phylogenetically distinct genotypes clustered in different geographic areas.[36–39] The most widespread geographically is genotype I, which was identified in North America, Europe, East and West Asia and the South Pacific and is associated with a broad spectrum of chronic diseases. Genotype II was isolated only in East Asia, and may be responsible for some of the milder forms of HDV disease in that region. Genotype III is exclusively found in northern South America, where HDV infection occurs in epidemics among Indians and exhibits a particularly severe course. Superinfection or mixed infections with different genotypes can occur, particularly in patients who are at high risk for multiple exposures. In these patients, a single genotype usually predominates, with the minor genotype representing only 10% of the total viral population.[40] The association between genotypes and disease pattern may be explained by the high rate of sequence divergence among the genotypes: up to 40% for the entire RNA genome and 35% for the amino acid sequence of HDAg. Furthermore, recent studies of HDV RNA replication in transfected cell lines have indicated that the HDV genotypes differ functionally as well as genetically.

## Natural history

### Acute HDV infection and disease

Three patterns of acute HDV infection have been described: two – co-infection and superinfection – occurring in the general population, the third – HBV-independent latent HDV infection – which in humans apparently occurs only in the liver transplant setting.

#### *Co-infection*

Co-infection occurs through simultaneous infection with HBV and HDV of a subject who has not been previously infected by HBV.

Most clinically apparent co-infections present as an icteric hepatitis with clinical features similar to those of acute hepatitis B, running a benign self-limiting course and evolving to chronicity in <7% of cases.[41–43] Unlike uncomplicated hepatitis B, co-infection tends to run a biphasic course with two peaks of liver necrosis a few weeks apart, where the first episode of hepatitis is associated with HBV and the second with HDV or vice versa.[44] The average form of co-infection may lack the early antigenaemic phase and the diagnosis can be supported only by an increase of IgM and IgG anti-HD. The antibody response to HDV is relatively slow. The initial

IgM response may be delayed for days to weeks after the onset of hepatitis and the IgG response may first appear during the convalescence phase. Prolonged monitoring for antibodies to HDV is therefore required to exclude or confirm HDV co-infection in patients presenting with HBsAg hepatitis (Fig. 37.1).

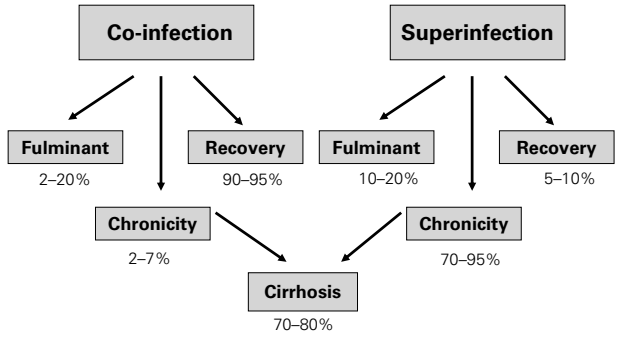

**Figure 37.1** Outcome of co-infection and superinfection with HDV with respect to the risk of developing fulminant hepatitis, chronicity and cirrhosis.

### *Superinfection*

Individuals chronically infected with HBV are prone to HDV infection. Because HBsAg expression is established prior to HDV exposure, in superinfection HDV finds a fertile ground for replication and for the full expression of its pathogenic potential.

The clinical presentation of HDV superinfection depends on whether the patient was a healthy carrier of HBsAg or whether clinical features of chronic hepatitis were present.

The acute phase is characterized by very high levels of HDV viraemia and expression of HDAg in >50% of hepatocytes. Severe acute hepatitis typically follows the peak of viraemia and coincides with the appearance of antibody to HDAg. The risk of fulminant hepatitis is high, especially in the setting of a pre-existing HBV-related liver disease[45–47] (Fig. 37.2). In an epidemic of HDV hepatitis in a community of intravenous drug users in the USA, 91% of patients with fulminant hepatitis had anti-HD in their serum versus 45% in the non-fulminant cases.[28] In tropical areas, fulminant hepatitis occurring during epidemics of HDV infection have a characteristic microscopic appearance of microvesicular steatosis and foamy degeneration,[22] features only occasionally observed in fulminant hepatitis D in developed countries.[48]

In superinfection, the antibody response is more uniform and consistent than in co-infection. There is a relatively brisk IgM and IgG anti-HD response, both antibody titres rise when superinfection progresses to chronicity. In at least 70% of cases, HDV superinfection does not resolve but becomes chronic, resulting in chronic type D hepatitis. In patients whose hepatitis D resolves, the IgM anti-HD disappears rapidly while the IgG declines slowly (Fig. 37.3).

### *Helper-independent latent HDV infection*

A third form of HDV infection was described in the transplant setting and is characterized by a helper-independent latent infection of the hepatocytes by HDV which can be rescued by the helper virus at a later time. Intranuclear HDAg can be detected in the grafted liver as early as a few hours after transplantation in the absence of both productive HDV infection (i.e. serum HDV RNA cannot be detected by hybridization assays) and HBV reinfection (i.e. undetectable HBsAg in serum). This situation is possibly due to reinfection of the

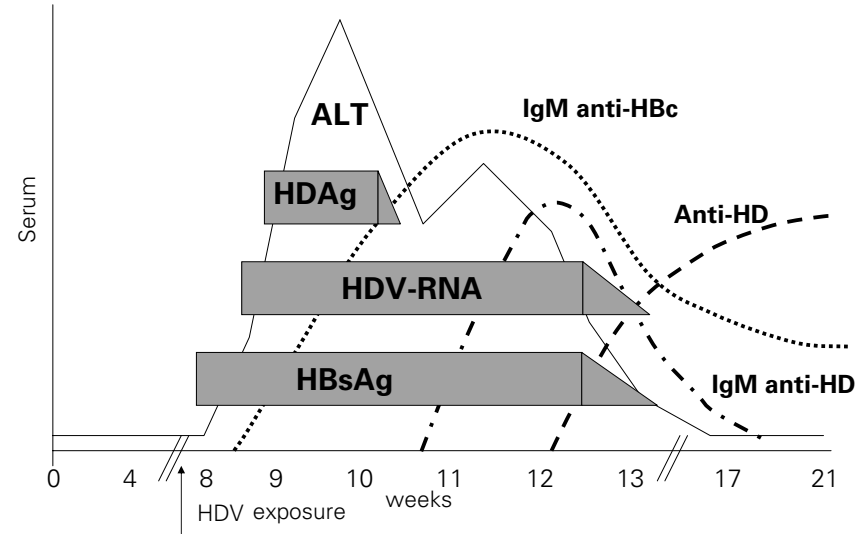

**Figure 37.2** Serological and serum biochemical changes associated with acute HDV co-infection. ALT, alanine aminotransferase; HDAg, hepatitis delta antigen; HDV-RNA, hepatitis delta virus RNA; anti-HD, antibody to HDAg; HBsAg, hepatitis B surface antigen; anti-HBc, antibody to hepatitis B core antigen.

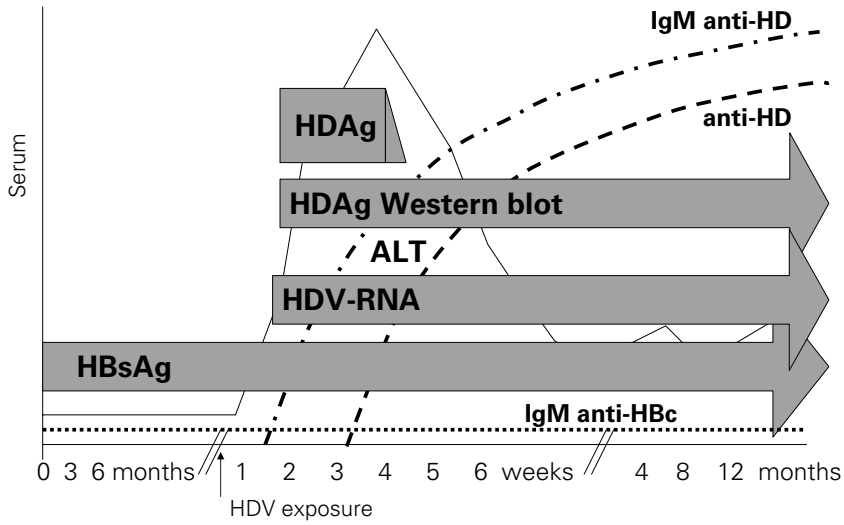

**Figure 37.3** Serological and serum biochemical changes associated with acute HDV superinfection. ALT, alanine aminotransferase; HDAg, hepatitis delta antigen; HDV-RNA, hepatitis delta virus RNA; anti-HD, antibody to HDAg; HBsAg, hepatitis B surface antigen; anti-HBc, antibody to hepatitis B core antigen

allograft by HDV alone, while simultaneous infection of the hepatocytes by HBV is prevented by hepatitis B immunoglobulins. During this phase there is no or limited evidence of liver disease. HD viraemia and hepatitis recur only when HBV evades neutralization, resulting in co-infection of the allograft and establishment of productive HDV infection.[49] According to our present understanding of the HDV life-cycle, during the non-productive phase, HDV can replicate its genome and produce HDAg inside the hepatocyte. Such incomplete virion lacking the HBsAg envelope cannot be exported out of the hepatocyte. When the hepatocyte is infected by HBV, the full HBsAg-coated virion of HDV can be assembled and exported out of the hepatocyte, and can infect contiguous hepatocytes or circulate.

This phenomenon has been reproduced *in vivo* in the woodchuck model of HDV infection. Woodchucks that have never been exposed to the woodchuck hepatitis virus (WHV) were inoculated with sera containing a high proportion of HDV versus WHV particles. HDV viraemia was undetectable despite the presence of intrahepatic HDAg. Productive HDV infection occurred only when the woodchucks were challenged – 1 month after the first inoculation – with a high infectious dose of WHV, which apparently rescued HDV replication.[50]

## Chronic HDV infection and disease

Throughout the 1980s, HDV infection was consistently associated with serious liver diseases spanning from fulminant hepatitis to chronic active hepatitis rapidly progressive to cirrhosis, liver failure and death or transplantation.[12] However, it is now clear that, at least in some areas, chronic infection can result in a relatively mild disease that is not significantly different from that due to HBV infection alone.

### *Cross-sectional studies*

In apparently asymptomatic HBsAg carriers with anti-HD the liver biopsy often shows occult but significant hepatic damage[51–57] (Table 37.1).[51,56–59]

In a study conducted in Italy, in 2487 individuals fortuitously found to have the HBsAg in the blood, 112 (5%) were anti-HD-positive. Liver function tests were impaired in 38% of the anti-HD-positive carriers but in only 9% of the 2375 anti-delta-negative subjects. Liver

biopsy specimens obtained from 31 antibody-positive and 97 antibody-negative subjects showed important histological changes in 61% of the 31 antibody-positive carriers (seven chronic active hepatitis, four active cirrhosis, eight inactive cirrhosis) but in only 19% of the 97 antibody-negative carriers.[58]

Another study conducted in 203 Italian HBsAg carriers showed that the 64 patients with positive HDAg on liver biopsy more frequently had severe chronic active hepatitis (CAH) (30% versus 12%) and less frequently chronic persistent hepatitis (CPH) (11% versus 29%) than the 139 HDAg-negative patients. Patients with HDAg-positive cirrhosis were significantly younger than those with HDAg-negative cirrhosis.[59] Similar findings were obtained for British patients.[55]

As in adults, chronic HDV hepatitis in children was usually accompanied by serious liver disease, which was unresponsive to immunosuppressive treatment. Serological evidence of HDV infection was found in 34 of 270 Italian children with HBsAg-positive liver disease. The prevalence of HDV infection increased in parallel with the histological activity of the disease and was maximal in children with cirrhosis. During 2–7 years of follow-up, the hepatitis deteriorated in 38% of the patients with delta infection and ameliorated only in 9%. By contrast the disease usually ran a mild course in the 236 delta-negative carriers of HBsAg, with remission in 55% and deterioration in only 7%.[60]

### *Prospective and retrospective-prospective studies*

In 1983, our group described the natural history of 101 chronic HDV patients followed for 2–6 years. At enrolment, the predominant liver disease was chronic active hepatitis in 93 patients with cirrhosis in 32; minor forms of chronic persistent or lobular hepatitis were seen in 12 patients. Cirrhosis developed in 41% of patients without nodular regeneration seen in the first biopsy specimen; five of these patients died. Treatment with prednisone or azathioprine did not induce histologic amelioration of delta hepatitis or prevent cirrhosis.[57]

Fattovich and co-workers compared 18 chronic HDV patients with 128 patients with chronic hepatitis B. During 1–15 years of follow-up, histological deterioration was documented in 77% of anti-HDV-positive patients but only in 30% of HBsAg carriers without HDV infection. In seven of the 10 anti-HDV-positive patients who showed transition from chronic active hepatitis to cirrhosis, this event was observed within the first 2 years of follow-up.[53]

In recent years, due to the availability of longer follow-up periods, natural history studies have been more focused on clinical end-points of HDV disease and less on intermediate markers of disease progression such as liver histology deterioration. Furthermore, these studies have correlated distinct histories of disease with the way of exposure to HDV and with the presence or absence of independent modulators of disease progression (co-infection with HIV and/or HCV, drug and alcohol abuse, poor socio-economic conditions).

While studies conducted in communities with possible interfering factors (poor hygienic conditions, institutionalization) show an association between HDV infection and greater risk of liver-related mortality,[61,62] other studies (preferentially enrolling patients from endemic areas around the Mediterranean basin) could not establish for HDV alone an independent role in leading to liver-related death.[63–65]

Data collected in a closed Greek community suggest that HDV infection, if contracted in an endemic context without frequent high-risk exposures, may run a mild course without overt liver disease in a significant proportion of cases.[66]

In a study conducted on 159 patients from northern and southern Italy enrolled over a period of two decades and followed up for 78 ± 59 months, we characterized in a subgroup of 10% of the patients a non-progressive form of chronic hepatitis D resembling the mild course described as predominant among HDV-infected persons in the Greek community of Archangelos.[67] In the other 90% of the patients, baseline histology was marked by severe hepatitis and cirrhosis and the disease was progressive, the mean interval from primary infection to compensated histological cirrhosis spanning 9 years. Once this histological stage was reached, the clinical disease slowed down and the medical conditions remained stable and compatible with a good quality of life for an average of 13 years, with a total delay of 22 years from primary infection to clinical decompensation[32] (Fig. 37.4).

Thus, the chronic disease caused by HDV appears to run a peculiar biphasic course. During the initial florid phase of HDV infection, the disease rapidly progresses to liver failure, accounting for the steep decrease in survival curves observed in both severe hepatitis and histological cirrhosis. If the patient survives, the disease slows, delaying decompensation for more than a decade.

A formal comparison of 90 HDV/HBV patients versus 88 pure HBV-infected patients was conducted in Sicily. Subjects with HBV/HDV disease had more frequently active necroinflammation (65% versus 27%) and histological cirrhosis (73% versus 35%) at presentation. The more severe histology was associated with a trend – although not statistically significant – towards major disease events such as death, liver failure and development of hepatocellular carcinoma (HCC).[68] A prospective study conducted in European HBV patients with histologically confirmed cirrhosis at enrolment assigned to HDV infection a role in increasing the risk of

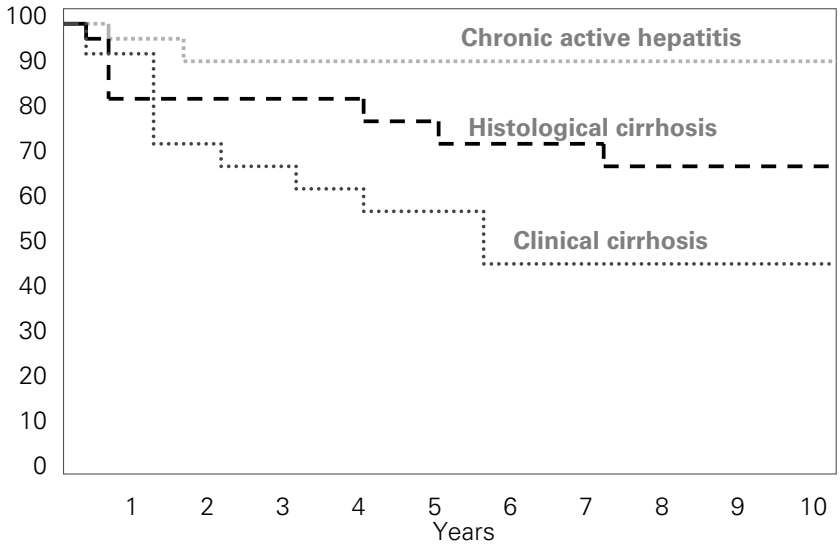

**Figure 37.4** Probability of survival of patients with chronic hepatitis D according to histology or clinical staging at enrolment.

liver decompensation and liver-related death (risk for decompensation and mortality increased by a factor of 2.2 and 2.0, respectively, in anti-HDV-positive relative to HDV-negative cirrhotic patients).[69] Such apparently limited influence of HDV as modifier of HBV infection natural history contrasts with the disproportionate impact of HDV in the liver transplant setting. In Italy, as elsewhere in Europe, the proportion of HDV patients receiving transplants in recent years amounted to 45% of HBsAg-positive cases versus a prevalence of HDV in the general HBsAg population of <10%. Furthermore, their age at the time of liver transplantation was significantly lower than that of cirrhotic patients transplanted for HBV infection alone.[70] Still follow-up periods that were too short and insufficient to detect divergencies in life expectancy between HDV/HBV and HBV patients, as well as a dilutional effect of the indolent non-progressive forms of hepatitis D, can account for such apparent discrepancies.

The relationship between HDV infection and the risk of HCC is controversial. In some parts of the world where HBV-related HCC is very common (such as Southern Africa and Taiwan), very few cases of HCC associated with HDV cirrhosis have been found.[71,72] Similar proportions of patients with cirrhosis with or without HCC were found to have serological markers of HDV infection in Italy,[68] but patients with HBV/HDV infection developed HCC earlier than patients with HBV infection alone.[73] Recently, Fattovich and co-workers have evaluated the impact of HDV infection on the clinical course of compensated cirrhosis type B in 200 European patients followed for a median period of 6.6 years. The median age at enrolment was lower (34 vs 48 years) in the 40 HBV/HDV-infected patients. The unadjusted Kaplan-Meier analysis of the cumulative incidence of HCC showed no significant difference between patients infected with HBV/HDV and HBV alone. However, after adjustment for age, clinical and serological differences at baseline, the risk for HCC was increased by a factor of 3.2 in anti-HDV-positive relative to HDV-negative cirrhotic patients. The adjusted estimated 5-year risk for HCC was 13%, 4% and 2% for anti-HDV-positive/HBeAg-negative, anti-HDV-negative/HBeAg-negative, and anti-HDV-negative/HBeAg-positive cirrhotic patients, respectively.[69]

## Factors influencing the outcome of delta hepatitis

The factors influencing the pathogenesis of HDV disease – HDV-related factors such as genotype, helper virus-related factors, such as levels of HBV replication, and host-related factors, such as immune response – may also influence its natural history.

### HDV-associated factors

Genotype II, which is predominant in the Far East, has been linked with a generally benign HDV disease.[74] Within this genotype an isolate (genotype IIb-M) associated with progressive disease has recently been separated.[75]

In the Mediterranean basin, genotype I represents the almost exclusive genotype and is associated with a broad spectrum of disease,[38,39] whereas in Taiwan and in Russia it appears to be responsible for fulminant hepatitis and rapidly progressive liver diseases.[37,76] On the other hand, all the cases of mild hepatitis D described

for the first time in the Archangelos community of Rhodes (Greece) are determined by genotype I but with an extraordinarily low sequence divergence.

HDV isolates responsible for the epidemics of fulminant hepatitis in Colombia, Venezuela and Peru all belong to a distinct viral genotype denoted genotype III, which is almost always joined with HBV genotype F.[36,77,78]

The mechanisms that link genotypes of HDV with clinical outcomes have not yet been fully elucidated. Genotypic variations are unevenly distributed along the sequences coding for HDAgs. Of these variations, the packaging signal at the C-terminus has a divergence of 74% between genotypes I and II. *In vitro* studies have shown that the package efficiency of genotype I HDV is higher than that of genotype II. Genotype II HDV therefore secretes fewer viral particles than genotype I HDV, which in turn may reduce the extent of infection of hepatocytes and result in less severe hepatic inflammation.[79]

An important factor modulating the speed of progression of HDV diseases is the replicative activity of HDV. Distinctly higher rates of serum HDV RNA have been reported in patients with severe hepatitis (76%) and with early florid histological cirrhosis (71%) than in those with late decompensated cirrhosis (33%).[32,74] This evidence suggests that HDV plays a role in driving severe hepatitis to cirrhosis, when cirrhosis is reached HDV replication abates, and this is likely to slow down further progression of the disease.

### Helper virus-associated factors

The presence and level of HBV replication play a role in determining the outcome of HDV infection. Patients with evidence of HBV replication – as detected by molecular hybridization methods – tend to have more severe liver disease and progress more rapidly to liver failure.[80] Detection of serum HBeAg and HBV DNA at baseline and the persistence of detetectable serum HBV DNA during follow-up have been recognized as significant risk factors for the development of end-stage liver disease (relative risk 9, 7 and 11, respectively).[32]

Spontaneous HBsAg clearance can occur over the years (10% during a 4-year follow-up), and in Italian patients has often been associated with improvement of the HDV disease.[81] Such a benefical effect has not been confirmed by Chen and co-workers in Taiwan, who showed progression to cirrhosis and HCC after HBsAg clearance only in patients with HDV or HCV co-infection.[82]

### Host-associated factors

At present, no data are available on the role of host genetic polymorphisms modulating immunologic-inflammatory response and fibrosis on the outcome of HDV disease.

In HIV-induced immunosuppression, simultaneous replication of both HBV and HDV is often detectable, leading to a rapidly advancing disease.[83] Progression to liver failure can be further accelerated if there is co-existent HCV infection.[84]

Cirrhosis seems to be more frequently observed in patients with multiple infections. The presence of a concomitant HCV infection induces a reciprocal inhibition between hepatitis B, D and C viruses. In 22 Spanish patients with HDV/HBV/HCV co-infection, HDV was the dominant virus and had a greater unfavourable influence on HCV than on HBV replication.[85] In French patients with triple infection, serum HCV RNA and markers of HBV replication were absent in 80%, suggesting that HDV acts as a dominant virus.[86] In contrast, of the three hepatotropic viruses HCV acted as the dominant one in co-infected patients studied in Taiwan.[87]

## Summary and conclusions

HDV was responsible for a high proportion of severe cases of acute and chronic liver disease all over the world during the 1970s and 1980s. Due to its dependence on HBV, in areas where vaccination against HBV is institutional and the risk of parenterally transmitted infection is perceived, its circulation is now sharply declining at a pace of approximately 1.5% per year. Such data would prelude the almost complete control of HDV infection in the near future.

Once considered almost invariably pathogenic and rapidly leading to liver failure and death, HDV is now associated with a broad spectrum of liver diseases which may or may not progress to cirrhosis and liver failure. HDV genotype seems to play a major role in determining the outcome of HDV disease, at least in some geographical areas.

The progressive variety of HDV hepatitis appears to run a peculiar biphasic course. During the initial florid phase, the disease can rapidly advance to cirrhosis and liver failure but, if the patient survives, disease activity slows down, delaying decompensation for more than a decade.

The diminishing epidemiological impact together with the disparate natural history has changed the medical scenario of chronic hepatitis D, which is now dominated by long-standing infections whose clinical expression is either an indolent non-progressive hepatitis that requires no therapy or cirrhosis for which ultimately only liver transplantation offers a therapeutic option.

# Chapter 38
# Treatment

Grazia Anna Niro, Floriano Rosina, Mario Rizzetto

Delta hepatitis is the most uncommon and possibly the most severe form of chronic viral hepatitis in humans. Acute infection with the hepatitis delta virus (HDV) is often severe, with a fatality rate of approximately 5%. Chronic delta hepatitis leads to cirrhosis in at least two-thirds of persons and at a younger age than in patients with HBV infection alone. Hepatitis D is most resistant to current antiviral therapies.

Being linked to hepatitis B virus (HBV) and only occurring in persons who have hepatitis B surface antigen (HBsAg) in serum, HDV is spread in the same ways as hepatitis B, through parenteral or sexual exposure to blood or body fluids. Up to 5% of the world's population is infected with HBV, and probably 5% of the HBV carriers have HDV superinfection.[1] Prevention of hepatitis B will also prevent hepatitis D, and the implementation of vaccination for hepatitis B is contributing to the current decline in HDV incidence. Nevertheless, there are still several millions of persons with chronic HDV infection and, until hepatitis B is fully eradicated, new cases of delta hepatitis will occur.

Although many viruses encode the majority of their replicative and processing enzymes, HDV apparently does not. The sole enzymatic activity that HDV possesses is a ribozyme that autocleaves the circular RNA, producing a linear molecule.[2] Other enzyme activities are apparently provided by the host cell. These features make the HDV difficult to eradicate, as most of the possible therapeutic targets are normal cellular proteins.

## Treatment of acute hepatitis D

Acute hepatitis requires the monitoring of the clinical and biochemical parameters of liver function to allow the early detection of progression to fulminant hepatitis. If fulminant hepatitis occurs, orthotopic liver transplantation is the only treatment.

Trisodium phosphonoformate (foscarnet) was used to treat three patients with fulminant HBV/HDV hepatitis; all three recovered.[3] Foscarnet is an inhibitor of the DNA polymerase and is, therefore, capable of interfering with HBV replication. Paradoxically, *in vitro* studies showed that foscarnet enhances rather than inhibits HDV replication,[4] so it is conceivable that remission of fulminant hepatitis occurred by chance rather than from the effect of foscarnet administration. The drug has not been used further. Recombinant interferon (IFN)-α-2c was administered to nine patients with fulminant HDV hepatitis. Eight died and in the survivor treatment for 3 months did not prevent the development of chronic delta infection and liver cirrhosis. IFN-α-2c has no therapeutic value in fulminant HDV hepatitis.[5]

## Treatment of chronic hepatitis D

Concomitant infection with an RNA (HDV) and a DNA (HBV) virus makes chronic hepatitis D more difficult to treat than chronic hepatitis B alone. As with hepatitis B, poor results were obtained in the treatment of hepatitis D with immunosuppressive and immunostimulant drugs.[6,7] In the mid-1980s, pilot clinical trials suggested that IFN-α could inhibit HDV replication and control hepatitis D in some groups of patients. Usually, however, this effect has not outlived the end of short-term IFN therapy.[8–10]

### IFN

#### *Clinical trials with IFN*

On the assumption that prolonged treatment with IFN might induce a therapeutic effect, several clinical trials based on the long-term administration of IFN were undertaken in the late 1980s (Tables 38.1 and 38.2).[8–24] The response, assessed on the normalization of serum alanine aminotransferase (ALT) levels and the clearance of serum HDV RNA, varied widely and occurred at different times from the beginning of treatment, sometimes after discontinuation of IFN. The rate of response was proportional to the dose of IFN. Patients treated with 9 million units (MU) responded better than patients treated with 3 MU.[12] Virological and biochemical evidence of relapse was common when IFN was reduced to 3 MU/$m^2$ after a 4-month course with 5 MU/$m^2$.[8,15] Sustained

**Table 37.1** Controlled trials of treatment of chronic HDV hepatitis with IFN

t.i.w., three times a week; NA, data not available.

responses were unusual and often incomplete, with ALT persistently normal despite the recrudescence of HDV viraemia.[12] Concomitant sustained biochemical and virological responses were usually accompanied by the clearance of serum hepatitis B surface antigen (HBsAg) and seroconversion to anti-HBs.[22,25,26] Loss of HBsAg has occurred after up to 12 years of continuous IFN therapy and was associated with improvement of fibrosis at liver histology.[27] Histological examination revealed a significant decrease in hepatic injury and in hepatitis D antigen (HDAg) staining in patients responding to IFN.[12,28]

More complex schedules and combinations of IFN with other antiviral drugs (e.g. acyclovir) were not more successful and reactivation during the follow-up was the rule.[18,20]

### *Side-effects of IFN*

The side-effects are those typical of IFN treatment, with a trend towards more frequent and severe psychiatric side-effects. Flu-like symptoms, fatigue and weight loss were seen in almost all treated patients. The severity of reactions was usually proportional to the IFN dose and to the age of the patient. In drug abusers, compliance is often poor and the intermittent use of IFN increases the incidence and severity of side-effects. One such patient committed suicide in the 11th month of treatment, and another attempted suicide shortly after discontinuation of treatment.[13,22] Ordinary patients may also become deeply depressed if treated with high doses for prolonged periods. In an Italian multicentre trial comparing the long-term administration of lymphoblastoid IFN 10 MU three times a week and 5 MU daily, one patient in the 10-MU arm committed suicide 15 days after treatment discontinuation; three other patients, one in the 10-MU arm and two in the 5-MU arm, required treatment discontinuation because of severe depression.[15] Seven (29%) of the 25 patients treated by Rumi *et al*.[23] had to stop IFN (6 MU three times a week) because of depression, fatigue, myalgias and liver decompensation.

t.i.w., three times a week; NA, data not available; HIV, human immunodeficiency virus.

Four patients had a severe hepatitic episode while on full dose IFN.[11,18] Liver kidney microsomal antibodies (anti-LKM) were present in one patient. However, in different trials 10 other anti-LKM-positive patients have completed cycles of IFN therapy without complications.[29,30]

IFN should be used cautiously in children with or cured of paediatric malignancies. Two of nine patients with compensated HDV cirrhosis developed a severe biochemical exacerbation during IFN therapy that led to fatal liver failure in one.[31]

### *Factors predictive of response to IFN*

Analysis of the pretreatment characteristics of patients has not identified differences between responders and non-responders to IFN with regard to demographic, clinical, serological, biochemical and histological findings.

Several adults and children with HDV infection and active HBV replication cleared HBV DNA and hepatitis B e antigen (HBeAg) from serum and seroconverted to anti-HBe during IFN therapy. This event usually occurred without relevant changes in liver chemistry and was not usually followed by return of ALT to normal levels.[13,19,26] In view of the poor prognosis of patients with active replication of both HBV and HDV,[32] therapeutic inhibition of HBV should nevertheless be considered a worthwhile therapeutic success.

Although disease of a short-standing nature may respond better,[21] young age may have an adverse in-

fluence. None of 10 children treated by Craxi *et al*.[19] improved clinically or histologically after treatment for a year. Among human immunodeficiency virus (HIV)-positive drug abusers, who had usually acquired HBV and HDV infection in the recent past, responses have occurred in those in whom immunocompetence was still preserved.[16,17,24]

No data are available as to whether HDV genotypes may influence the rate of response to IFN.

### *Mechanism of action of IFN*

The mechanism of action of IFN in chronic hepatitis D is poorly understood. In HDV transfected hepatoma cell lines, HDV replication is not affected by IFN.[33,34] *In vitro* experiments apparently contrast with the results observed in patients in whom response to IFN is often characterized by a concomitant reduction in HDV viraemia and ALT levels, suggesting a direct antiviral effect of the cytokine on HDV.

A major difference between these two models is that patients are always co-infected with HBV. It is conceivable, therefore, that in keeping with the frequent clearance of serum HBsAg in long-term responders, the IFN activity against HBV may play a crucial role. In HBsAg-negative long-term responders, HDV RNA and HDAg are no longer detectable in serum and liver.[22,25,26] Patients who do not clear HBsAg may enter a sustained biochemical and histological remission, despite persistence of active HDV replication.[12,35] IFN may be able to induce the emergence of less pathogenic or non-pathogenic mutants. Alternatively, it could accelerate the rate of mutation at the termination codon for delta antigen (codon 196), leading to overproduction of the non-cytotoxic large delta antigen (HDAg-p27).

In patients who respond to IFN, the inhibition of viral replication is associated with a high stability of the viral genome before and during treatment. A wide range of quasi-species before treatment and modifications of the viral genome during treatment might be responsible for the re-emergence of HDV during or after therapy.[36]

## Other treatments

Animal (woodchuck) and cell culture (woodchuck hepatocytes) systems are available to screen antiviral compounds for activity against HDV. So far, antiviral agents have not proven beneficial.

### *Suramin*

Suramin *in vitro* blocks entry of HDV virions into hepatocytes.[4] It is also known to act on hepadnaviruses and retroviruses, but the drug is too toxic for long-term use in humans.

### *Acyclovir*

Acyclovir, used previously and unsuccessfully as an adjuvant therapy in IFN-treated patients,[20] seems to enhance rather than inhibit HDV replication *in vitro*.[4]

### *Ribavirin*

Ribavirin, a nucleotide analogue, inhibits HDV replication in cell culture.[4] It was given at 15 mg/kg/day orally for 16 weeks to nine patients but had to be suspended in two of them after 2 weeks, in one because of haemolytic anaemia and in the other because of intractable itching. No significant virological or biochemical results were seen.[37] Negative results were also obtained in another small randomized series.[38]

### *THF γ-2*

THF γ-2, a synthetic thymus-derived octapeptide possessing a wide range of immunomodulatory effects, has been effective in chronic infection by HBV. The drug was used in 11 patients with chronic HDV disease without any consistent virological or biochemical effect.[39,40]

### *Deoxynucleotide analogues*

Although HBV is not involved in the replicative cycle of HDV, the HBsAg represents the envelope of HDV without which HDV cannot be secreted out of the hepatocyte. Repression of HBsAg production long enough for the infected hepatocytes to die could lead to eradication of HDV infection by preventing the spread of infectious virions to contiguous hepatocytes. This reasoning has provided the rationale for testing the therapeutic potential of deoxynucleotide analogues in hepatitis D (e.g. famciclovir, lamivudine, etc.).

In a pilot study, 15 adult patients (13 men, 2 women), aged 20–52 years, with chronic delta hepatitis were treated with famciclovir 500 mg three times a day for 6 months and were then followed up for 6 months post-treatment. HBV DNA levels decreased in 9 of the 15 patients but rose again after treatment. Famciclovir had no effect on ALT, HBsAg levels or serum HDV RNA. There was no improvement in liver histology.[41]

Five patients received lamivudine 100 mg orally daily for 12 months.[42] Despite a general reduction of HBV DNA so that viraemia was undetectable in four patients and decreased by 5 logs in the other, ALT remained abnormal, HDV RNA detectable and HBsAg positive in all. Liver biopsy showed no consistent improvement in

inflammatory or fibrotic score. Thus, the inhibitory effect of lamivudine on HBV was not sufficient over 1 year to produce a remission of hepatitis D. However, HDV disease remission was reported after 28 months of treatment with lamivudine 150 mg/day.[43]

A more extensive study has compared a 12-month versus a 24-month course of lamivudine 100 mg/day.[44] A total of 31 patients was randomized to treatment, 11 patients received placebo and 20 received lamivudine for 12 months. Thereafter, all were given lamivudine on an open-label basis for 12 months and followed up for a further 16 weeks. At the end of treatment, HDV RNA was negative and ALT normal in three patients. However, only two patients remained virus-free at the end of follow-up. Nineteen paired biopsies were available pre- and post-treatment. Five patients had a >2 point decrease in the Ishak score and were defined as responders. No significant differences in necroinflammation and fibrosis scores were observed in the two groups. One patient exhibited a complete response and became HBsAg-negative (normal ALT, negative HDV RNA, histological improvement). Lamivudine treatment for 12 or 24 months did not significantly affect biochemical, virological or histological parameters of chronic delta hepatitis in the others.

To evaluate the effect of the combination of lamivudine with high-dose IFN-α therapy, eight patients with chronic hepatitis D were treated with lamivudine for at least 24 weeks. Lamivudine was then combined with a high dose of IFN-α followed by a regular dose (9 MU three times per week) and the patients were followed up for 12 weeks post-therapy. The HBsAg concentration in serum decreased in two patients. The drop of HDV RNA in plasma from baseline during treatment was not significant. At the end of treatment, ALT had normalized in one patient and decreased in three other patients, but three of these four patients showed a biochemical rebound after withdrawal of therapy. The histology activity index (HAI) indicated a drop from a median score of 7 at baseline to 5 at the end of treatment. However, an increase in fibrosis from a median grade of 2 at baseline to 3 at the end of treatment was observed.[45]

Available evidence does not therefore support the use of deoxynucleotide analogues for the treatment of chronic hepatitis D.

## Current medical treatment

At present, IFN still represents the only treatment for chronic hepatitis D. Available data show that a proportion of patients respond to IFN if high doses (i.e. 9–10 MU three times a week) are administered for a sufficient length of time. Because HDV superinfection runs a chronic course in >90% of cases and early administration of IFN may improve the response rate, treatment should begin in patients with acute hepatitis progressing to chronicity as soon as the acute phase is over. Patients with a chronic history and without decompensated liver cirrhosis should be treated as soon as a diagnosis is made.

Parameters predictive of response are still unidentified. Whereas in chronic HBV and hepatitis C virus (HCV) infection response to IFN occurs within 3 months from the beginning of the treatment, in HDV infection response can take up to 10 months. Thus, IFN should be administered for at least a year before a patient is regarded as a non-responder.

A major challenge is when to stop therapy in a patient with a good initial response. Loss of serum HDV RNA and HDAg may not reflect the clearance of the virus, as patients who respond to treatment can lose the serum viral markers but may relapse once treatment is stopped. Treatment, however, can be safely interrupted if serum HBsAg has disappeared.

## Future perspectives

Interest in the therapy of chronic hepatitis D by pharmaceutical companies has much reduced in recent years. The dramatic reduction of HDV infection in Western countries accounts for the absence of interest in treatment of chronic delta hepatitis with new drugs such as pegylated IFN (PEG-IFN). Due to its weekly administration, PEG-IFN could nevertheless represent a reasonable therapeutic option for the long-term treatment required for chronic hepatitis D.

New treatment perspectives will probably rely on the knowledge of HDV structure, life-cycle and interaction with HBV.

The HDV RNA contains a ribozyme whose activities are important to the viral life-cycle and which depends on a unique pseudoknot structure. As is the case with other ribozymes, the autocleavage activity of the genomic HDV ribozyme is strongly inhibited *in vitro* in the presence of different aminoglycosides. Although none of the aminoglycosides that were effective *in vitro* exerted suppressive effects *in vivo* in cell lines, these observations suggest a potential strategy for anti-HDV therapy.[46]

### *Antisense oligonucleotides*

Antisense oligonucleotides hold considerable promise as therapeutic agents against several classes of viral infections. Recently, an analysis has begun of the effects of antisense oligonucleotides on HDV RNA replication in transfected cells in culture. Oligonucleotides directed against the self-cleavage domain were highly effective at reducing the level of replicating genomic HDV RNA (>90%). Transfection and treatment of chronically HBV-

producing cell lines are also under investigation to model the modulation of HDV replication under conditions that mimic *in vivo* conditions more closely.[47]

### *Prenylation inhibitors*

The essential role of prenylation in HDV assembly suggests a basis for a novel anti-HDV strategy. Mice were treated with prenylation inhibitors FTI-277 and FTI-2153. Both agents were effective in clearing HDV viraemia dependent on the duration of treatment.[48]

The HDV virion is composed of three general elements: an RNA genome, the delta antigen present in two isoforms and an envelope surrounding the other elements. Only the large delta antigen is capable of promoting particle formation with the HBsAg envelop protein. The molecular basis for this selective role in assembly lies within the 19 amino acids unique to delta antigen. In particular, the last four amino acids constitute a 'CXXX' box which is the substrate for a family of enzymes termed prenyltransferases.[48]

## Transplantation

Liver transplantation provides a valid treatment option for end-stage HDV liver disease. As with other viral disorders, transplantation is aggravated by the risk of reinfection, but this is significantly lower for HDV than for HBV and HCV, and the clinical course of recurrent hepatitis is milder than for HBV. Of 27 patients who underwent transplantation and who received no or only short-term prophylaxis with human immunoglobulins against the HBsAg, 22 (80%) became reinfected with HDV, but only 11 (40%) experienced a recurrence of hepatitis.[35] A high risk of reinfection (80%) was also reported in 14 untreated transplant recipients with HDV, but again the rate of hepatitis relapse was lower than for transplant recipients with hepatitis B.[49] Twenty-five of the 27 patients in the first study and all the patients in the second were alive 1–4 years after transplantation.

Of five transplant recipients with recurrent hepatitis D followed up long term (>8 years), three have a mild form of chronic hepatitis, one has a chronic active hepatitis and one developed a decompensated cirrhosis requiring retransplantation 5 years after the first graft. IFN (3–5 MU three times a week for up to 3 months) has not proved efficacious in these patients. In another seven HDV patients who underwent transplantation and received short-term prophylaxis, four became reinfected with HBV and HDV. Three cleared both viruses after an episode of acute hepatitis, whereas one developed cirrhosis 11 months after transplantation.[50]

The prospect of an uneventful clinical course after transplantation can be improved further by long-term administration of hyperimmune serum against HBsAg. The 5-year survival rate of 76 transplant recipients in Paris for terminal delta cirrhosis was 88%, with reappearance of HBsAg in only 9% under long-term anti-HBs prophylaxis.[51]

Apart from providing a valid therapeutic option, transplantation is a unique model for studying the biology and pathology of HDV infection. This model has shown that HDV can establish subclinical infections in the grafted liver independently of an overt HBV infection, but cooperation with HBV is necessary for disease expression. Disease recurrence is heralded by the exponential increase of HDV replication after full reactivation of HBV.[35]

Liver specimens from nine transplant recipients with relapsing hepatitis D, for whom an adequate histological follow-up was available, have been examined in detail.[52] Whereas in four patients a rise in aminotransferase heralding the return of hepatitis D corresponded with necroinflammation, in five patients the histology corresponded with a syndrome of degenerative lesions of the hepatocytes consisting of balloon-like degeneration, microsteatosis and macrosteatosis, and eosinophilic changes to the cytoplasm without inflammation. In contrast to the pattern of recurrent HBV in the former group, which comprised productive HBV infection accompanied by the full battery of HBV markers, the pattern of HBV reinfection in the latter patients was atypical. HBV DNA in the serum and hepatitis B core antigen (HBcAg) in the liver were absent. In four of these five patients, HBV infection converted to the typical productive pattern within a few weeks, and concurrently the histology changed to the classic necroinflammatory picture of viral hepatitis. These cytopathic changes, which may accompany non-viral acute hepatitis syndromes such as fatty liver of pregnancy,[53] Reye's syndrome,[54] and tetracycline and valproic acid toxicity,[55] appear also to be a feature of human HDV infection, causing fulminant hepatitis in tropical areas.[56] In transplant recipients, this unusual histological pattern was associated with incomplete HBV synthesis, which presumably resulted from some inhibitory interaction of the HDV on the HBV replicative cycle. We speculate that, as a result of this interaction, the expression of nucleocapsid HBV antigens is abrogated and the host immune reaction to the virus is abolished. The cytopathic changes could therefore be related to a direct effect of HDV. In most transplant recipients, however, HBV suppression was only transitory, infection of the graft rapidly resuming inflammatory virulence with expression of the HBcAg and the induction of the usual lymphocytotoxic reaction.

## Conclusion

The medical treatment of chronic hepatitis D rests at present on IFN, which should be administered at high

doses (9–10 MU three times a week) to patients with compensated liver disease and as soon as chronic HDV disease is diagnosed. Treatment should be prolonged for 12 months, as response – clearance of HDV RNA and normalization of ALT levels – can be delayed and sometimes occurs after the end of the treatment. A sustained response is accompanied by the clearance of the HBsAg from serum. Careful medical supervision of treated patients is mandatory for early detection of major medical and psychiatric complications.

Patients with decompensated HDV liver disease should be considered for liver transplantation. As in the case for other viral disorders, transplantation for HDV disease is associated with a risk of reinfection but this risk is much decreased if adequate protection with hyperimmune serum against HBsAg is given.

The strategy of antiviral treatment is changing, from the use of non-specific drugs, such as IFN, to molecularly tailored drugs able to interfere with crucial viral replicative processes. New insights on the replication cycle of HBV have identified potential targets for antiviral therapy, and now the nucleoside analogues are of proven value in the treatment of hepatitis B. These drugs have also been applied to the treatment of chronic hepatitis D, based on the concept that HBV provides the surface antigen (HBsAg) for the assembly of HDV and its propagation. These drugs therefore represent an indirect therapeutic target for hepatitis D. Finally, in recent years the basic knowledge on HDV pathobiology has been exploited, with the development of specific drugs on the basis of such knowledge. It is time to rethink the treatment of chronic delta hepatitis as the treatment of HDV infection and not as the treatment of HBV in order to suppress its helper function to the HDV, the latter approach having been, in the main, unsuccessful. In this regard, antisense oligonucleotides and prenylation inhibitors designed to interfere selectively with the life-cycle of HDV appear the best therapeutic perspective.

# Hepatitis E Virus

# Chapter 39
# Structure and molecular virology

David A Anderson, R Holland Cheng

Hepatitis E virus (HEV) is a major health problem in many developing areas of the world due to its enteric mode of transmission. HEV infection of swine, and possibly other animals, is common throughout the world, and animal strains provide a reservoir for sporadic zoonotic infection in countries where human HEV is not considered endemic. Virions of HEV are naked, icosahedral particles of approximately 32–34 nm diameter (Fig. 39.1),[1] most likely comprising a single viral protein which encapsidates the single-stranded, positive-sense RNA genome of approximately 7200 nt.

HEV was originally classified within the Caliciviridae on the basis of capsid morphology, biophysical characteristics and overall genome organization, but more detailed sequence analysis[2] resulted in its removal from this family and HEV was considered as an unassigned genus, 'Hepatitis E-like viruses', in the 7th ICTV report.[3] HEV is now classified as the type species of the genus Hepevirus, family Hepeviridae in the 8th ICTV report.[4]

Extensive progress has been made in the development of HEV diagnostics and experimental vaccines based on heterologous expression systems for viral proteins, but the lack of reliable cell culture systems has precluded any detailed studies of HEV replication. The recent description of infectious cDNA clones of HEV[5,6] and the characterization of an HEV-like virus in chickens[7] provide new leads with which to study these areas.

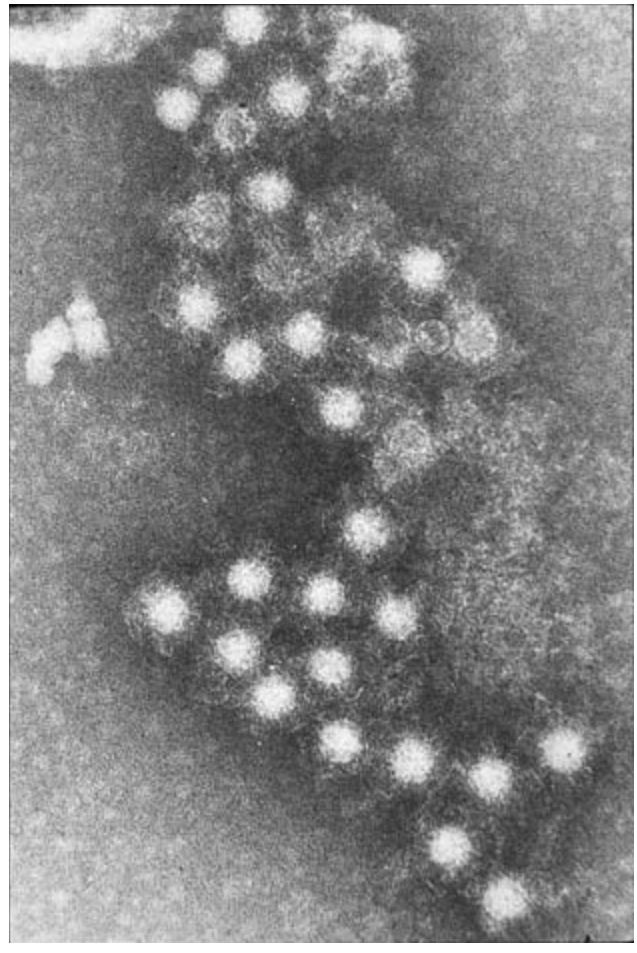

**Figure 39.1** Particles of HEV from the stools of an experimentally infected macaque, complexed with acute phase patient serum. (Photo courtesy of Prof. Zhuang Hui, Beijing Medical University; reproduced from Anderson and Shrestha,[28] with permission.)

## Physico-chemical properties

Virions of HEV are much less stable than those of hepatitis A virus (HAV), being sensitive to conditions such as CsCl and freeze-thawing that have no effect on HAV. This lower stability is likely to be a major factor in the low secondary attack rate for HEV. Virions have a sedimentation coefficient of 183S, and a buoyant density of 1.29 g/cm$^3$ (measured in potassium tartrate/glycerol).[8] The single capsid protein is encoded by open reading frame (ORF) 2, expected to yield a protein of 660 amino acids. However, the capsid protein of authentic viral particles has not been characterized.

## Genome organization

A schematic of the HEV genome and encoded proteins is shown in Fig. 39.2.[1] The 7204 nt infectious cDNA clone of the SAR-55 strain of HEV described by Emerson and colleagues[6] can be assumed to be full-length. Most isolates of HEV are close to this length, with the larger swine,[9] US-2[10] and T1 strains[11] having insertions of around 54 nt within ORF1, while the recently described avian HEV is substantially smaller at 6654 nt due to deletions in both ORF1 and ORF2.[7]

The 5′ end of the genome has a 7-methylguanosine cap,[12] as predicted on the basis of a putative methyltransferase in the viral polyprotein.[13] This cap is essential for infectivity of RNA transcribed from cDNA.[6] Notably, the first report of a putative infectious cDNA clone of HEV[14] did not include a 5′ cap, which would be expected to reduce its replicative capacity.

The viral RNA has short, highly conserved 5′ and 3′ untranslated regions (UTRs) of 25 and 68–75 nt, respectively (Fig. 39.2), which are likely to function in RNA replication and/or encapsidation as for many other RNA viruses. Three ORFs, organized as 5′-ORF1-ORF3-ORF2–3′ with ORF3 and ORF2 largely overlapping, encode the viral proteins (described here as PORFs): PORF1 (replicative polyprotein), PORF3 (unknown function) and PORF2 (capsid protein), respectively (Fig. 39.2). Subgenomic RNAs have been detected in the liver of HEV-infected macaques,[13] but nothing is known of the promoters for these putative subgenomic RNAs. Further studies are also required to determine which RNAs encode each of the viral proteins.

## Genotypes

Early studies identified the prototype Burmese[13,15] and divergent Mexican strains of HEV,[16] but more recent studies have greatly expanded the known diversity of HEV (see Huang FF *et al*.[7] and Schlauder GG, Mushahwar IK[17] for detailed reviews). This list now includes putative 'genotypes' (as defined by Wang and colleagues[18]). The Burmese and related strains (including most Chinese strains) are classified as genotype 1, the Mexican strain is classified as genotype 2, the swine HEV strain discovered in the USA[9] and closely related strains isolated from patients infected in the USA[10] are classi-

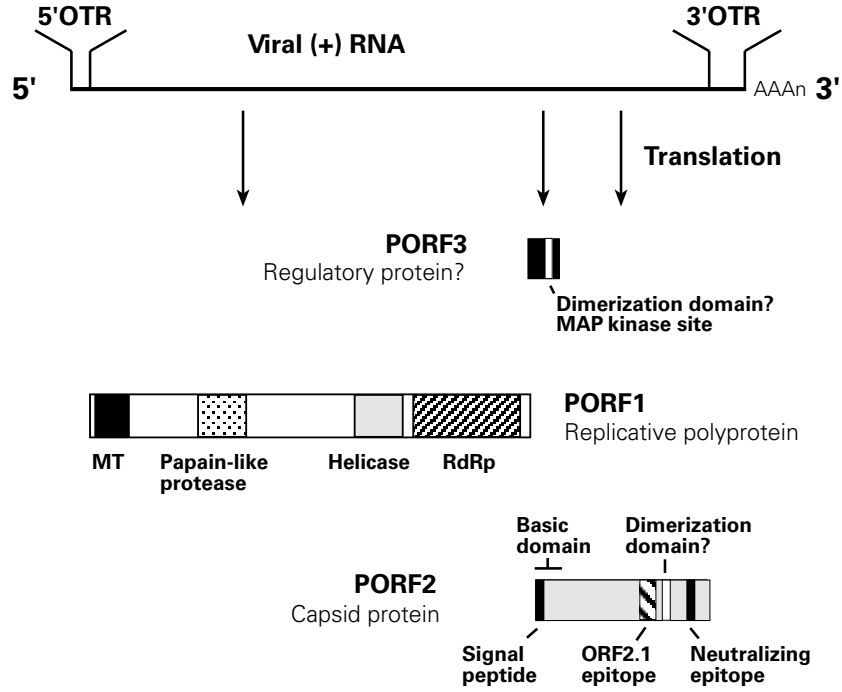

**Figure 39.2** Genome organization and protein domains of HEV. The genome of around 7200 nucleotides contains a 5′ 7-methylguanosine cap and highly conserved 5′ and 3′ untranslated regions (UTRs) of 25 and 68–75 nt, respectively. Three open reading frames (ORFs), organized as 5′-ORF1-ORF3-ORF2–3′, encode the viral proteins which may be translated from a set of subgenomic mRNA molecules. The PORF1 polyprotein contains protein domains consistent with replicative proteins (methyltransferase, protease, helicase, RNA-dependent RNA polymerase – RdRp), and PORF2 is the major capsid protein. The function of PORF3 is unknown, but it may have regulatory or replicative functions. Linear antigenic domains have been identified by peptide scanning throughout each of the three proteins, while within PORF2 a conformational, immunodominant epitope (the ORF2.1 epitope) is found between aa 394 and 457, and a conformational, neutralizing epitope is found between aa 578 and 607. (Modified from Anderson *et al*.,[28] with permission.)

fied as genotype 3, and distinct isolates from patients in China (T1 strain)[18] and both patients and swine in Taiwan[19,20] are classified as genotype 4. Until recently, the original Mexican strain was the only known representative of genotype 2. However, two reports have described strains isolated in Nigeria that appear to be genotype 2,[21,22] whereas other African strains are genotype 1.[23]

Analysis of shorter genome fragments, available from a much wider range of isolates, has led to the suggestion that there may be many more genotypes of HEV.[17] Formal classification of HEV genotypes, subgenotypes and strains will require consensus on the level of genetic heterogeneity for each classification, but should focus on utility for understanding HEV epidemiology and evolution.

Although Balayan and colleagues reported the experimental infection of pigs with HEV in 1990,[24] the isolation and subsequent characterization of swine strains of HEV endemic in the USA[9] provided the foundation for dramatic advances in our understanding of HEV. Recent descriptions of HEV-related viruses from chickens, causing big liver and spleen disease[25] and hepatitis-splenomegaly,[7,26] demonstrate that this viral family is more extensive than previously suspected, and may provide very useful experimental models for understanding HEV biology and replication. The avian HEV-like virus has been fully sequenced,[7] but due to its very low sequence homology with human and swine strains (around 50% at the nucleotide level, compared with a minimum of 75% between mammalian strains) it is uncertain whether this should be considered a strain of HEV, or rather the type species of a second genus within the Hepeviridae family.

Cross-species infection has been experimentally established for swine and human HEV,[27] although it is also likely that some strains are unable to cross species. The detection of endemic human cases of HEV corresponding to local swine HEV strains in many developed countries[10,19] demonstrates that cross-species infection does occur at significant rates in nature, and this poses a particular diagnostic challenge due to substantial variations in many epitopes. The sensitivity of diagnostic assays based on many HEV antigens is affected by amino acid variations in the encoded proteins. However, amino acid sequences are more highly conserved between the genotypes than are nucleotide sequences. The strongly immunodominant ORF2.1 epitope appears to be conserved between divergent genotypes[28,29] including swine.[30,31] ELISAs based on baculovirus-expressed, recombinant truncated PORF2 from both swine and human strains have been shown to have equivalent reactivity with sera against the full range of HEV genotypes, suggesting that there is no significant difference in the overall antigenic profile of the viruses.[32] Variable results are obtained using linear peptides and recombinant antigens that probably represent minor epitopes,[33] and these are less suitable for diagnostic use.

## Viral proteins

### ORF1

Translation of ORF1 yields a polyprotein (PORF1) of approximately 186 kDa[34] containing sequence motifs consistent with methyltransferase, papain-like protease, RNA helicase and RdRp activities[13] (Fig. 39.2). The sites of proteolytic cleavage and the sizes of mature proteins are unknown. However, functional methyltransferase activity of an approximately 110-kDa membrane-bound PORF1 product has been demonstrated in ORF1-transduced insect cells.[35]

Expression of PORF1 alone in HepG2 cells or in an *in vitro* translation system failed to demonstrate any proteolytic processing into mature products.[34] However, the same authors have subsequently used domain-specific antibodies to detect proteins of 35 kDa (methyltransferase), 38 kDa (helicase) and RdRp (36 kDa) in HepG2 cells transfected with a putative infectious cDNA clone of HEV,[14] leading to the conclusion that PORF1 processing can only occur in the context of the replication cycle. Further studies are clearly required to delineate the functional products of PORF1.

The organization of predicted enzyme domains within PORF1 is very different in HEV (Fig. 39.2) compared with Caliciviruses, with HEV PORF1 grouping instead with the non-structural polyprotein of rubella virus, a member of the enveloped Togaviridae family.[36] HEV is obviously very distinct from the togaviruses, justifying its revised taxonomic status as a member of the new family Hepeviridae.[4]

### ORF2

The capsid protein (PORF2) is translated as a 660 aa protein, including a predicted N-terminal signal peptide[13] (Fig. 39.2). Heterologous expression of PORF2 in mammalian cells indeed leads to some degree of translocation due to this signal peptide, marked by N-glycosylation of the protein[37,38] with asparagine 310 being the major glycosylation site.[39]

To date, the capsid protein of authentic HEV particles has not been characterized, and the role of glycosylation remains unresolved. Jameel and colleagues have demonstrated cell surface expression and export of PORF2 to the media,[37] although glycosylation is not required for export.[39] Deletion of the first 34 aa of PORF2 prevents translocation, glycosylation and surface expression,[39] consistent with the predicted role of aa 1–22 as a signal sequence.[13] In contrast, we have been unable to detect surface expression or export of PORF2,[38] but have

instead observed that translocated and glycosylated PORF2 is rapidly degraded within the cell.[40] Studies of HEV virions will be required to determine the nature of the mature capsid protein.

The region between aa 22 and 111 shows significant variation between HEV isolates, but always contains a high proportion of arginine residues. It appears likely that this basic region of the capsid protein is required for interaction with the negatively charged viral RNA.

PORF2 contains a number of linear B-cell epitopes identified by peptide scanning, but these most probably represent only a minor amount of total antibody reactivity. More importantly, there are significant neutralizing epitopes in the region 578–607[41] and a conformational, immunodominant epitope spanning 394–468[29] (Fig. 39.2). Individual monoclonal antibodies to this immunodominant ORF2.1 epitope can block around 60% of total convalescent antibody binding to HEV virus-like particles (VLPs).[29] However, there is no evidence that antibodies to this epitope are neutralizing.

When PORF2 is expressed in insect cells, it is cleaved at a predominant site between aa 111 and 112 and at various sites within the C-terminus of the protein. At least some of these truncated forms of PORF2 have the ability to self-assemble into VLPs or subviral particles (SVPs),[42–46] and cryoelectron microscopy has revealed structural details of such particles[47] (see below). One feature of such VLPs is prominent protrusions that suggest dimeric subunits.[47] Dimer formation has also been observed following expression of PORF2 in yeast systems.[48,49] Interestingly, we have found that the recombinant ORF2.1 protein expressed in *Escherichia coli* also forms dimers, with dimer formation dependent on a leucine zipper-like hydrophobic α-helix in the region 500–514 (Fig. 39.2). Ablation of dimer formation through mutagenesis of this region also destroys the distal, conformational epitope spanning 394–457 (Clements and Anderson, unpublished observations). As this epitope is immunodominant in both ORF2.1 and VLPs,[29] we conclude that there is an important role for dimer formation in the overall structure of the virus.

## ORF3

ORF3 partially overlaps both ORF1 and ORF2 (Fig. 39.2). PORF3 may be translated from the same subgenomic RNA as PORF2[11] or from a discrete subgenomic RNA. Alternatively, PORF3 could be translated from a 'bicistronic' subgenomic RNA, a mechanism which is used by feline calicivirus for its overlapping ORF2 and ORF3 proteins.[50]

PORF3, with a molecular mass of ≈ 13 kDa, is quite variable between HEV strains, but in all cases appears to be very basic (with an isoelectric point around 12.5). PORF3 is commonly reactive with patient antibody. However, it should be noted that reactivity is also seen to epitopes within the non-structural (PORF1) protein of HEV,[51] and PORF3 is not generally considered a structural protein.

Jameel and colleagues have extensively characterized the possible roles of this small protein. PORF3 is associated with the cytoskeleton via the N-terminal hydrophobic α-helix and is phosphorylated at serine residue 80 by mitogen-activated protein kinase (MAPK).[52,53] PORF3 also appears to form dimers via a second hydrophobic α-helical domain, overlapping the MAPK site. These properties are intriguing and suggest that PORF3 may have regulatory functions in virus replication or assembly, but the precise role of PORF3 remains unclear.

## Replication cycle

Our knowledge of HEV replication is poor, due largely to the lack of practicable cell culture systems for the virus and its genetic distance from well-studied viral families. Propogation of HEV has been clearly demonstrated in primary macaque hepatocytes,[54,55] but the level of replication is too low to allow detailed studies of replication. Two groups have reported the detection of cytopathic HEV replication in continuous cell cultures,[56–59] but there have been no independent confirmations of these reports, and contamination by adventitious agents cannot be excluded.

Emerson and colleagues have developed both infectious cDNA clones[6] and replicons[5] of HEV, and these are likely to provide the basis for greatly improved understanding of HEV replication. The development of subgenomic HEV replicons, in which PORF2 and PORF3 have been replaced with green fluorescent protein (GFP), has already demonstrated, perhaps surprisingly, that these proteins are dispensable for genome replication.[5] It can also be hoped that the avian HEV-like virus will prove less refractory to cell culture and may provide essential clues to the overall replication cycle of these viruses, in much the same way that duck hepatitis B virus played a central role in understanding the replication of hepadnaviruses.[60]

In the absence of specific data, the general outline of HEV replication can only be inferred (Fig. 39.3). HEV ingested in water or food must reach the liver via blood, either via direct uptake of the inoculum through the gastrointestinal mucosa into the circulation, or following one or more rounds of amplification in enterocytes, as appears to be the case for HAV.[61] Virus will then interact with one or more specific receptors/co-receptors on the basolateral domains of hepatocytes. Preliminary evidence suggests that HEV VLPs can bind specifically to the basolateral domains of polarized HepG2 cells in

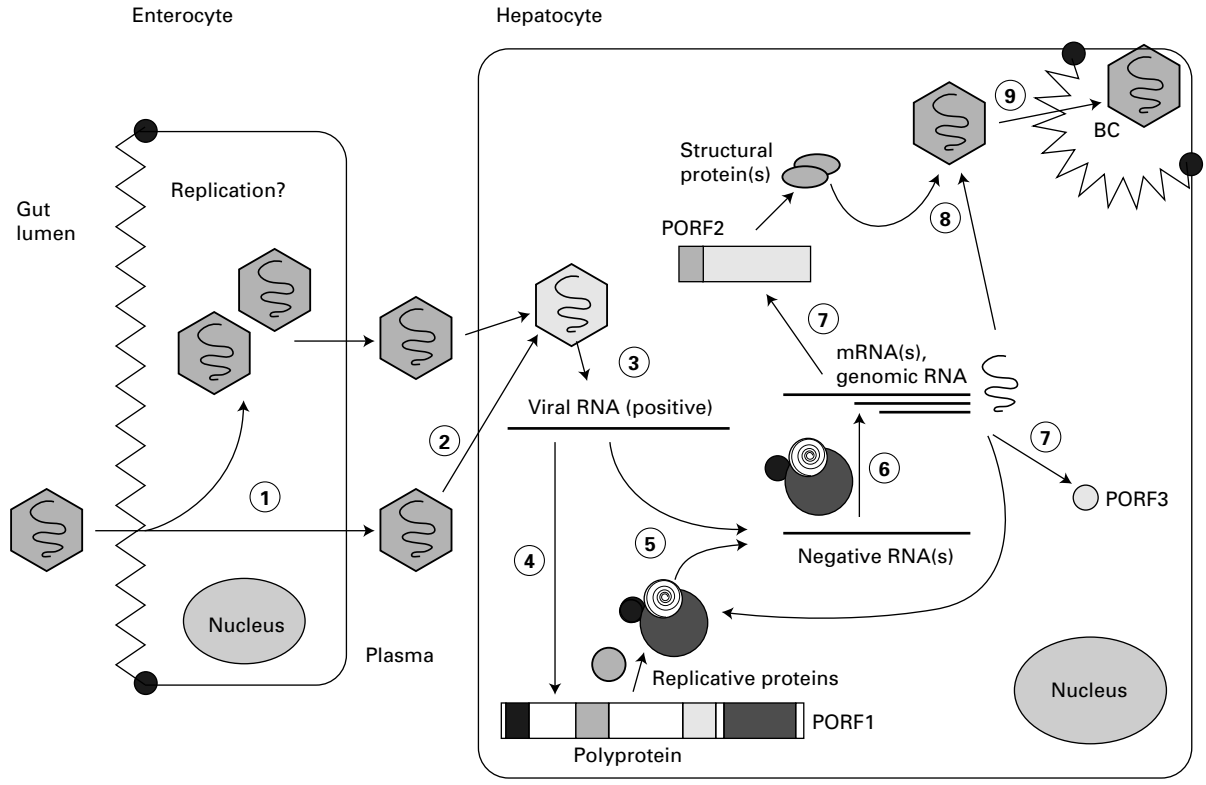

**Figure 39.3** Putative replication cycle of hepatitis E virus (HEV). From the gut lumen, HEV particles enter at the apical surface of the mucosal epithelia (1) where they may either replicate, or be transferred directly by transcytosis through the basolateral domains to the plasma. Virions reach the liver where they attach to an unidentified receptor on the basolateral surface of hepatocytes, leading to virus penetration (2) and uncoating of the genome (3) within the cell. Translation of the input genome (4) yields the PORF1 polyprotein which is cleaved at unknown sites to yield the replicative proteins, which copy the input genome to yield full-length negative-strand RNAs (5), followed by subgenomic positive-strand (messenger) RNAs and full-length positive-strand RNAs (new viral genomes) (6). These subgenomic RNAs are translated to yield further molecules of PORF1, PORF2 (capsid) and PORF3 (regulatory) proteins (7). PORF2 and new viral genomes assemble into virions (8) and progeny virus is released through the apical domain (9) to the bile canaliculi (BC) and ultimately the faeces.

culture (Snooks and Anderson, unpublished observations) (Plate 39.1, found between p. 786–7),[29,42] but the nature of this putative receptor is unknown.

Following penetration and uncoating of the virus, the input viral RNA serves as mRNA for the translation of PORF1 (and possibly PORF3), after which the PORF1 polyprotein is cleaved by viral proteases to yield the mature replicative proteins. The RDRP/helicase complex then copies the input viral genome to yield negative-strand RNA, which in turn serves as a template for the transcription of further positive-strand RNA molecules, including new genomes and subgenomic mRNAs for PORF2 and PORF3. There are some experimental data to support the production of subgenomic RNAs, as multiple RNA species have indeed been detected in the liver of HEV-infected primates.[13]

HEV genomic RNA then assembles together with PORF2, but the site of HEV assembly in the cell, and the role of proteins other than the capsid protein PORF2 in assembly, are unknown. At least two key questions remain unanswered. Firstly, are endoplasmic reticulum (ER) translocation and glycosylation involved in HEV assembly? A large proportion of PORF2 is membrane-associated and glycosylated following heterologous expression in mammalian cell culture,[37] but this glycosylated protein appears to be rapidly degraded, while around 5% of the newly synthesized protein fails to undergo translocation to the ER and remains in a stable, unglycosylated state in the cytosol.[40] Secondly, what is the size of the mature capsid protein? Expression of PORF2 in insect cells results in cleavage between aa 111 and 112, releasing the basic N-terminal domain and allowing the proper antigen folding of the downstream sequences.[42,46,62,63] As noted previously, the N-terminal domain may normally function in binding of the genomic RNA for packaging, and it is thus likely that this remains part of the viral particle during assembly, but it is equally possible that it may be cleaved at some stage

during viral assembly or maturation. Differences in antigen folding are also evident with a range of C-terminal truncations. Characterization of HEV virions should be a high priority.

Mature HEV is finally released from the cell. A small amount of HEV is found in plasma during infection, consistent with release of progeny virus through the basolateral domains of hepatocytes leading to spread through the liver, but the majority of virus appears to be excreted through the biliary system to complete the transmission cycle, corresponding with release of virus through the apical domain of hepatocytes. However, in the case of HAV, we have found that the majority of virus is initially released at the basolateral domain of polarized hepatocytes *in vitro* (Snooks and Anderson, unpublished observations), suggesting a more complex pathway for excretion of these enterically transmitted viruses.

## Structure and assembly

Virions of HEV isolated from the bile or faeces are non-enveloped, icosahedral particles of around 32 nm diameter. Naked particles demonstrate some limited surface morphology, but this is generally obscured by the use of antibody to complex virions for electron microscopy (Fig. 39.1).

Expression of full-length PORF2 in mammalian cells results in large amounts of protein degradation, with most intact PORF2 accumulating as insoluble aggregates,[40] or alternatively in PORF2 glycosylation and export.[37,39] The reasons for these differences are unclear, but neither of these pathways yields any particles resembling HEV virions in mammalian cells. In contrast, early reports of full-length PORF2 expression in insect cells included the detection of small numbers of VLPs,[45,64] later shown to be dependent on a fortuitous proteolytic cleavage between aa 111 and 112. Subsequent studies showed that the yield of VLPs was enhanced by expression of truncated (aa 112–660) rather than full-length PORF2.[42,65,66] However, the truncated product undergoes further proteolytic processing prior to assembly in some cases,[42,44–46,67] and the heterogeneity of PORF2 products in insect cells has made it difficult to interpret the precise relationships between processing and subviral particle assembly. From available studies, it appears that PORF2 fragments 112–660 aa (62 kDa),[46,65,67] 112–625, 636 or 640 aa (56.5–58.1 kDa)[43,62] and 112–578 aa (50 kDa)[42,47] assemble into VLPs or other subviral particles, whereas the intermediate fragment 112–609 aa (55 kDa) is not particulate.[44,68] Interestingly, the non-particulate 55-kDa antigen is the leading HEV vaccine candidate,[63] which suggests that higher-order structures are not essential for at least some protective epitopes.

HEV VLPs are smaller than the intact virus particle, but Cheng and colleagues have used cryoelectron microscopy to give the first indications of HEV structure[47] (Plate 39.2, between p.786–7). A most striking feature of the VLP structure is the presence of dimeric subunits (Plate 39.2b).[47] Results of the cryoelectron microscopy analysis suggest that HEV VLPs are assembled as a T = 1, icosahedral particle containing 30 dimeric subunits of 50-kDa PORF2, with the potential to form an intact virion of the correct size with a T = 3 arrangement of 90 dimeric subunits (Plate 39.2c and Plate 39.2d).[47] One candidate for PORF2 dimerization is a leucine zipper-like hydrophobic α-helix in the region of 500–514 aa (Clements and Anderson, unpublished observations).

While it must be noted again that these observations have been made in the context of heterologous expression of PORF2, such studies provide some hypotheses that should be testable using infectious cDNA clones. Native virions should be produced and further analysed by cryoelectron microscopy and other structural means, but in the interim it is likely that constructs of various capsid fragments can be used to functionally characterize the dimeric interaction domain of PORF2, the mapping of antigenic domains on the particle, and the polypeptide termini in the viral capsid assembly pathway.

# Hepatitis E as a zoonotic disease

Xiang-Jin Meng

Accumulating evidence indicates that there are animal reservoirs for the hepatitis E virus (HEV) and that hepatitis E is a zoonotic disease (Table 40.1).[1–59]

## Swine hepatitis E virus (swine HEV)

### Discovery

The first evidence of HEV infection in pigs came from a study by Balayan *et al*.[31] who reported an experimental cross-species infection of domestic swine with an Asian strain of human HEV. Unfortunately, the virus used in that study was not molecularly characterized, and subsequent efforts to reproduce their results by two independent laboratories in the United States using well-characterized infectious stocks of an Asian strain (Sar-55) and a Mexican strain (Mex-14) of human HEV were unsuccessful.[60,61] Detection of HEV antibodies (anti-HEV) and RNA was also reported from pigs in the Kathmandu Valley of Nepal.[41] However, the identity of the virus infecting Nepalese pigs was not determined.

In 1997, Meng *et al*.[1] discovered and characterized the first animal strain of HEV, swine HEV, from pigs in the United States. Serological survey of pigs revealed that the majority of adult pigs in the midwestern United States were positive for anti-HEV, suggesting that pigs were exposed to an agent antigenically related to HEV.[1] In an attempt to identify the agent responsible for the seropositivity in pigs, a prospective study was conducted in a commercial swine farm in Illinois. Twenty piglets born to both anti-HEV seronegative and seropositive sows in a swine farm were closely monitored for more than 5 months for evidence of HEV infection. The first piglet seroconverted to anti-HEV at 14 weeks of age, followed within a few weeks by seroconversion of piglets in other pens housed in the same building (Fig. 40.1).[1] By 21 weeks of age, 16 of the 20 piglets monitored in this prospective study had seroconverted to anti-HEV. A novel virus ge-

netically closely related to human HEV, designated swine HEV, was molecularly identified and characterized from the acute phase sera of the naturally infected piglets. Specific-pathogen-free (SPF) pigs were experimentally infected with the acute phase sera (containing swine HEV) of naturally infected pigs, and the same virus was recovered from experimentally infected SPF pigs.[61,62]

## Genomic organization and genotypes

The complete genomic sequence of swine HEV has been determined.[32,63,64] The genomic organization of swine HEV is very similar to that of human HEV, which contains a short 5′ non-coding region (NCR), followed by three partially overlapping open reading frames (ORFs), and a short 3′ NCR. ORF1 encodes a single polypeptide of 1709 amino acid residues. Several putative functional domains and motifs similar to human HEV have been assigned to the ORF1 of swine HEV: a methyltransferase domain at the 5′ end, a papain-like cysteine protease (PLP), a proline-rich domain that may provide flexibility, a hypervariable region (HVR), a helicase and an RNA-dependent RNA polymerase (RdRp).[32,63,64] ORF2 encodes an immunogenic capsid protein of 661 amino acid residues. The function of the small ORF3 of swine HEV (123 amino acid residues) is unknown, but it has been reported that the ORF3 of a human HEV is a cytoskeleton-associated phosphoprotein that may be involved in virus replication.[65]

At least four major genotypes of human HEV have been recognized worldwide:[66–69] genotype 1 (primarily Burmese-like Asian strains), genotype 2 (a single Mexican strain), genotype 3 (strains from rare endemic cases in the United States, Japan and Europe) and genotype 4 (variant strains from sporadic cases in Asia). Swine HEV isolates identified thus far from pigs in different countries all belong to either genotype 3 or 4, and shared significant sequence identity with and, in a few cases had identical sequence to, genotypes 3 and 4 of human HEV strains in the same geographic regions.[2–30,68] Genotype 3 and 4 strains are primarily responsible for sporadic cases of human hepatitis E. Genotype 1 or 2 strains, which are responsible for hepatitis E epidemics in many developing countries, have not been identified in pigs.

## Transmission and pathogenesis

Like human HEV, the transmission route for swine HEV is presumably faecal-oral. Faeces from infected pigs contain large amounts of viruses[61,62,70] and are probably the main source of virus for transmission. It has been demonstrated that, under experimental conditions, a sentinel uninoculated SPF pig housed in the same room with a swine HEV-inoculated pig became infected about 2 weeks after the experimentally inoculated pig had become infected.[32] It is thought that pigs acquire infection through direct contact with infected pigs or through ingestion of faeces-contaminated feed or water. However, experimental reproduction of swine HEV infection in pigs via the oral route of inoculation proved to be difficult,[71] even though pigs can be readily infected by swine HEV via the intravenous route of inoculation.[61,62] Other route(s) of transmission cannot be ruled out.

Little is known regarding the pathogenesis of swine HEV. Clinical disease was absent in naturally infected pigs.[1] In a prospective study, four piglets naturally infected with swine HEV were necropsied during the acute stage of infection. Gross lesions were not detected in the

liver or 18 other tissues and organs examined during necropsy. However, all four necropsied piglets had microscopic evidence of hepatitis characterized by mild to moderate multifocal and periportal lymphoplasmacytic hepatitis with mild focal hepatocellular necrosis. All four piglets also had lymphoplasmacytic enteritis, and three piglets had mild multifocal lymphoplasmacytic interstitial nephritis.[1] Under experimental conditions, SPF pigs experimentally infected with swine HEV or with a strain of human HEV remained clinically normal.[62] However, the infected pigs did have mildly to moderately enlarged hepatic and mesenteric lymph nodes from 7 to 55 days post-inoculation (DPI). Microscopic lesions characterized by mild-to-moderate multifocal lymphoplasmacytic hepatitis and focal hepatocellular necrosis were observed in experimentally infected pigs (Fig. 40.2).[62] Hepatic inflammation and hepatocellular necrosis peaked in severity at 20 DPI. HEV RNA was detected in faeces, liver tissue and bile of infected pigs from 3 to 27 DPI.[62]

The initial site of swine HEV replication in pigs is still not known. In primates and pigs experimentally infected with swine HEV, virus replication in the liver has been documented.[66] It is believed that, after replication in liver, swine HEV is released to the gallbladder from hepatocytes and then is excreted in faeces. However, it is not known how the virus reaches the liver. Williams *et al*.[70] studied the potential extrahepatic sites of HEV replication in pigs experimentally infected with swine HEV and the US-2 strain of human HEV. As a positive-sense RNA virus, HEV produces an intermediate negative-strand viral RNA during virus replication. By using a negative-strand-specific reverse transcriptase-polymerase chain reaction (RT-PCR), replicative negative-strand HEV RNA,

indicative of virus replication, was detected in the livers as well as several extrahepatic tissues and organs including small intestine, colon, hepatic and mesenteric lymph nodes from infected pigs.[70] By using *in situ* hybridization, Choi and Chae[72] also detected swine HEV RNA in hepatocytes and bile duct epithelium as well as in small and large intestines, lymph nodes, tonsil, spleen and kidney. The clinical and pathological significance of these extrahepatic sites of virus replication is not known.

## Incidence of infection in pig farms

Sero-epidemiological studies have demonstrated that swine HEV infection is ubiquitous in pigs worldwide in both developing and industrialized countries, regardless of whether HEV is endemic in the respective human population (Table 40.2).[1,9,15,27,33,41,46,47,73–79] Anti-HEV prevalence in pigs is age-dependent. Most pigs younger than 2 months of age are seronegative, whereas the majority of pigs over 3 months of age, when pigs are moved to pens where there is increased opportunity for environmental faecal contamination, are seropositive.[45,67] The seropositivity rates varied from herd to herd, and from region to region (Table 40.2). Sows with high anti-HEV titres can passively transfer anti-HEV to their piglets, and thus some piglets are born seropositive.[1] Maternal antibody usually waned by 8–9 weeks of age, at which point most piglets acquired infection. Some SPF pigs raised in good

biosecurity environments in the United States (Meng *et al*., unpublished data) and 17% of wild boars in Australia[74] were also tested positive for anti-HEV. The ubiquitous nature of swine HEV provides ample opportunities for potential zoonotic transmission.

Swine HEV RNA is frequently detected in the sera and faeces from pigs of 2–4 months of age, the period in which active swine HEV infections occur (Table 40.3).[3,9,10,20,21,27,41,47,73,75–81] Most adult pigs, although positive for IgG anti-HEV, are free of swine HEV RNA.[45,67] Faeces appear to be better than sera for the detection of swine HEV RNA, as faecal virus shedding of swine HEV lasts longer than viraemia, and there are more viruses in faeces than in sera.[61,62,70] Thus far, only genotypes 3 and 4 swine HEV strains have been identified from pigs (Table 40.3).

## Experimental cross-species infection by HEV

Under experimental conditions, swine HEV infected non-human primates (rhesus monkeys and a chimpanzee).[32] Two rhesus monkeys experimentally inoculated with a $10^{4.5}$ 50% pig infectious dose of swine HEV seroconverted to anti-HEV 4 weeks post-inoculation, developed viraemia and shed virus in faeces. Biochemical evidence of hepatitis was observed, as there was an elevation of serum liver enzymes, isocitrate dehydrogenase (ICD) and alanine aminotransferase (ALT), in infected primates (Fig. 40.3).[32] Mild acute viral hepatitis characterized by focal necroinflammatory changes was detected in liver biopsies near the time of serum liver enzyme elevations. The chimpanzee inoculated with swine HEV also became infected, as swine HEV RNA was detected in faeces of the inoculated chimpanzee, and seroconversion to anti-HEV occurred at 6 weeks post-inoculation.[32] Both rhesus monkeys and the chimpanzee infected with swine HEV remained clinically normal. Experimental infection of non-human primates, the surrogates of man, with swine HEV demonstrated that swine HEV can cross species barriers, therefore possibly infects humans.

A central Asian strain of human HEV was reportedly transmitted to domestic swine, and the infected pigs developed clinical hepatitis.[31] However, others failed to infect SPF pigs experimentally with human strains of

*The genotype 3 swine HEV isolates isolated in Taiwan were identified from breeding sows imported from the USA.

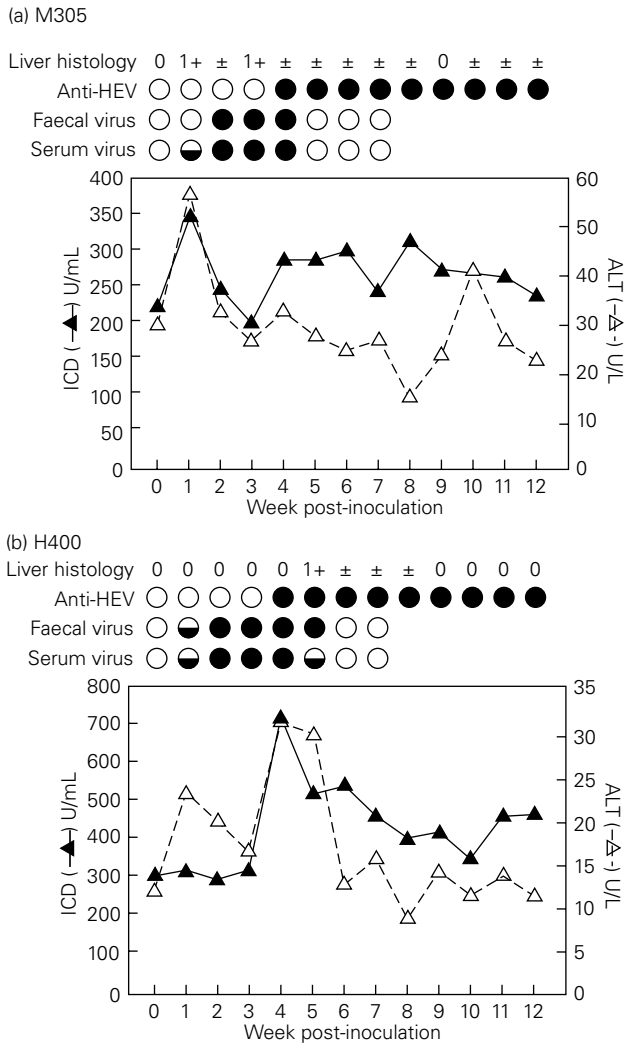

**Figure 40.3** Experimental cross-species infection of rhesus monkeys by swine HEV. Levels of serum liver enzymes (ALT and ICD) are plotted. Presence (filled circle) or absence (open circle) of anti-HEV and swine HEV RNA in serum and faeces is indicated. Half-filled circles indicate detection of swine HEV RNA only by a nested PCR. The degree of histological liver lesions observed in liver biopsies is indicated (scale of 0 to 4+). Modified with permission from the American Society for Microbiology from Meng *et al*.[32]

HEV. Meng *et al*.[61] were unable to infect crossbred SPF swine with an Asian strain (Sar-55, genotype 1) or a Mexican strain (Mex-14, genotype 2). Similarly, Platt *et al*.[60] could not infect SPF swine experimentally with the Mexican strain of human HEV. It is possible that these epidemic strains of HEV (genotypes 1 and 2) may have a more limited host range than swine HEV, which belongs to either genotype 3 or 4. In fact, when SPF swine were inoculated with a genotype 3 human HEV (strain US-2), the inoculated pigs rapidly became viraemic and seroconverted to anti-HEV within 2 weeks post-inoculation, suggesting that the US-2 strain of human HEV is already competent to replicate in swine and may be of swine origin. One infected pig even spread, through direct contact, the US-2 human virus to an uninoculated pig housed in the same room.[32] The virus recovered from infected pigs has been partially sequenced and confirmed to be the same virus used in the inoculum.

Experimental interspecies transmissions of HEV have also been reported in other animal species. Usmanov *et al*.[39] have reported experimental infections of lambs with human HEV isolates Osh-225 and Osh-228. The inoculated lambs developed clinical signs of acute hepatitis, and shed virus in faeces. It has been reported that rodents are susceptible to experimental infection by human HEV.[39] Wistar rats experimentally inoculated with a human stool suspension containing HEV became infected, as HEV RNA was detected in faeces and serum, and HEV antigen was detected in the liver and several other tissues of the inoculated rats.[39] However, others failed to confirm the rat transmission results with a genotype 1 human HEV, a genotype 3 swine HEV, a genotype 4 swine HEV, and an avian HEV (J.C. Wu, personal communication; Sun and Meng, unpublished data). However, it is important to note that serial passages in laboratory rats with a virus of rat origin are successful, but the rat virus has not yet been genetically characterized.[68]

## Novel strains of human HEV closely related to swine HEV

Hepatitis E was generally not considered to be endemic in industrialized countries. Most reported clinical cases in industrialized countries had a history of travelling to endemic regions,[66,68,82–85] although in some cases this risk factor was absent.[86–88] In the United States, two cases of acute hepatitis E have been reported, one in Minnesota and one in Tennessee.[2,8] The patient from Minnesota (US-1) had no history of travelling outside the USA, whereas the patient from Tennessee (US-2) had travelled to Mexico prior to the diagnosis of hepatitis E. The two US strains of human HEV (US-1 and US-2), which belong to genotype 3, are most closely related to the genotype 3 swine HEV recovered from a pig in Illinois (about 98% sequence identity in ORF1). Another unique HEV strain was identified from a US patient who had recently returned from vacation in Thailand, an HEV endemic country. Sequence analyses revealed that this HEV strain was most similar to the US swine and human HEV strains.[16]

Novel strains of human HEV closely related to swine HEV have also been reported in other countries. Numerous genotype 4 strains of human HEV have recently been identified from patients with sporadic cases of hepatitis E in Taiwan and China.[3,5,9,10,12,18,19,21,29,47] These genotype 4 isolates are genetically distinct from the genotype 1

epidemic strains in the region, but are very closely related to swine HEV isolates identified from pigs in Taiwan and China. Similarly, both genotype 3 and 4 strains of human HEV were recently identified from Japanese patients with sporadic cases of acute hepatitis E, and found to form phylogenetic clusters with the genotype 3 and 4 swine HEV isolates recovered from Japanese pigs[17,22–24,26,28,64,73] (Fig. 40.4). A genotype 4 Japanese human HEV isolate HE-JA1 shared 99% sequence identity over the entire genome with a Japanese swine HEV isolate, swJ13–1.[26] In India, the epidemic strains in humans belong to genotype 1, but the virus recovered from Indian pigs was found to be genotype 4, which has not yet been identified from humans in India.[78,79] A Spanish E11 strain of HEV of possible swine origin is closely related to two Spanish strains of human HEV but is less related to other known strains of HEV.[15] Similarly, novel genotype 3 strains of human HEV from patients with acute hepatitis E in the Netherlands and New Zealand are closely related to genotype 3 strains of swine HEV in the respective regions.[20,25,77] The fact that the genotype 3 or 4 swine virus is closely related to the viruses responsible for sporadic cases of human hepatitis E in the same geographic regions provides further supporting evidence that swine are reservoirs for HEV, at least for genotypes 3 and 4 strains.

## Anti-HEV prevalence in swine and other animal handlers

The demonstrated ability of swine HEV to infect across species raises concerns for potential zoonotic infection in high-risk groups such as pig handlers. In Taiwan where HEV was not considered to be endemic, Hsieh *et al*.[9] found that about 27% of the Taiwanese pig handlers were positive for anti-HEV compared with only about 8% of control subjects. Recently, a total of 465 swine veterinarians were tested for IgG anti-HEV using recombinant capsid antigens from swine HEV and a Pakistani Sar-55 strain of human HEV.[35] Among the 295 swine veterinarians from eight US states from which 400 normal

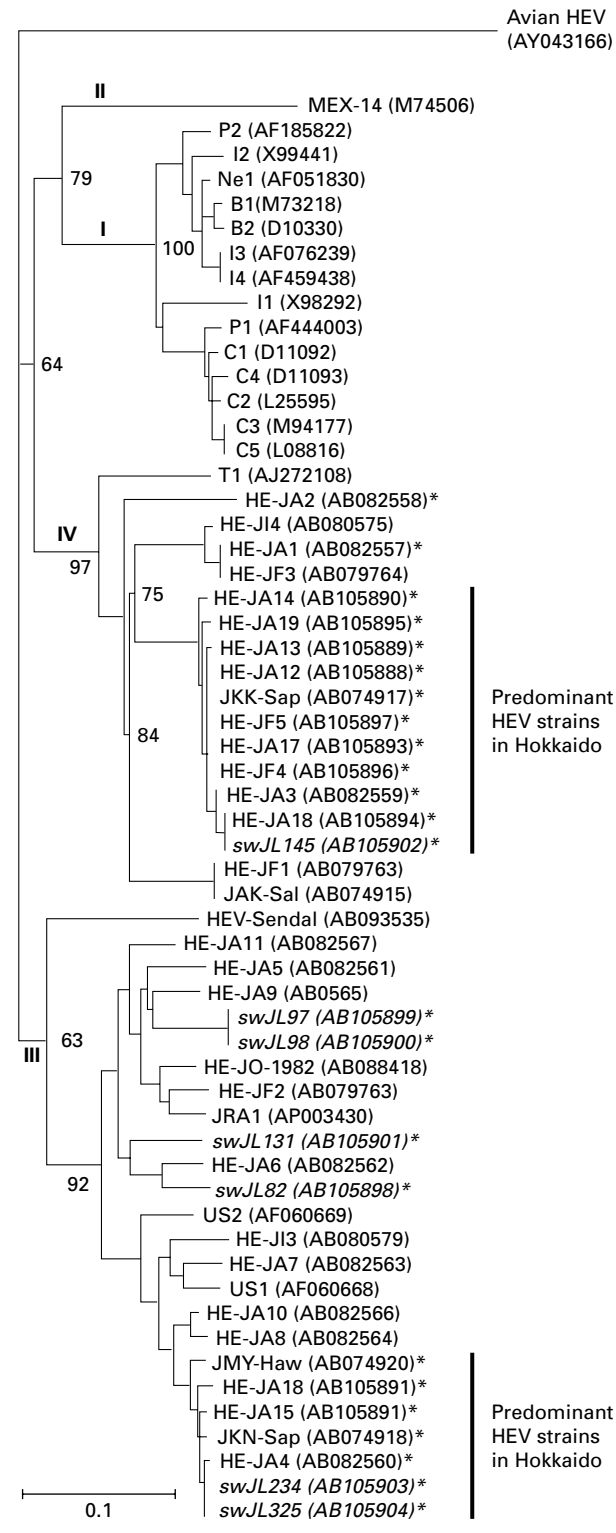

**Figure 40.4** Genotype 3 and 4 swine HEV strains are very closely related to, or in a few cases indistinguishable from, genotype 3 and 4 human HEV strains in Japan, and hepatitis E may be food-borne via consumption of undercooked pig livers in Japan.[28] The phylogenetic tree based on a 412-bp sequence of the ORF2 region of selected genotype 1–4 HEV strains (accession numbers in parentheses) was constructed by the neighbour-joining method with avian HEV from a chicken as an outgroup. The seven swine HEV isolates (swJL82, swJL97, swJL98, swJL131, swJL145, swJL234 and swJL325) identified from packaged pig livers sold in grocery stores in Hokkaido, Japan are shown in italics. Those isolates from Hokkaido, Japan are indicated with an asterisk. Bootstrap values obtained from 1000 resamplings are indicated at major branches. Reproduced with permission from the Society for General Microbiology from Yazaki *et al*.[28]

US blood donors were available, about 23% (swine HEV antigen) or 27% (Sar-55 antigen) of swine veterinarians were positive for anti-HEV compared with 17% (swine HEV antigen) or 18% (Sar-55 antigen) of normal blood donors. Swine veterinarians in the USA were 1.51 times (swine HEV antigen, $p = 0.03$) and 1.46 times (Sar-55 antigen, $p = 0.06$) more likely to be anti-HEV-positive than normal US blood donors. Veterinarians who reported having needle-stick injuries while performing procedures on pigs were about 1.9 times more likely to be seropositive than those who did not. Also, subjects from traditional major swine-rearing states appear to be more likely to be seropositive than those from traditionally non-swine-rearing states. For example, subjects from Minnesota, a major swine-rearing state, are about five to six times more likely to be seropositive than those from Alabama, which is traditionally not a major swine-rearing state.[35] Drobeniuc *et al*.[34] also assessed the anti-HEV prevalence and risk factors to HEV infection in 264 swine farmers and 255 control subjects in Moldova. About 51% of swine farmers were anti-HEV-positive, whereas only 25% of control subjects with no occupational exposure to swine were seropositive. Swine farmers who reported cleaning barns or assisting at pig births were 2.46 times more likely to be seropositive than controls.[34] In a cross-sectional serosurvey, Withers *et al*.[59] found that swine workers (n = 165) in North Carolina had a 4.5-fold higher anti-HEV prevalence (10.9%) than the control subjects (2.4%, n = 127). These data provided compelling evidence that hepatitis E is a zoonotic disease, and that pigs are reservoirs.

The existence of a population of anti-HEV-positive individuals in industrialized countries could be explained by subclinical infection of humans with swine HEV.[35,45,67,89] However, city dwellers in the USA and many other industrialized countries, who have no significant exposure to pigs except possibly as food, are also found to be positive for anti-HEV.[45,66,68] Therefore, other animal species may also serve as reservoirs for HEV. Karetnyi *et al*.[58] tested anti-HEV prevalence in selected populations of Iowa including 87 field staff members of the Department of Natural Resources (DNR) and 332 normal blood donors. The DNR field workers showed significantly higher anti-HEV prevalence than normal blood donors ($p < 0.05$), suggesting that human populations with occupational exposure to wild animals have increased anti-HEV prevalence. Therefore, the risk for zoonotic HEV infection is not limited to swine handlers, as many domestic and farm animals were also found to be positive for HEV antibodies.

## Serological evidence for other potential animal reservoirs

In addition to swine, anti-HEV has been detected in several other animal species including rodents, chickens, dogs, cats, sheep, goats, cattle and non-human primates, suggesting that these animals have been exposed to HEV (or a related agent) and thus might serve as reservoirs.[36,43,44,46,47,49–52,59]

Rodents are frequently found in both urban and rural environments and thus could potentially play an important role in HEV transmission. Kabrane-Lazizi *et al*.[43] reported that about 77% of the rats from Maryland, 90% from Hawaii and 44% from Louisiana were positive for IgG anti-HEV. Rats from urban as well as rural areas are seropositive. The anti-HEV prevalence rate increases in parallel with the estimated age of the rats. All three different species of wild rats (*Rattus norvegicus*, *R. rattus* and *R. exulans)* are strongly positive for anti-HEV. Favorov *et al*.[44] tested a total of 806 rodents of 26 different species caught in the USA for anti-HEV prevalence, and the highest prevalence rate was found in the genus *Rattus* (59.7%). Rodents from urban habitats had a significantly higher anti-HEV prevalence rate than rodents captured from rural areas.[44] In Japan, about 32% of Norway rats (*R. norvegicus*) and 13% of black rats (*R. rattus*) tested positive for IgG anti-HEV.[51] In contrast, none of the 32 *R. norvegicus* rats from India were anti-HEV-positive, whereas about 55% of *Bandicota bengalensis* rats and 16% of *R. rattus rufescens* rats from India were positive for IgG anti-HEV.[46] In Nepal, about 13% of *R. rattus brunneusculus* rats and about 21% of *B. bengalensis* rats were positive for anti-HEV.[52] Interestingly, anti-HEV was not detected in mice in several studies.[46,51,52,59] The results from these studies suggest that there is a widespread infection of rats by HEV (or a related agent) in different countries. He *et al*.[52] recently reported the detection of HEV sequences from rats caught in Nepal. The authors reportedly amplified a 405-bp HEV sequence from the serum samples of four rats, and showed that the HEV sequences from rats are most closely related to two Nepalese human HEV isolates with 95–96% nucleotide sequence identity. However, GenBank database Blast search revealed that the HEV sequence from the four Nepalese rats actually had 100% sequence identity to that of a Pakistani strain of human HEV (Abb-2B) isolated from a 1988 outbreak in Abbottabad, Pakistan by the same group.[90] Unfortunately, the authors failed to report or discuss this intriguing fact in the publication.[52] Therefore, it remains to be determined whether or not the HEV sequence amplified from the rats in the study is indeed of rat origin. Other groups could not amplify HEV sequences from infected rats with degenerate primers based on known HEV strains,[68] suggesting that the virus infecting rats is probably very divergent genetically from the known HEV strains.

Anti-HEV was also reportedly detected in 44% of chickens and 27% of dogs in Vietnam.[36] About 29–62% of cows from three HEV endemic countries (Somali,

Tajikistan and Turkmenistan), about 12% of cows from Ukraine, and about 42–67% of the sheep and goats from Turkmenistan have also tested positive for anti-HEV.[36] Arankalle *et al*.[46] reported that about 4–7% of cattle and 23% of dogs in India had antibodies to HEV. A variety of non-human primate species were also found positive for IgG anti-HEV.[38,40,49] However, the source of seropositivity in many of these animal species, with the exception of pigs and chickens, could not be definitively identified, as virus was either not recovered from these species or the recovered virus was not sequenced to confirm its identity. The specificity and sensitivity of these anti-HEV serological assays are also not known, although some anti-HEV assays are validated with serial serum samples from animals experimentally infected with different HEV strains.[45,91] Therefore, the interpretation of these serological data should be cautious. Nevertheless, the existence of a population of animal species positive for anti-HEV further supports the argument that animal reservoirs for HEV exist.

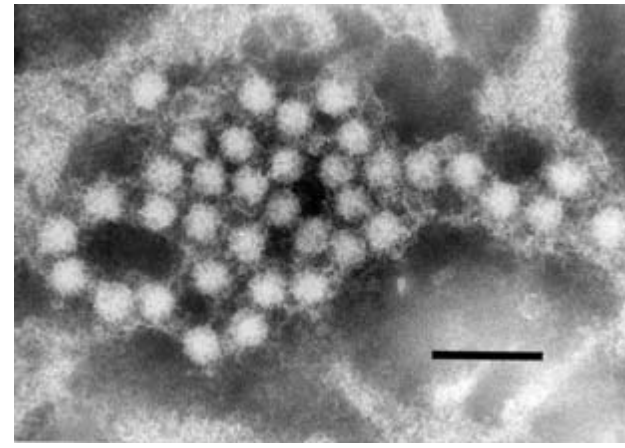

**Figure 40.5** Electron micrograph of avian hepatitis E virus (avian HEV) particles from a bile sample of a chicken with hepatitis-splenomegaly syndrome. Negative staining, bar = 100 nm. Reproduced with permission from the Society for General Microbiology from Haqshenas *et al*.[53]

## Discovery of avian HEV in chickens that is antigenically and genetically related to human HEV

Payne *et al*.[56] first reported the identification of a virus associated with big liver and spleen disease (BLS) of chickens in Australia, and determined the sequence of a 523-bp fragment of the BLS virus (BLSV). The BLS disease affects commercial broiler breeder flocks and causes decreased egg production and slight increase in mortality in broiler breeder flocks in Australia.[92] Analyses of this 523-bp sequence indicated that BLSV is genetically related to human HEV with about 62% nucleotide sequence identity.[56]

Haqshenas *et al*.[53] isolated a virus genetically related to human HEV from bile samples of chickens with hepatitis-splenomegaly (HS) syndrome in the USA. HS syndrome is an emerging disease in chickens in North America, but the cause was unknown. Based upon the similar genomic organization and significant sequence identity of this novel chicken virus with HEV, it is designated as avian HEV to distinguish it from human and swine HEV. Electron microscopic examination revealed that avian HEV, a non-enveloped virus particle of 30–35 nm in diameter, is morphologically similar to human HEV (Fig. 40.5).[53] The complete genomic sequence of avian HEV is about 6.6 kb in length, which is about 600 bp shorter than the genomes of human and swine HEV.[93] Like human and swine HEV, the avian HEV genome consists of a 5′ NCR, followed by three ORFs and a 3′ NCR. The nucleotide sequence identity in the entire genome between avian HEV and other HEV strains is only about 50%.[48,93] The helicase gene is the most conserved between avian HEV and other HEV strains, displaying 57–60% nucleotide sequence identities. The RdRp gene and the putative capsid gene (ORF 2) of avian HEV shares 52–53% and 48–51% nucleotide sequence identities with the corresponding regions of other known HEV strains, respectively. Avian HEV shares about 80% nucleotide sequence identity with the Australian BLSV, suggesting that BLS in Australia and HS syndrome in North America may be caused by variant strains of the same virus.[53,93] Among the four recognized genotypes of HEV, the inter-genotypic sequence difference is about 25–30%.[22,23,69,73] Therefore, avian HEV, with about 40–50% sequence difference with known HEV strains, is distinct. However, cross-antigenicity study revealed that avian HEV shares common antigenic epitopes in its putative capsid protein (ORF2) with swine and human HEVs as well as with BLSV and thus, avian HEV is not only genetically but antigenically related to human and swine HEV as well.[54] Phylogenetic analyses indicate that avian HEV may represent a fifth genotype of HEV or may belong to a separate genus.[48,93]

Like swine and human HEV, avian HEV isolates from chickens in different geographic regions are heterogeneic, and avian HEV infection is widespread in chicken flocks in the USA.[48] A total of 1276 chickens of different ages and breeds from 76 different flocks in five states (California, Colorado, Connecticut, Virginia and Wisconsin) were tested for the prevalence of avian HEV antibody using a recombinant avian HEV capsid protein as the antigen.[48] About 71% of chicken flocks and 30% of chickens were positive for antibodies to avian HEV. Like swine HEV, avian HEV antibody prevalence in chickens is also age-dependent: about 17% of chickens younger than 18 weeks were seropositive, whereas about 36% of adult chickens were seropositive. Avian HEV isolates re-

covered from chickens with HS syndrome in five states displayed 78–100% nucleotide sequence identities to each other, and 56–61% identities to known strains of human and swine HEV.

Cross-species infection by avian HEV has been demonstrated, as avian HEV recovered from a chicken with HS syndrome infected turkeys (Sun *et al*., unpublished data). However, an attempt to experimentally infect two rhesus monkeys with an infectious stock of avian HEV was unsuccessful.[93] Thus, it appears that, unlike swine HEV, avian HEV may not infect humans, but additional studies are warranted to further assess the potential zoonotic risk of avian HEV.

## Other potential zoonotic concerns

### Food and environmental safety

As a faecal-orally transmitted disease, waterborne epidemics are the characteristic of hepatitis E outbreaks.[66,82,83,85] The existence of a number of potential animal reservoirs for HEV raised concerns for food and environmental safety. Faeces from infected pigs are found to contain large amounts of virus[61,62,70] and thus, in areas where swine are raised, swine manure and faeces could be a source of contamination of irrigation water or coastal waters with concomitant contamination of produce or shellfish.[94] Swine HEV has been detected in swine manure and waste water associated with hog operations.[95,96] In addition, strains of HEV of both human and swine origins have been detected in sewage water.[4,15,27,97,98] Consumption of contaminated shellfish has been implicated in sporadic cases of acute hepatitis E.[99,100]

There is a potential risk of transmitting swine HEV via either drinking faeces-contaminated water or consuming contaminated food such as pork products. Yazaki *et al*.[28] recently reported that sporadic cases of acute hepatitis E in Hokkaido, Japan may be foodborne with a zoonotic origin. Nine of the 10 patients with sporadic acute hepatitis E in Hokkaido had a history of consuming grilled or undercooked pig livers at about 2–8 weeks prior to the onset of disease. About 2% of the packaged raw pig livers sold in local grocery stores were positive for swine HEV RNA,[28] although it is not known if the virus in the packaged pig livers is still infectious. Most importantly, the sequences of seven swine HEV isolates recovered from packaged pig livers in grocery stores are very closely related, or identical in a few cases, to the viruses recovered from human hepatitis E patients (Fig. 40.4). For example, swine HEV isolate swJL145 detected from a packaged pig liver had 100% sequence identity to the virus recovered from an 86-year-old hepatitis E patient in Hokkaido. Retrospective interviews were subsequently conducted for 22 randomly selected acute hepatitis patients of non-E aetiology in the same hospital. None reported having consumed pig livers before disease onset,[28] suggesting that consumption of undercooked pig livers is a potential risk factor for HEV infection ($p < 0.01$).

More recently, Tei *et al*.[57] reported a cluster of four cases of human hepatitis E in two families who shared and consumed raw deer meat 6–7 weeks before the onset of disease. An HEV sequence was detected from the leftover frozen deer meat, and found to have 99.7–100% nucleotide sequence identity to the viruses recovered from the four patients. Family members who ate none or little deer meat were not infected. Although these findings appear to provide direct evidence of zoonotic transmission of HEV, additional studies are warranted to more definitively assess the zoonotic risk of HEV in deer and other animal species. It is important to isolate and fully characterize HEV strains from naturally infected deer, and to determine the anti-HEV prevalence in deer populations.

### Xenozoonotic risk

Due to the shortage of human organ donors, xenotransplantation with pig organs is currently under intensive research and pigs may become the organ donors of choice.[67] Swine HEV is ubiquitous in pigs and has the ability to infect across species barriers. Therefore, xenozoonosis due to the transmission of swine HEV from pig xenografts to human recipients and the potential subsequent transmission of the virus to others are possible.[67] Although swine HEV appeared to cause only subclinical infection in pigs and non-human primates under experimental conditions, it may become pathogenic in immunosuppressed xenograft recipients, as a result of species-jumping or adaptation.[67] Unlike porcine endogenous retrovirus, xenograft donor pigs free of swine HEV can be generated through strict breeding procedures. Piglets negative for swine HEV have been successfully generated through segregated early weaning from pregnant SPF sows experimentally infected with swine HEV[101] (Brad Thacker, personal communication). Thus, the potential xenozoonotic risk of swine HEV in xenotransplantation is preventable through adequate screening and strict breeding procedures for donor pigs. Serological assays alone are inadequate in screening swine HEV infection in donor pigs, as anti-HEV generally appears at least 2 weeks after infection. Viraemia and faecal virus shedding occur in infected pigs earlier than anti-HEV and thus, seronegative pigs could still harbour swine HEV.[61,62,70] A sensitive RT-PCR assay should be used in combination with serological assays to screen xenograft donor pigs.

## Acknowledgements

I wish to thank Drs Robert H. Purcell and Suzanne U. Emerson in the Laboratory of Infectious Diseases at the National Institutes of Health, Bethesda, MD; Dr Patrick G. Halbur at Iowa State University, Ames, IA; Drs F. William Pierson and Thomas E. Thomas at Virginia-Maryland Regional College of Veterinary Medicine; and Drs H.L. Shivaprasad and Peter R. Woolcock at the University of California, Davis for their support and collaboration. The author's research on HEV is supported by grants from the National Institutes of Health (AI01653, AI46505, AI50611), the U.S. Department of Agriculture-National Research Initiatives Competitive Grants Program (NRI2002–35204–12531) and the National Pork Board (NPB01–004).

# Chapter 41
# Epidemiology, clinical and pathologic features, diagnosis, and experimental models

Kris Krawczynski, Rakesh Aggarwal, Saleem Kamili

Hepatitis E, previously known as enterically transmitted non-A, non-B hepatitis, was first recognized as a distinct clinical entity in the 1980s, when sera from persons affected during a large waterborne epidemic of acute hepatitis during 1955–1956 in Delhi, India and another epidemic in Kashmir, India tested negative for serological markers of acute hepatitis A and B.[1–3] The occurrence of the first recorded epidemic of hepatitis E as late as 1955 and the infrequency of this disease in developed countries suggest that hepatitis E is a new, emerging infectious disease. However, several epidemics of enterically transmitted hepatitis with epidemiologic features resembling those of hepatitis E outbreaks occurred in Europe and the United States in the 18th and 19th Centuries.[4,5] It is conceivable, therefore, that hepatitis E virus (HEV) infection may have been more widespread in the past and has only recently become restricted to certain geographic regions, mostly underdeveloped with poor environmental sanitation.

**Table 41.1** Epidemiologic features of hepatitis E

| |
|---|
| Large outbreaks in developing countries affecting several thousand persons |
| Sporadic hepatitis cases frequent in disease-endemic areas |
| Sporadic hepatitis cases uncommon in non-endemic areas (occur mainly among travellers to disease-endemic areas) |
| Faecal-oral transmission (usually through contaminated water) |
| Highest attack rate among young adults aged 15–40 years, with relative sparing of children |
| Insignificant person-to-person transmission |
| No evidence of parenteral or sexual transmission |
| Mother-to-newborn (transplacental) transmission probable |
| High mortality rate (15–25%) among pregnant women, especially those in third trimester |

## Epidemiology

### Hepatitis E in disease-endemic regions

Regions of the world can be considered as hepatitis E disease-endemic or non-endemic based on the periodic occurrence of disease outbreaks. Several large epidemics of hepatitis E, characterized by the epidemiologic features summarized in Table 41.1, have been observed in the Indian subcontinent, and in developing countries of south-east and central Asia.[1,2,6,7] Outbreaks of hepatitis E have been observed in the Middle East, and northern and western parts of Africa. In North America (Mexico), two small outbreaks were reported in the year 1986–1987 (Fig. 41.1).[8,9] The hepatitis E outbreaks in HEV-endemic regions are large,[1,2,6,7] frequently affecting several hundred to several thousand persons. Their time-course varies from single-peaked outbreaks lasting a few weeks to prolonged, multi-peaked epidemics lasting for over a year. The outbreaks recur with a periodicity of 5–10 years. The exact reason for this phenomenon remains unknown. The outbreaks frequently follow heavy rainfall and floods, but sometimes may occur in hot and dry summer months.

In areas where hepatitis E outbreaks occur, HEV infection accounts for a substantial proportion of acute sporadic hepatitis in both children and adults. In India, HEV infection accounts for 50–70% of all patients with sporadic viral hepatitis.[10,11] Demographic and clinical features of patients with sporadic hepatitis E (age distribution, severity and duration of illness, worse prognosis among pregnant women and absence of chronic sequelae) closely resemble those of epidemic hepatitis E.[12–14]

#### *Transmission, routes of spread and attack rates in disease-endemic regions*

The faecal-oral route is the predominant mode of transmission of epidemic HEV infection. Most reported outbreaks have been related to consumption of fae-

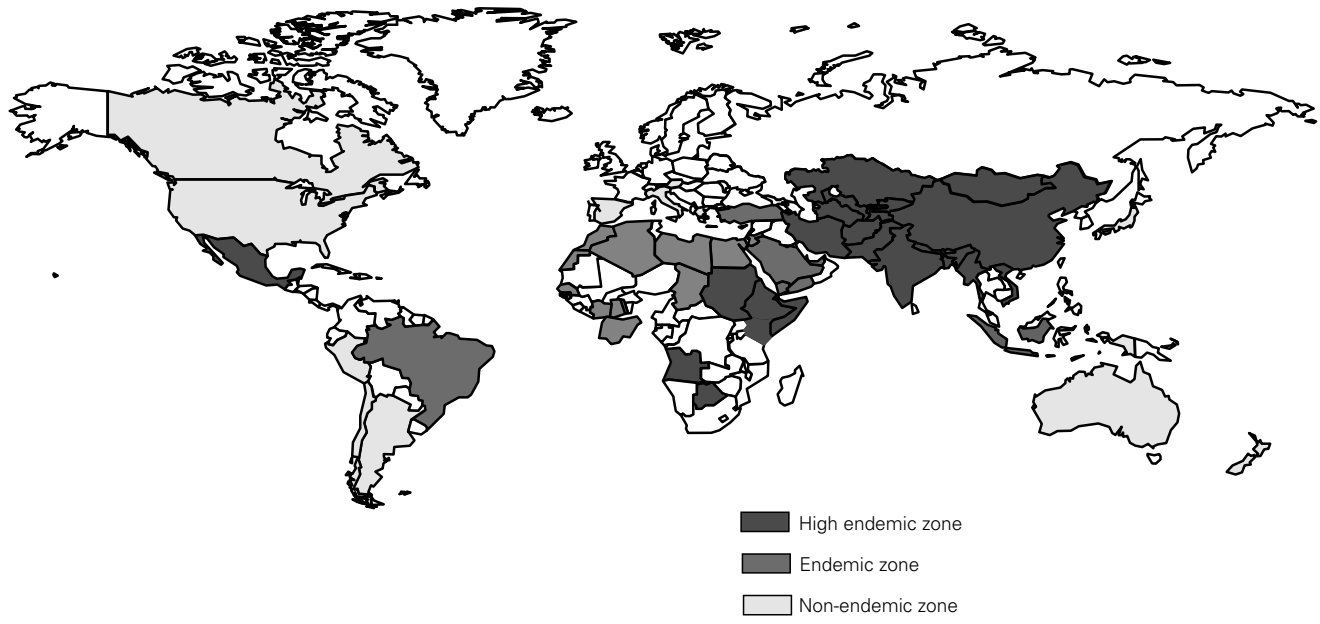

**Figure 41.1** Geographical distribution of hepatitis E.

cally contaminated drinking water.[1,2,6,15] The outbreaks frequently follow heavy rains and floods, when water sources become contaminated.[2,15] Some epidemics have occurred in hot summer months, when the diminution of water flow rate in rivers and streams may increase the concentration of contaminants, thereby increasing the risk of infection.[6,16] In some outbreaks, contamination of water occurred in leaky water pipes with intermittent water supply passing through areas contaminated with sewage, where a negative pressure in the pipes during periods of no flow leads to suction of contaminants. In south-east Asia, disposal of human excreta into rivers, and use of the same river water for drinking, cooking and personal hygiene has been shown to be associated with recurrent epidemics,[17] possibly through continuous existence of conditions that allow faecal contamination of water. In some small outbreaks of HEV infection in China that occurred after community feasts, food-borne transmission has been postulated.[7] However, these reports did not include any control data or results of serologic investigations.

During hepatitis E outbreaks, person-to-person transmission of HEV appears to be distinctly uncommon.[2,18] Such transmission is also uncommon from patients with sporadic HEV infection in disease-endemic regions.[19] The mode of transmission responsible for sporadic hepatitis E thus is unclear. Secondary attack rates among household contacts of patients with hepatitis E cases are only 0.7–2.2%[2,20] in contrast, 50–75% of susceptible household contacts of patients with hepatitis A become infected.[21] Even when multiple cases occur among members of a family, this is related to exposure to a common source of contaminated water rather than to person-to-person spread.[18] Presumed nosocomial spread of HEV has been reported in South Africa, where three health-care workers who treated a patient with fulminant hepatitis E developed acute hepatitis 6 weeks later.[22]

Vertical transmission of HEV infection from mother to infant has been reported. In one study, five of six babies born to mothers with either acute uncomplicated or fulminant hepatitis E in the third trimester of pregnancy had HEV RNA in their blood samples taken at birth, suggesting transplacental transmission of infection.[23] However, in an experimental study, HEV-infected pregnant rhesus monkeys failed to transmit the virus to their offspring.[24] Until recently, HEV was believed not to be transmitted through transfusion of blood or blood products because individuals with symptomatic HEV infection are unlikely to donate blood and HEV viraemia does not become chronic. Accordingly, anti-HEV antibody prevalence rates among patients with haemophilia and thalassaemia, who frequently receive transfusions, and among intravenous drug users are not higher than those in the general population.[25] However, a recent study has documented the presence of HEV viraemia among healthy blood donors and transmission of this infection to transfusion recipients in a disease-endemic region.[26]

During hepatitis E outbreaks, overall attack rates range from 1% to 15%, being much higher among adults (3–30%) than those among children below 14 years of age (0.2–10%).[1,6,15,27] In most reports, the male-to-female ratio among cases has varied from 1:1 to 4:1; it is unclear whether this reflects greater frequency of exposure among men or a true difference in susceptibility. The outbreaks are characterized by a particularly high attack

rate and mortality among pregnant women.[1,2,6,7] In an epidemic in Kashmir, India, attack rates among those in the first, second and third trimesters were 8.8%, 19.4% and 18.6%, respectively, as compared with 2.1% among non-pregnant women and 2.8% among men.[28]

## Hepatitis E in disease non-endemic regions

In non-endemic regions, where outbreaks have not been reported, the disease accounts for <1% of reported cases of acute viral hepatitis, and indigenous transmission of hepatitis E in these regions appears to be rather rare. A few isolated sporadic cases have been described from the USA, countries in Europe (including Austria, Spain, Italy, Greece and Turkey),[29–33] developed countries in Asia (Japan, Taiwan, Hong Kong),[34–36] South America (Argentina)[37] and Africa (Egypt, Senegal and Tunisia).[38,39] Most of the sporadic cases in non-endemic regions have been associated with travel to HEV-endemic regions,[40,41] although some cases, including two cases in the USA,[42–44] have been reported among persons with no history of travel to disease-endemic countries. Recent Japanese cases have been associated with consumption of inadequately cooked animal meat that contained HEV.[45]

## HEV molecular epidemiology and seroprevalence rates

Nucleotide sequences have been determined for HEV isolates from disease-endemic countries and from non-endemic regions. Four genotypes of HEV have been proposed: genotype 1 comprises south-east and central Asian isolates from Burma, Pakistan, India and China; genotype 2 comprises a single Mexican isolate; genotype 3 comprises US human and swine isolates; and genotype 4 comprises new Chinese isolates.[37,46–48] A variant strain of HEV has also been reported from tissue and faecal specimens of wild-trapped rodents from Nepal.[49] More recently, a novel virus related to HEV was identified in chickens with the hepatitis-hepatosplenomegaly syndrome in the United States. Genomic sequence analysis of the avian HEV in the helicase region reveals its partial identity (58–60% in amino acid and nucleotide sequences) to other HEV strains.[50] Comparison of nucleotide sequences in HEV isolates derived from patients affected during an outbreak in the disease-endemic region showed a high degree of identity.[51] Clinical and epidemiological differences have been observed between HEV strains within the same genotype.[52] It has been suggested that different strains may co-exist in a single population, some causing epidemic disease and others sporadic disease.[52]

Anti-HEV IgG antibody has been found in healthy subjects living in all geographical areas, although its prevalence differs significantly in various countries. In disease-endemic areas of Asia and Africa, the prevalence of antibody to HEV in documented endemic regions has been much lower than expected (3–26%), and the prevalence of such antibody in non-endemic regions has been much higher than anticipated (1–5%). In most disease-endemic areas, anti-HEV has been detected in up to 5% of children younger than 10 years of age. This proportion increases to 10–40% among adults older than 25 years of age.[53,54] However, in a report from India, anti-HEV antibodies were detected in >60% of children below the age of 5 years.[55] The differences between different disease-endemic areas may be related to varying epidemiological conditions in different geographic areas, differences in diagnostic techniques used, or both.

In developed countries of Europe and North America, 1–5% of the population has anti-HEV.[56,57] This range appears to be relatively high compared with the low rate of clinically evident hepatitis E disease in these areas. Several assays were applied to both acute hepatitis E and population studies for detection of IgG anti-HEV. In a direct comparison using a panel of coded sera,[58] sensitivity rates of these assays were found to vary widely from 17% to 100%, and concordance rates among reactive sera ranged from none to 89% (median 32%). In another study, in which two different serologic tests for anti-HEV were used, it was found that concordance between the two tests was only 27%.[59] It remains unclear whether the anti-HEV seroreactivity in non-endemic areas reflects subclinical and/or anicteric HEV infection, serologic cross-reactivity with other agents, false-positivity of serologic tests, transmission of infection by contact with various animal reservoirs (swine, rodents), or a combination of all these factors.

## Reservoirs of HEV

In disease-endemic areas, the source of HEV for maintaining the disease in a population has not been completely determined, and the existence of many reservoirs has been postulated. Based on data from a small group of patients, it has been suggested that protracted viraemia and prolonged faecal shedding of HEV may have a role in the continuous contamination of sewage.[60] However, recent data generated from studies on a larger number of patients showed that the period of viral shedding in the faeces is much shorter.[61] Subclinical HEV infections that maintain the presence of the virus in a population during inter-epidemic periods may be a potential reservoir of HEV in disease-endemic regions. In the experimental model of HEV infection in cynomolgus macaques, which faithfully reproduces HEV infection in humans, animals with HEV infection but without biochemical evidence of liver injury excreted large amounts of HEV infectious to HEV-naïve animals.[62] Shedding of large quantities of viable virus

during subclinical infection in humans may, therefore, represent a potential reservoir of HEV during inter-epidemic periods. Existence of a reservoir of HEV in the form of subclinical infection in a population could be similar to the continuous presence of polio virus in areas where that infection used to be endemic.[63] HEV shed by individuals with subclinical infection may contaminate drinking water supplies during periods of flooding of river systems, leading to large outbreaks. However, more epidemiologic and laboratory data are needed to confirm the existence of continuous subclinical circulation of HEV in disease-endemic areas.

A zoonotic reservoir of HEV has also been suggested, based primarily on anti-HEV reactivity of serum specimens obtained from various animal species and on fragmentary genomic sequence data. Anti-HEV antibodies have been detected in pigs in several endemic regions such as Nepal, China, India and Thailand, and in several non-endemic regions including the USA, Canada, Korea, Taiwan, Spain and Australia.[64–69] Anti-HEV has also been detected in chicken, cattle, sheep and rodents in several disease-endemic regions[64] and in 44–90% of rats in different parts of the USA.[70–72] The discovery of a swine HEV and the demonstration of a genetic relationship of animal HEV strains from the USA, Taiwan and Spain with human isolates from these respective geographical areas may support this hypothesis.[29,44,73] Nucleotide sequence homology between HEV RNA isolated from some Japanese hepatitis E patients and those from the undercooked animal meat that they had eaten may also support animal-to-human transmission.[45] Although the infrequent occurrence of clinically overt HEV infection in non-endemic areas with a high prevalence of anti-HEV among pigs and rats may depend on better sanitation, good water quality, and attention to personal hygiene, it is inconsistent with the hypothesis of universal zoonotic origin of hepatitis E. Moreover, Asian and Mexican strains of HEV associated with large outbreaks of hepatitis E have failed to induce infection in experimentally inoculated pigs.[42,74,75] More molecular data are needed before the zoonotic reservoir can be implicated as playing a major role in the epidemiology of hepatitis E, especially given that genomic sequences of HEV strains isolated from animals varied from those found in humans in a hepatitis E-endemic region in India.[76]

In summary, current epidemiologic data indicate that large outbreaks, sporadic hepatitis E cases and subclinical HEV infection in the disease-endemic regions originate from an environmental, human, or yet to be identified animal HEV reservoir. Poor general sanitation, contamination of drinking water supplies and lack of attention to personal hygiene are important factors contributing to the spread of infection in these areas.

## Clinical and pathological features

The incubation period of hepatitis E is variable and has ranged from 2 to 10 weeks during waterborne outbreaks with a short and well-defined period of water contamination.[2,77] Clinical manifestations of HEV infection are similar to those of acute infection with other hepatitis viruses and encompass a wide spectrum of symptoms (Table 41.2). Acute icteric hepatitis is the most common recognizable form of illness associated with HEV infection. This illness is usually insidious in onset and has an initial prodromal phase lasting about 1–4 days, with a variable combination of flu-like symptoms, fever, mild chills, abdominal pain, anorexia, nausea, aversion to smoking, vomiting, clay-coloured stools, dark or tea-coloured urine, diarrhoea, arthralgias, asthenia and a transient macular skin rash (Table 41.3).[1,7,8,78–81] These symptoms are followed in a few days by the appearance of jaundice. The onset of the icteric phase is frequently heralded by darkening of the urine and may be accompanied by lightening of stool colour or itching. Physical examination reveals jaundice and a mildly enlarged, soft and slightly tender liver. A soft splenomegaly is observed in nearly one-quarter of patients.[81]

Laboratory test abnormalities include bilirubinuria, variable degree of rise in serum bilirubin (predominantly conjugated), marked elevation in serum alanine aminotransferase (ALT), aspartate aminotransferase and gamma-glutamyl transferase activities, and a mild rise in serum alkaline phosphatase activity. An elevation of aminotransferase levels may precede the onset of symptoms by as long as 10 days and reaches a peak by the end of the first week. As the illness subsides, aminotransferase levels decrease significantly, followed by diminution in serum bilirubin level, and liver function test values usually return to normal by 6 weeks.[81] The magnitude of transaminase elevation does not correlate well with the severity of liver injury. Some patients show

**Table 41.2** Clinical features of hepatitis E

| |
|---|
| Incubation period 2–10 weeks |
| Variable clinical manifestations including: |
| icteric hepatitis |
| severe hepatitis leading to fulminant hepatic failure |
| anicteric hepatitis |
| inapparent, asymptomatic infection |
| Clinical illness similar to other viral hepatitis (except among pregnant women) |
| Milder illness in children |
| Low mortality rate (0.07–0.6%) |
| High attack rate in pregnant women, particularly those in second and third trimesters |
| High mortality (15–25%) among pregnant women |
| No relation with chronic hepatitis, cirrhosis or hepatocellular carcinoma |

**Table 41.3** Clinical findings in hepatitis E outbreaks

| Pruritus | 14 | 47 | 20 | 14 | 59 |

mild leukopenia and relative lymphocytosis. The illness is usually self-limiting and typically lasts 1–4 weeks.[80,81] Histopathological features of hepatitis E are similar to those of other forms of acute hepatitis, such as the presence of ballooned hepatocytes and acidophilic bodies, and focal and confluent hepatocyte necrosis with collapse and condensation of the underlying reticulum. Nearly half of hepatitis E patients have cholestatic hepatitis, which is characterized by canalicular bile stasis and gland-like transformation of parenchymal cells. In these patients, degenerative changes in hepatocytes are less marked and polymorphonuclear infiltration is prominent.[82] In both forms, lobules and enlarged portal tracts show inflammatory infiltration.

No evidence of chronic hepatitis or cirrhosis has been detected among patients followed up clinically and with liver biopsies after acute hepatitis E.[9,82,83] A few patients, however, have a prolonged course with marked cholestasis (cholestatic hepatitis), including persistent jaundice and prominent itching. In these cases, laboratory tests show elevations in alkaline phosphatase and bilirubin levels even after transaminase levels have returned to normal. The prognosis is good, as jaundice finally resolves spontaneously after 2–6 months.

HEV-infected individuals may develop non-specific symptoms, resembling those of an acute viral febrile illness without jaundice (anicteric hepatitis). In its most benign form, HEV infection is entirely inapparent and asymptomatic, and passes unnoticed. The exact frequencies of asymptomatic infection and of anicteric hepatitis are not known, although these probably far exceed that of icteric disease.

In a small proportion of patients, disease is more severe and is associated with subacute (or late-onset) or fulminant hepatic failure (FHF) that can be rapidly fatal. In patients with severe liver injury, a large proportion of hepatocytes are affected, leading to submassive or massive necrosis and collapse of liver parenchyma. In disease-endemic regions, hepatitis E is an important cause of FHF. HEV infection (alone or in combination with other hepatitis viruses) in India was responsible for 62% of adult patients and 40% of children with sporadic FHF.[14,84,85] It has also been suggested that serious forms of hepatitis such as FHF and subacute hepatic failure may result from a combined infection with hepatitis B virus (HBV) and HEV.[12,86] In a recent study, Hamid *et al*. showed that hepatitis E infection in patients with pre-existing liver cirrhosis may lead to worsening of their clinical state.[87]

The case-fatality rate in HEV infection has ranged from 0.5% to 4%.[20,88] However, these reports are based on hospital data and thus underestimate the total number of persons affected and may overestimate mortality. Population surveys during outbreaks report lower mortality rates varying from 0.07% to 0.6%.[6,81,88] In an epidemic in Ethiopia, none of the 423 soldiers with icteric hepatitis developed FHF or died.[79] Pregnant women, particularly those in the second and third trimesters, are more frequently affected during hepatitis E outbreaks and have a worse outcome. Mortality rates among pregnant women, especially those infected in the third trimester, have ranged between 5% and 25%.[15,20,27,28] FHF developed in 22.2% of the affected pregnant women, in comparison with 2.8% and 0% of affected men and non-pregnant women, respectively.[28] Frequency of abortions, stillbirths and neonatal deaths is also increased among pregnant women with HEV infection.[27] The reason for particularly severe liver damage in pregnant women with hepatitis E remains unknown.

## Diagnosis

### Detection of antibodies to HEV

Historically, the fluorescent antibody blocking assay (FA) was one of the earliest tests used for identification of antibodies that react with HEV antigen (HEVAg) identified in hepatocytes of experimentally infected macaques.[89] Although the FA assay enabled the serologic identification of HEV infection in various geographic regions of the world,[89] it does not distinguish between recent and past infections, and requires liver

tissue substrate that contains HEVAg from HEV-infected primates.

Enzyme immunoassays (EIAs) for the detection of IgM and IgG antibodies to HEV have been developed in several laboratories using recombinant HEV antigens expressed in *Escherichia coli* or insect cells, and synthetic peptides corresponding to immunogenic epitopes of HEV.[56,90–94] A synthetic gene encoding multiple linear immunodominant antigenic epitopes from ORF2 and ORF3 regions has been synthesized, expressed as a protein and used in a solid-phase EIA.[95] Recently, a capture EIA format was shown to be more sensitive in detecting IgM, especially in the presence of high concentrations of IgG antibodies.[96] Although commercial kits for the detection of IgM and IgG anti-HEV are available from vendors in various countries, there is no commercial test for the detection of anti-HEV currently licensed for clinical use in the United States. The commercial kits and many 'in-house' EIAs use epitopes from two geographically distinct HEV strains representing diverse antigenic domains as target antigens.[58] Antigenic domains that contain strong IgG and IgM antigenic epitopes have been identified at the amino- and carboxyl-terminus of the ORF2 encoded protein[97] and have been shown to be more sensitive than ORF3-derived antigens, when used for detection of IgM and/or IgG anti-HEV.[98] A highly conserved conformational epitope mapped to 267 amino acids at the carboxyl-terminus of HEV ORF2 protein has been used in a sensitive and specific EIA format for the detection and quantification of both acute and convalescent phase HEV-specific IgG.[99]

In clinical studies, determination of IgM anti-HEV is important for diagnosis of acute HEV infection, whereas the detection of IgG anti-HEV may be indicative of convalescent phase or past infection. During acute HEV infection, IgM anti-HEV appears in the early phase of clinical illness, preceding the IgG anti-HEV by a few days, and disappears over a 4–5-month period.[100] In one study, 100%, 50% and 40% of sera collected from patients during various hepatitis E outbreaks 1–40 days, 3–4 months and 6–12 months after the onset of jaundice, respectively, tested positive for IgM anti-HEV.[91] In outbreak settings, IgM anti-HEV has been detected in >90% of patient serum samples obtained within 1 week to 2 months after the onset of illness.[100] The IgG response appears shortly after the IgM response, and its titre increases throughout the acute phase into the convalescent phase, and remains high from 1 to 4.5 years after the acute phase of illness.[56,100] In one study, anti-HEV was detected in 47% of persons 14 years after acute HEV infection,[101] but the exact duration of persistence of anti-HEV is not known.

As EIAs are the most convenient, inexpensive and suitable assays for routine diagnosis of HEV infection as well as for sero-epidemiologic surveys, their sensitivity and specificity need to be improved. Currently used diagnostic assays for detection of anti-HEV have a wide range of sensitivity between 17% and 100%, when applied to specimens from non-endemic areas.[58] Further studies on standardization of diagnostic anti-HEV tests may benefit from the availability of a reference reagent for human anti-HEV serum developed by the Expert Committee on Biological Standardization of the World Health Organization.[102]

## Detection of HEV-like particles and HEV RNA

The identification of HEV in faeces, bile, blood and liver has been accomplished by the use of immune electron microscopy (IEM) with immunoglobulin preparations obtained from hepatitis E patients during early convalescence.[103] Serologic cross-reactivity was observed between virus-like particles (VLPs) from epidemics of hepatitis E in Mexico, the former Soviet Union, Burma, Nepal, Pakistan, Sudan and Somalia, suggesting the existence of a single viral serotype associated with these epidemics.[103,104] For routine diagnostic use, IEM is not practical because visualization and identification of the virus is limited to samples with an abundance of VLPs.

A more efficient and a highly sensitive method for detection of HEV is the polymerase chain reaction (PCR). Several reverse transcriptase PCR (RT-PCR) assays have been developed for detecting genomic sequences of HEV in clinical and environmental samples.[29,105–109] HEV RNA sequences have been identified in stool and serum samples from patients and experimentally infected primates during the acute phase of hepatitis E.[61,110] Although various regions of sequence variation and conservation have been identified in the HEV genome, there is no preferred region selected for amplification. Primers based on either the RNA-dependent RNA polymerase region in ORF1 or the ORF2 gene are most often used for amplification of HEV genomic fragments.

HEV RNA can be detected in faeces of most patients with acute hepatitis E by RT-PCR during the initial few weeks.[61,111] In some patients, persistence of positive RT-PCR results for as long as 52 days has been reported.[60] HEV RNA has regularly been found in serum by RT-PCR in virtually all patients in the first 2 weeks after the onset of illness.[111] Prolonged periods of HEV RNA positivity in serum ranging from 4 to 16 weeks have also been reported.[60,112] However, a recent, more extensive study did not find any evidence of prolonged viral excretion or viraemia,[61] and no studies reported the presence of HEV in body fluids other than serum. Generally, RT-PCR for HEV RNA is less suitable than serologic identification of IgM anti-HEV for routine diagnosis of HEV infection because HEV RNA may be degraded during faecal shedding of the virus, and the short viraemic phase usually occurs before the disease is clinically apparent.

## Experimental HEV infection

Experimental HEV infection in humans[112,113] and primates[89,114–117] provided the most informative data on the pathogenetic events of the infection resulting from intragastric or intravenous administration of the virus. In 1983, a human volunteer ingested acute phase stool suspension from a water-borne epidemic of non-A hepatitis in central Asia, and provided detailed clinical and biochemical data on the course of infection.[113] This experimental infection led to the identification of VLPs in stool specimens by immune electron microscopy with the use of anti-HEV antibodies obtained from the same individual during convalescence. The discovery of HEV allowed definition of the aetiological agent of the acute viral hepatitis transmitted by the faecal-oral route (hepatitis E). In 1993, another human volunteer provided a set of clinical, virological and serological data that further characterized hepatitis E.[112] The incubation period of the disease in the human volunteers ranged from 4 to 5 weeks, HEV VLPs were found in stools 4–5 weeks after exposure, and elevated enzyme activity reached the highest levels at 6–7 weeks after exposure. HEV RNA in serum was first detected on day 22 post-exposure, a week before onset of disease on day 30, and anti-HEV antibody was detected 7 weeks post-infection. HEV infection in both volunteers resolved clinically with a return of liver enzyme activity to the normal range.

Experimental infection has successfully been attempted in non-human primates, such as chimpanzees, macaques (cynomolgus, rhesus and pigtail monkeys) and African green monkeys among the Old World species, and marmosets (tamarins) and owl monkeys among the New World species.[118] The levels of virus excretion, liver enzyme elevations and histopathologic changes in liver varied significantly in these animals.[119] Experimental, direct intrahepatic inoculation of chimpanzees and rhesus monkeys with RNA transcripts from full-length functional clones of HEV cDNA induced virological, pathological and serological characteristics typical of hepatitis E, and established a direct aetiological link between the genetic material of HEV and the disease.[120]

In intravenously inoculated cynomolgus macaques, the average incubation period for acute hepatitis E measured by a significant increase of ALT activity values is about 21 days. HEVAg was detected in hepatocytes on about day 7 post-infection and was found in 70–90% of hepatocytes at the peak of viral replication (K. Krawczynski, unpublished data) that occurred before or concurrently with the onset of ALT elevation and histopathological changes in the liver.[115,116] Both IgM and IgG anti-HEV have been detected in serum in assays using immunoreactive epitopes of ORF2 and ORF3. The IgM antibody level decreases rather precipitously, reaching negligible levels in the early convalescent phase followed by high titres of IgG anti-HEV detected during convalescence. The antibodies have been observed as long as 10 years after onset of acute hepatitis E in chimpanzees experimentally infected with serum specimens derived from Tashkent, Pakistan and Mexico.[121]

The variety of patterns of experimental infection in cynomolgus monkeys and chimpanzees resembles clinically overt or subclinical HEV infection in humans. In experimentally infected chimpanzees, the course of infection and disease measured by virus replication, antiviral humoral immune response and ALT activity was significantly different among individual animals.[110] These differences in virological, immunological and pathological sequelae of infection may be explained by either individual host susceptibility to HEV infection or the size of the dose of infectious HEV. Inoculum titration experiments in cynomolgus macaques have shown that animals infected with decreasing infectious doses had less marked clinical and pathological evidence of liver disease. Inoculation of the end-point dilution of an infectious inoculum (Mexico strain) was marked by seroconversion to anti-HEV only. No evidence of the virus shedding in stools, HEVAg in the liver or liver pathology was found. These observations indicated that the clinical presentation of hepatitis E in a primate model depends on the size of the infectious dose, and the severity of infection seems to be directly related to the infectivity titre of the challenge inoculum.[62] The subclinical infection caused by the smaller infectious dose was associated with faecal viral excretion similar in magnitude to that observed in the clinical form of the disease. The virus shed during subclinical infection was viable and capable of transmitting HEV infection to naïve cynomolgus macaques.[62]

In summary, several elements of pathogenesis of HEV infection can be outlined based on data from human volunteers and patients, and those from experimentally infected animals (Fig. 41.2). The virus enters the host primarily through the oral route, but there have not been enough clinical and experimental data collected to document that HEV reaches the liver from the gastrointestinal tract through portal circulation. In experimentally infected primates, HEV RNA appears in serum, bile and faeces a few days before the onset of ALT rise.[110,114,116,122,123] HEVAg in hepatocytes has been detected simultaneously with HEV identified in bile and faeces during the second or third week after inoculation, before or concurrently with the onset of ALT elevation and morphological changes in the liver.[89] These findings suggest that HEV may be released from hepatocytes into bile during the initial, highly replicative phase of infection, before the occurrence of the most prominent histopathological changes in the liver. The onset of ALT elevation and the occurrence of pathological changes in the liver generally correspond to the detection of anti-HEV in serum and

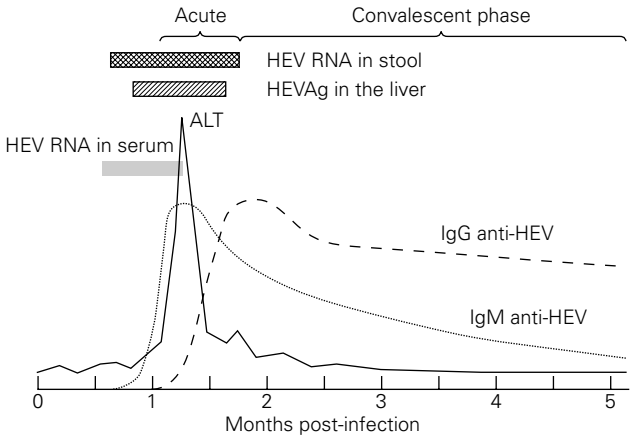

**Figure 41.2** Pathogenetic events in hepatitis E virus infection.

with decreasing levels of HEV antigen in hepatocytes. Lymphocytes infiltrating liver in experimentally infected monkeys have a cytotoxic/suppression immunophenotype.[124] Preliminary results of cellular immunity studies in hepatitis E patients indicate that lymphoproliferative responses to HEV peptides from ORF2 and ORF3 regions occur in patients with acute hepatitis E.[125] Concordance of pathological, virological and serological findings in hepatitis E suggests that the pathomechanism of the disease may be immune-mediated rather than related to cytopathic effect of HEV.

# Chapter 42
# Prevention

Robert H Purcell, Suzanne U Emerson

## Introduction

Hepatitis E virus (HEV) is a small hepatatropic virus that is enterically transmitted and causes an acute, self-limiting hepatitis[1] (Chapter 39). Infection with HEV may be asymptomatic or may cause hepatitis ranging from mild to fulminant. Fulminant hepatitis E is most common in pregnant women. Hepatitis E is the most common form of sporadic and epidemic acute hepatitis in adults throughout most of Asia. At present, there are no effective means of prevention other than interdiction of transmission.

## Epidemiology

### History

Until the 1970s, all water-borne epidemics of hepatitis in Asia were thought to be caused by hepatitis A virus (HAV). However, with the development of sensitive assays for antibody to HAV, it became apparent that virtually everyone in developing countries was exposed to HAV by age 5 years.[2] Most of these infections went unrecognized, but they provided lifelong immunity against hepatitis A. Thus, the epidemics of viral hepatitis must have been caused by a previously unrecognized agent.[3,4] In 1983, Balayan *et al*. first visualized the virus, demonstrated by immune electron microscopy the development of antibody to it during convalescence and transmitted the agent to cynomolgus monkeys.[5] In 1990, Reyes *et al*. cloned and sequenced genomic RNA from the virus and it was subsequently named hepatitis E virus.[6–8]

In retrospect, epidemics of hepatitis E were probably misdiagnosed long before the 1970s. Outbreaks of hepatitis occurring in previous centuries and the early 20th Century were known variously as 'campaign jaundice' and 'infective hepatitis'.[9] Before the discovery of hepatitis E, these historical outbreaks of hepatitis were thought to have been caused by HAV. However, the epidemiological descriptions of such diseases resemble those of hepatitis E, not hepatitis A.[10]

### Geographic distribution and genetic variation

Clinical hepatitis E is found principally in developing countries with tropical and subtropical climates. The disease is largely limited to those regions with substandard water and sewage systems, in keeping with the faecal-oral transmission of this virus. In regions of high endemicity, transmission via blood transfusion is a rare but possible occurrence because of the transient viraemia associated with infection.[11,12]

Hepatitis E is clinically important primarily in developing countries of south-east and central Asia, the Middle East and North Africa.[13] Epidemic hepatitis E has also been reported in Mexico.[14] Individual cases of hepatitis E have been reported occasionally in industrialized countries, including the United States and several European countries.[15,16] Strains of HEV recovered from within one geographic region generally are genetically similar and characteristic of that region, and differ from strains indigenous to other regions. However, the overall heterogeneity of HEV strains is not great, and all strains recovered to date appear to belong to the same serotype. On the basis of analyses of completely or partially sequenced strains, HEV can be classified into four major genotypes: a heterogeneous group of Asian and African strains (genotype 1), strains recovered from Mexico and Nigeria (genotype 2), strains recovered from cases in North America (United States), South America (Argentina), several European countries (Italy, Greece, Spain, Austria, the Netherlands) and Asia (Japan) (genotype 3), and strains isolated from cases in China, Taiwan and Japan (genotype 4).[1]

### Host range and animal models

Chimpanzees, Old World monkeys (rhesus, cynomolgus, pigtail macaques, African green monkeys) and New World monkeys (owl monkeys, squirrel monkeys, tamarins) have been reported to be susceptible to experimental infection with HEV.[17] Extensive studies in primates have confirmed the utility of these animals, especially chimpanzees, rhesus monkeys and cynomol-

gus monkeys, for experimental transmission of human strains of HEV. In addition, wild rhesus monkeys in India, wild cynomolgus monkeys from Asia and captive rhesus monkeys within North American breeding colonies have been demonstrated to acquire antibody to HEV in a pattern strongly suggestive of endemic infection. However, a virus has not yet been recovered from these animals, and it is not clear whether rhesus monkeys are infected with a unique simian HEV or whether human strains of HEV are circulating in monkey populations. As in humans, hepatitis E in non-human primates is acute and self-limiting. Unlike experimental hepatitis caused by the other human hepatitis viruses, experimental hepatitis E is dose-dependent. High doses of virus are associated with histological and biochemical evidence of hepatitis, but lower doses of virus are more likely to be associated with normal liver histology and normal serum liver enzyme values.[18–20] It is not known whether this is true for hepatitis E in humans, but epidemiological patterns suggest that it is. The immune response to HEV infection in non-human primates is similar to that in humans. Chimpanzees, rhesus monkeys and cynomolgus monkeys have been very useful for evaluating approaches to passive and active immunoprophylaxis against hepatitis E.

Although there were early reports of transmission of HEV to swine, sheep and rats, it was molecular and serological studies that provided enough information for these studies to be evaluated, confirmed and extended.[21–24] In 1997 Meng *et al*. recovered a unique HEV strain from domestic swine in the United States.[25] The virus was the first documented genotype 3 isolate, and it was subsequently shown that two human isolates in the United States were closely related to the swine isolate.[15] Genotype 3 strains of HEV have been recovered from swine throughout the United States, Canada and Mexico, and in Europe, New Zealand and Japan. Genotype 4 strains of HEV have been recovered from swine in Taiwan, Japan and India. These are closely related to genotype 4 isolates from humans. Attempts to confirm early reports of transmission of HEV from humans to swine could not be confirmed with genotype 1 and genotype 2 isolates.[26] However, human genotype 3 isolates have been transmitted to swine.[27] A retrospective analysis of the original report of transmission of a human HEV isolate to swine has revealed that the human virus was genotype 1 but the virus recovered from the swine was genotype 3, indicating that the inoculated piglets were probably undergoing an inter-current infection with swine HEV at the time of the experiment.[28] This is consistent with observations that most swine are infected within the first few months of life.[25] In addition, genotype 3 and possibly genotype 4 HEV strains recovered from swine have been experimentally transmitted to rhesus monkeys, a surrogate of man (V. Arankalle, personal communication).[27] This suggests that genotypes 3 and 4, at least, are spread zoonotically to man, and this was confirmed recently in reports of the transmission to humans of genotypes 3 and 4 HEV by ingestion of raw boar liver or undercooked commercial pig liver, and of a family outbreak of hepatitis E following the ingestion of raw Sika deer venison in Japan.[29–31] In the latter study, HEV genomic sequences were recovered both from patients and from frozen stored venison and the sequences were identical.

As with swine, attempts to confirm earlier reports of the transmission of human strains of HEV to rats were not successful: strains of genotypes 1, 2 and 3 of known infectivity titre could not be transmitted to laboratory rats (S.U. Emerson, unpublished data).[32] However, a very high proportion of sera from urban rats as well as indigenous species of rats in the United States were positive for anti-HEV, and this was confirmed in Indian rats and other related species.[32–34] A transmissible agent was recovered from two of over eighty sera collected from urban rats in the United States.[35] The agents were difficult to transmit, replicated to relatively low titre ($10^3$–$10^5$ rat infectious doses) and were avirulent, but infected rats regularly developed anti-HEV that could be detected with an ELISA that utilized antigen from a human genotype 1 HEV strain. Genomic RNA from the rat HEV strains could not be amplified by reverse transcription-polymerase chain reaction (RT-PCR) with primers that could amplify low titres of genotypes 1–4, suggesting that the rat virus was genetically different from the human and swine strains of HEV. The rat virus could not be transmitted to rhesus monkeys, suggesting that it is not zoonotically spread to humans (Purcell RH, unpublished data).

Antibody to HEV has been found in the sera of a number of other species of animals, including sheep and cattle. Nothing is known about the viruses that infect these and other species but, because sheep and cattle are such an important source of food worldwide, zoonotic spread via beef and lamb could be important.

Recently, HEV strains were found to be the cause of a disease of chickens called 'big liver and spleen disease' in Australia and 'hepatitis-splenomegaly syndrome' in the United States.[36,37] Although serologically related to human and swine strains of HEV, the avian HEV strains were genetically quite different from the mammalian strains. Avian HEV was not transmissible to rhesus monkeys and is therefore not likely to be a threat to humans.[38]

## Cell culture

Attempts to replicate HEV in cell culture have generally been unsuccessful or difficult to reproduce. Early reports of success utilized cells not readily available to others.[39]

More recently, Meng *et al*. reported limited replication of one HEV strain in PLC/PRF/5 cells, as measured by RT-PCR.[40] The cells were used for preliminary evaluation of neutralizing antibody to HEV. Recently, after the development of an infectious cDNA clone of HEV, several primate cell lines, including human hepatoma cell lines, were shown to support the replication of HEV following transfection of the cells with RNA transcripts of the cDNA clone.[41] However, the virus did not spread in the cells. More recently, HepG2 human hepatoma cells have been infected with wild-type HEV. However, the sensitivity of the cells for direct infection was low. Nevertheless, they have been used for studies of virus inactivation and neutralization (S.U. Emerson, unpublished data).

## Epidemiologic perspective

HEV is the single most important cause of acute clinical hepatitis in adults in south-east and central Asia and the second most important cause of such disease in the Middle East and North and West Africa[1] (see Chapter 41). The more spectacular form of the disease, epidemic hepatitis E, is actually a relatively uncommon occurrence, and by far the majority of the cases occur as an endemic or sporadic disease. Most of the cases reported in industrialized countries occur in travellers recently returned from an endemic area, but rare cases of hepatitis E that appear to have been contracted locally do occur in industrialized countries.[16,42]

Questions remain about the relative sensitivity and specificity of serological tests for anti-HEV.[43] However, with more sensitive tests, a picture of the worldwide distribution and seroprevalence of HEV infection is emerging. Surprisingly, the prevalence of antibody to HEV in documented endemic regions is much lower than expected when compared with the seroprevalence of another enterically transmitted hepatitis virus, HAV, and the prevalence of anti-HEV in non-endemic regions, assayed by the same ELISA, has been much higher than anticipated. In fact, it has been comparable to that of HAV in some studies,[44–46] although there have been exceptions to this rule.[47] The age-specific acquisition of anti-HEV is also quite different from that of anti-HAV. The seroprevalence of the former peaks in older children and young adults and plateaus thereafter, whereas anti-HAV peaks in younger children in developing countries. In industrialized countries, both antibodies increase in prevalence with age. This pattern of antibody acquisition has been shown to represent the 'cohort effect' (e.g. a high prevalence of infection in early times and a lower prevalence of infection in recent times) for hepatitis A, but the significance of the pattern is not known for hepatitis E, as the pattern is similar in developing and industrialized countries. Evidence that such antibody patterns accurately reflect the existence of HEV in industrialized countries comes from studies of viruses in sewage from such countries. Clemente-Casaresa *et al*. recovered HEV strains from sewage collected in Spain, France and the United States.[48] All of the HEV sequences recovered were genotype 3, the most common genotype in all three countries. The prevalence of HEV in sewage samples was surprisingly high, comparable to that of HEV in sewage samples collected in India, a country in which HEV is highly endemic.[49,50]

Differences in the epidemiology of hepatitis A and hepatitis E may be explained by the following: (1) HEV of genotypes 1 and 2 may grow to higher titre and/or may be more virulent than genotype 3 and 4 viruses. Indeed, genotype 3 viruses of swine and human origin cause little or no disease in experimentally infected swine, and the same appears to be true for experimentally infected rhesus monkeys.[27,51] However, neither virus grows to high titre and the relative attenuation may be the result of the second characteristic of HEV; (2) the clinical expression of HEV infection is dose-dependent and hepatitis is not regularly observed in experimentally infected animals until the challenge titre reaches or exceeds 10 000 infectious doses[20] (R.H. Purcell, unpublished data). This would suggest that both the strain of HEV and the level of contamination of water and food define the incidence of disease more than the incidence of infection, and disease might occur more readily in the immunologically or physiologically compromised individual in industrialized countries. In fact, that is what is seen: the mean age of cases of hepatitis E caused by genotype 1 or 2 in developing countries is in the mid-20s, whereas the mean age of hepatitis E cases caused by genotype 3 or 4 is almost 60 years of age in industrialized countries (R.H. Purcell, unpublished data).

## Populations at risk

Based on seroprevalence studies, it has been estimated that a third of the world's population has been infected with HEV. The case-to-infected ratio for HEV was reported to be between 1:4 and 1:3 for young adults in Nepal.[52,53] Such figures suggest that about 500 million of the world's population have been clinically ill from hepatitis E, a very large disease burden for populations whose health is already compromised. Thus, the general populations, and especially the poorer rural populations of developing countries of Asia, the Middle East and Africa, are at risk of contracting hepatitis E and would be candidates for a hepatitis E vaccine.

Other groups at special risk of contracting hepatitis E may be recipients of blood transfusions and patients on maintenance haemodialysis in regions where HEV is highly endemic.[11,12,54] Groups at special risk of severe hepatitis E include pregnant women and patients with

chronic liver disease. Groups in industrialized countries at higher than average risk of acquiring hepatitis E are the military and other visitors to regions where hepatitis E is highly endemic. In addition, swine handlers in several countries have been shown to have a higher prevalence of anti-HEV than matched controls.[45,55] Finally, those who eat raw or uncooked food that may be contaminated (pork, shellfish, etc.) may be at higher risk of infection.[29–31,56,57]

### The virus genomic organization, antigenic composition and epitopes

Hepatitis E virus is the first member of a newly proposed virus family, Hepeviridae and the only member of the only genus, Hepevirus.[58] Its genome is single-stranded positive-sense RNA. It is capped at its 5′ end and polyadenylated at its 3′ end. It contains three open reading frames (ORFs): ORF1 encodes the non-structural proteins, ORF2 encodes the capsid protein and ORF3 encodes a small protein of unknown function. Proteins encoded by all three ORFs are immunogenic but the ORF2 protein is the most immunogenic, the ORF3 protein is intermediate in immunogenicity and the ORF1 proteins are the least immunogenic. On the basis of antibody mapping with synthetic peptides, a number of linear epitopes have been identified on HEV-encoded proteins. At least 12 such epitopes have been identified among the non-structural proteins, especially in the protein believed to encode the viral RNA polymerase.[59] Three major epitopes found, respectively, in the amino-terminal, central and carboxy-terminal regions of the capsid protein have been reported.[59,60] Similarly, a major epitope is found in the carboxy-terminal region of the ORF3 gene product.[60] The most highly conserved epitopes are those found in the capsid protein and, thus, this protein has been of most interest for the development of diagnostic assays and for vaccine development. Although originally thought to be linear in nature, the epitopes associated with the capsid protein have been shown to be conformational. The principal neutralization epitope was originally localized to the amino acid sequence between amino acid 578 and 607, but the smallest peptide retaining the conformation of this epitope was shown to span the amino acids from 459 to 607.[61,62] This peptide is encompassed within the smallest peptide that stimulated neutralizing antibody (aa 452–617) described by Meng *et al*.[63] and within the peptide said to form a homodimer that reacts with convalescent sera (aa 394–607) described by Zhang *et al*.[64] The peptide described by Zhou *et al*. also reacted with two neutralizing monoclonal antibodies, detected convalescent antibodies in rhesus monkeys infected with each of the four major genotypes of HEV, and the ELISA results obtained with this peptide correlated with protection against challenge with HEV in monkeys that had been vaccinated with recombinant hepatitis E vaccine.[62]

### Immune response and serologic assays

Little is known about the cellular immune response to HEV, but both IgM anti-HEV and IgG anti-HEV appear late in the acute phase of the infection and correlate with diminishing viraemia but also with increasing signs and symptoms of hepatitis, consistent with the belief that hepatitis E is an immunity-mediated disease.[65] IgM antibodies disappear after several months but IgG antibodies persist, although not at the levels observed in early convalescence. Antibodies to the ORF3 protein diminish in titre more rapidly than antibodies to the ORF2 protein. Consequently, antibodies to the ORF3 protein are useful for diagnostic purposes, but not for epidemiological studies of antibodies acquired in the past. In contrast, antibodies to the ORF2 protein can be detected decades after the primary infection and are useful for epidemiological studies. Antigens that contain the conformational neutralization epitope in the carboxy portion of the ORF2 protein are the most useful for serological studies.[62,66,67] This epitope is masked in the full-length ORF2 protein and is best displayed on the more soluble truncated forms of the antigen (see below).

## Prevention

### Sanitation

The role of improved sanitation and public hygiene in the control of hepatitis E is somewhat difficult to assess. Industrialized countries with a high level of public sanitation do not experience epidemics of water-borne hepatitis E or significant endemic or sporadic disease, although hepatitis A continues to be an important cause of clinical disease in some of these countries, for example, the United States.[68] In developing countries, even where the prevalence of antibody to HAV is extremely high, the prevalence of antibody to HEV is much lower. These observations suggest that HEV is either less readily spread or less stable in the environment than HAV or that other factors are involved. It is difficult at present to assess the importance of animal reservoirs for the maintenance of HEV in the environment but this clearly needs to be studied. Judged by the prevalence of HEV in sewage samples, HEV is present in the environment of industrialized as well as developing countries.[48,50] This suggests that factors other than sanitation and public hygiene are important. Regardless of mechanisms of transmission, however, improved sanitation is important in controlling all infectious diseases

that have faecal-oral transmission as a prominent part of their epidemiology.

## Passive immunoprophylaxis

Evidence that prior exposure to HEV, as measured by pre-existing anti-HEV, is associated with protection against subsequent exposure to the virus has come from epidemiological studies of water-borne epidemics of hepatitis E in Pakistan.[69,70] In these epidemics, which occurred among members of the military, the clinical attack rate (as measured by hospitalization) among the cohort of 63 individuals who lacked anti-HEV at the beginning of the epidemics was 37%. In contrast, not a single one of the 46 individuals who were positive for IgG anti-HEV at the beginning of the epidemics was hospitalized. Evidence that this protection was probably antibody-based comes from other epidemiological and laboratory-based studies. Immunoprophylaxis trials of normal immune globulin in countries where HEV is endemic have not demonstrated statistically significant protection, even when the globulin was manufactured within the country, but they have provided suggestive evidence.[14,71–75] The failure to demonstrate significant protection in such studies probably resulted from the relatively low titres of anti-HEV found in such globulin preparations. Also, the immune globulin was usually administered late in the epidemic, thereby diminishing the chances of administering it early enough to protect before exposure to the virus. However, direct demonstration of the protective efficacy of anti-HEV has come from studies in which convalescent plasma or serum obtained from naturally infected patients or experimentally infected non-human primates was infused into naïve non-human primates, which were then challenged with HEV.[76,77] The immune globulin protected the animals against hepatitis. In contrast, serum or plasma from non-infected humans or non-human primates, when infused into naïve animals, failed to protect against subsequent challenge with virulent HEV. Thus, if an immune globulin preparation with a sufficiently high titre of anti-HEV could be prepared, it probably would be efficacious in preventing HEV when administered before exposure. Other evidence that antibodies protect against hepatitis E comes from studies of monoclonal antibodies that can neutralize HEV.[78] These monoclonal antibodies, which were derived from a combinatorial library obtained from the bone marrow of an experimentally infected chimpanzee, are virtually identical to globulins of human origin. They were capable of neutralizing HEV in a model system in which the monoclonal antibody was incubated overnight with HEV and then the mixture was inoculated intravenously into naïve rhesus monkeys. The neutralizing monoclonal antibodies protected the rhesus monkeys not only from hepatitis but also from infection, whereas rhesus monkeys inoculated with HEV and an irrelevant monoclonal antibody were infected and developed hepatitis.

## Active immunoprophylaxis

### *Historical aspects*

Early studies of recurring epidemics of hepatitis E in the same communities revealed that second cases of hepatitis E did not occur in individuals who had developed hepatitis in a previous outbreak. Similarly, non-human primates that were infected with hepatitis E and rechallenged subsequently were protected against a second case of hepatitis E, even when the rechallenge occurred several years later.[79–82] These observations, coupled with the observation that antibody to HEV correlated with protection against hepatitis E in humans, as well as monkeys,[69,70,83] strongly suggested that vaccines would protect.

### *Candidate HEV proteins for vaccine development*

Among the HEV proteins, those encoded by ORF1 are non-structural and therefore not accessible to antibody. A vaccine prepared from ORF1 proteins would have to protect solely through cellular immune mechanisms. Furthermore, these proteins are among the least immunogenic of the virally encoded proteins of HEV. It is not known whether the protein encoded by ORF3 is structural or non-structural. It is immunogenic but, as noted, antibody to it is relatively short-lived and relatively genotype-specific. Furthermore, antibody to the ORF3 protein does not neutralize HEV.[84] Thus, the protein encoded by ORF2, the capsid protein of the virus, is the best candidate for a hepatitis E vaccine. Its sequence is highly conserved and antibody to it is long-lived and cross-reactive among diverse strains.[43] Finally, antibody to the ORF2 protein neutralizes HEV *in vitro* and protects non-human primates against HEV following challenge with virulent virus.[63,77,78,84,85]

### *Recombinant proteins expressed from the HEV ORF2*

As HEV grows poorly in cell culture, proteins for diagnostic use and vaccine development have been expressed as recombinant proteins in a variety of systems, but principally from *Escherichia coli* as fusion proteins or in insect cells from baculovirus vectors (Table 42.1). Although the first candidate HEV vaccine was expressed in *E. coli*, the proteins derived from bacteria have been used principally as antigens for diagnostic purposes.[86–94] Neither the least truncated nor the most truncated of these proteins expressed in *E. coli* has been widely used because truncated proteins of intermediate size have provided better sensitivity for detecting anti-HEV in ELISA and Western

blot assays.[43] Their increased sensitivity appears to result from their ability to fold into native configurations that display conformational epitopes.[89,90]

One truncated ORF2 protein expressed in *E. coli* has proven to be useful both for serodiagnosis and as a candidate vaccine.[64,95] This protein, truncated to amino acid 394 at its amino-terminus and to amino acid 607 at its carboxy-terminus, is said to form homodimers that express a conformational epitope, but only in its dimerized form.

Similarly, proteins expressed in insect cells have been useful for detecting anti-HEV, but full-length ORF2 proteins are relatively insoluble and relatively insensitive for use as an antigen in serological tests.[96–104] However, proteins expressed in certain insect cell systems are post-translationally processed in several ways. First, at least some of the proteins are larger than their amino acid sequence would predict. Proteins with calculated molecular masses of 50 and 53 kDa were actually 53.8 and 56.1 kDa, respectively, when measured by mass spectrometry.[101] The ORF2 protein contains three putative glycosylation sites and seven sites for myristylation, but it is not clear whether the extra mass is the result of glycosylation, myristylation, or some other form of protein modification.[105,106] Second, proteinases, which are probably encoded by the baculovirus vector, cleave the ORF2 protein between amino acids 111 and 112, thereby removing the hydrophobic signal sequence of the protein and rendering it more soluble.[99,107] Third, proteinases successively truncate the protein from the carboxy end, yielding a series of proteins of different sizes and with different characteristics. For example, proteins that are approximately 55 kDa and larger are retained within the insect cell and, following cell lysis, they can be purified to a high degree of homogeneity as monomers.[99–101] In contrast, some proteins of approximately 53 kDa and smaller are secreted from insect cells and form virus-like particles (VLPs) that are smaller than the intact virion of HEV,[97,101] although the exact size of one of these proteins[97] has been the subject of speculation. The VLPs have been shown to be highly ordered icosahedrons with two-, three- and fivefold symmetry.[103] VLPs have also been reported in preparations of the larger proteins, but these are either formed inefficiently, require specific conditions to form or they may be the products of smaller forms of the protein that exist as minor populations in the preparations.[102,107–109] More importantly, the larger and smaller proteins differ in another important respect. Those proteins described in Table 42.1 that are approximately 54–56 kDa or larger contain the most important

conformational neutralization epitope found to date in the ORF2 protein. This epitope requires the carboxy portion of the peptide that extends to amino acid 607.[61–63]

### *Protein-based vaccines*

The first reported candidate vaccine for hepatitis E was a fusion protein expressed in *E. coli* from a truncated ORF2 gene.[110] The 440 amino acid protein, designated trip E-C2, was administered intramuscularly in two 80-μg doses with alum adjuvant 1 month apart to four cynomolgus monkeys. Two of the monkeys were given a third dose of vaccine without alum 7 weeks later. All the animals were challenged either with the homologous Burma strain of HEV (genotype 1) or with a Mexican strain of the virus (genotype 2). Neither challenge virus had been titred for infectivity, but both had been shown to be infectious in previous studies of non-human primates. Neither of the monkeys that received only two doses of vaccine was protected against hepatitis. Only the monkey that received three doses of vaccine and was challenged with the homologous Burmese strain of HEV appeared to be protected from infection as well as hepatitis.

In another study, a 214 amino acid peptide spanning amino acids 394–607 was expressed as a GST fusion protein in *E. coli* from a truncated ORF2 gene of a Chinese strain of HEV (genotype 1).[95] After purification of the fusion protein, the GST portion was removed from the ORF2 protein and the latter was used to immunize three rhesus monkeys; 100 μg of the protein was administered in four weekly intramuscular doses. The first contained complete Freund's adjuvant and the remaining three contained incomplete Freund's adjuvant. All three animals developed antibody during the course of immunization. The animals were challenged 2 weeks after the last immunization with an untitred pool of the homologous Chinese HEV strain. Following challenge, neither vaccinated nor negative control monkeys developed hepatitis, but all three control monkeys shed HEV, whereas the vaccinated monkeys did not shed virus following exposure to this apparently attenuated challenge virus.

Several candidate vaccines expressed from baculovirus vectors in insect cells have been studied. These vaccine candidates represent the various cleavage products derived from the 72-kDa full-length ORF2 protein when expressed from baculovirus in insect cells.

A 62-kDa protein, encompassing amino acids 112–660 (the carboxy-terminus of the protein), was purified and used to immunize three cynomolgus monkeys.[100,111] The protein was alum-precipitated as a 20-μg formulation and administered intramuscularly twice, with a 4-week interval. The three vaccinated monkeys and three control monkeys were challenged intravenously with 1000 50% monkey infectious doses ($MID_{50}$) of the heterologous Mexican strain (genotype 2) of HEV 6 weeks after the last vaccination. All three vaccinated monkeys were protected against hepatitis and two of the three were protected against infection. All three control monkeys developed hepatitis.

In another study, a 55–56-kDa protein, spanning amino acids 112–607 of the ORF2 protein derived from a Pakistani strain (genotype 1) of HEV, was expressed from baculovirus in insect cells, purified and used to immunize six cynomolgus monkeys.[77,107] Four monkeys received a single 50-μg dose with alum intramuscularly and two monkeys received a second dose of vaccine 1 month after the first dose. One month after the final dose of vaccine, the six vaccinated monkeys and five control monkeys were challenged with 1000 or 10 000 $MID_{50}$ of the homologous Pakistani HEV strain. All vaccinated monkeys were protected against hepatitis after challenge, but only the monkeys that received two doses of vaccine were protected against infection. In contrast, all five control monkeys developed hepatitis.

In a subsequent study, four groups of four rhesus monkeys each were vaccinated twice with graded doses of vaccine consisting of 50 μg, 10 μg, 2 μg or 0.4 μg in alum adjuvant.[107,112] All the animals developed antibody after the first dose and high levels of antibody after the second dose. All the animals were protected against hepatitis after challenge with 300 000 $MID_{50}$ of the homologous Pakistani strain of HEV (genotype 1) administered intravenously. However, all of the animals were infected, probably because of the very high challenge dose. Four additional monkeys that had been immunized with the highest dose of vaccine were challenged with 100 000 $MID_{50}$ of the heterologous Mexican strain (genotype 2) of HEV. All were protected against hepatitis but not infection. In contrast, eight monkeys that had received placebo all developed hepatitis following challenge with the Pakistani or the Mexican strain of virulent HEV. In addition, four rhesus monkeys were challenged with the homologous virulent Pakistani virus and vaccinated with a 50-μg dose of vaccine 48 hours after challenge, followed by a booster dose 1 month later. The purpose of this study was to evaluate the feasibility of post-exposure vaccination against hepatitis E. All four animals developed hepatitis as well as infection, and the only difference between this group and the placebo group was that the duration of viraemia and viral excretion was reduced slightly in the vaccinated group. Thus, unlike post-exposure vaccination for hepatitis A, post-exposure vaccination for hepatitis E was not protective.

In an extension of this study, the duration of protection and the effect of a third dose of vaccine were examined.[114] Sixteen seronegative rhesus monkeys were randomly assigned to six groups. Two groups each of four monkeys were inoculated intramuscularly at 0 and 1 month with 50-μg doses of vaccine and chal-

lenged with a homologous strain of HEV 6 or 12 months after the second vaccination. Two groups, each of two monkeys, were similarly immunized and given a third dose of vaccine at 5 or 11 months after the second vaccination. They were challenged 1 month after the third vaccination. Two other groups, each of two monkeys, were inoculated with placebo at 0 and 1 month and challenged at 6 or 12 months after the second inoculation. The challenge dose in this experiment was approximately 300 000 $MID_{50}$ of the virulent Pakistani Sar-55 strain of HEV. Six of eight monkeys challenged 6 or 12 months later were protected against viral hepatitis (one in each group developed hepatitis), whereas all of the monkeys that received a third dose of vaccine at 6 or 12 months after initial vaccination were protected against hepatitis. In contrast, all animals receiving the placebo developed hepatitis. The third dose of vaccine elicited a brisk and anamnestic antibody response. The anti-HEV titre of monkeys receiving the third dose of vaccine was approximately 30–60-fold higher than that of monkeys receiving two doses, at the time of challenge. The data suggest that anti-HEV would fall to below protective levels by approximately 2 years after vaccination if a third dose of vaccine was not administered.

A recombinant 53-kDa truncated form of ORF2 protein has also been tested for protective efficacy in rhesus monkeys.[114] The only neutralization epitope identified to date is located at least partially between amino acids 578 (the carboxy end of the 53-kDa protein) and 607 (the carboxy-terminus of the 56-kDa protein). Six rhesus monkeys were immunized twice with 385 ng of alum-precipitated 53-kDa protein, the molar equivalent of the smallest dose (400 ng) of 56-kDa protein tested previously and shown to be protective. Monkeys were challenged with 10 000 or 100 $MID_{50}$ of the homologous Pakistani virus 1 month after the second dose of vaccine. Monkeys receiving a placebo were similarly challenged. Antibody titres were similar to those observed previously following vaccination with the 56-kDa protein. Vaccination with the 53-kDa protein greatly reduced virus shedding but did not protect against hepatitis following the high-dose challenge. Neither hepatitis nor virus replication was detected in vaccinated monkeys receiving the low-dose challenge, whereas one of two placebo recipients developed hepatitis and both were infected. Thus, surprisingly, the 53-kDa protein was at least partially protective, suggesting that one or more additional neutralization epitopes are present in the truncated ORF2 proteins or that small amounts of larger forms of the protein were present in the vaccine preparation.

VLPs that spontaneously form from truncated ORF2 proteins expressed from baculovirus in insect cells have also been used for vaccine development. Originally detected in preparations of ORF2 protein expressed from a full-length ORF2 sequence that was spontaneously truncated to smaller forms, they were subsequently associated predominantly with 53-kDa and smaller forms of the protein.[101,102] VLPs were independently identified in preparations of expressed and secreted truncated ORF2 protein that was said to be 50 kDa in size,[103] but subsequent analyses put its size at approximately 54 kDa.[115] Surprisingly, the amino and carboxy ends of this protein were mapped to amino acids 112 and 608, respectively.[116] Thus, this protein appears to be virtually identical to the 56-kDa protein described previously.[101] The latter VLPs have been shown to have icosahedral symmetry, to be approximately 24 nm in diameter, and to induce both systemic and intestinal antibodies when administered orally as a vaccine to mice.[115]

Cynomolgus monkeys were similarly inoculated orally with purified recombinant HEV VLPs without adjuvant.[82] Two monkeys were administered 10 mg of VLPs on days 0, 7, 21, 36 and 80. Two additional monkeys were given saline orally according to the same schedule. The four monkeys were challenged on day 100 with HEV obtained from an Indian patient. The infectivity titre of the challenge inoculum was not fully determined but was said to be '$>5 \times 10^3$ monkey infectious dose'. Two cynomolgus monkeys that had been experimentally infected with HEV previously were also challenged and served as protected controls. Both monkeys that were vaccinated with saline were infected and developed hepatitis. Neither animal that had been infected previously was infected or developed hepatitis. Neither animal that was vaccinated with VLPs developed hepatitis and one was protected from infection. The other had transient and low-level shedding of the virus into the faeces. Thus, the vaccinated monkeys were completely protected against hepatitis and partially protected against infection. However, the cost of such a vaccine may make it prohibitive if comparable or larger doses of vaccine and regimens of administration are required for human vaccination, as one oral dose of this vaccine was equivalent to approximately 25 000 doses of a potent parenterally administered vaccine and one protective oral immunization regimen required vaccine sufficient for over 60 000 protective immunizations with the parenterally administered vaccine.[112]

VLPs have been further modified to bear antigenic epitopes of other agents. These have also been shown to elicit intestinal antibodies but not serum antibodies.[116] VLPs have even been used as vehicles for delivering heterologous DNA vaccine in this novel combination of two vaccination approaches.[108] Oral administration to mice of HEV VLPs loaded with HIV envelope cDNA resulted in significant levels of specific IgG and IgA antibody to the HIV envelope in faecal extracts and sera of the mice. Cytotoxic T-lymphocyte responses were also elicited. Finally, a truncated HEV ORF2 protein has been expressed in tomatoes.[117] Approximately 60 ng of ORF2 protein was

detected per gram of fresh tomatoes.[117] However, based on the oral vaccinations described above, one would need to feed a primate almost one metric ton of fresh tomatoes in order to provide protection against hepatitis E. Some approaches to vaccine development are more clever than practical.

### *DNA vaccines*

Significant progress has been made in the development of DNA vaccines to HEV. Early studies demonstrated an immune response in mice to vaccination with ORF2 cDNA and evidence of immunological memory in mice that had lost demonstrable antibody over time.[118,119] Better immune responses to HEV DNA vaccine were obtained when the DNA was co-delivered with cytokine genes (interleukin-2, granulocyte-macrophage colony-stimulating factor) or cytotoxic T-lymphocyte antigen 4, which targets the DNA to antigen-presenting cells.[120,121]

HEV DNA vaccines have also been tested in cynomolgus macaques, which permit evaluation of efficacy.[123] When four macaques were intramuscularly immunized with four sequential 100-μg doses of HEV DNA vaccine derived from the sequence of a Burmese strain, all four animals developed anti-HEV. Following challenge with 1000 $MID_{50}$ of a heterologous (Mexican) HEV strain, two of the four were protected against infection, as well as hepatitis, whereas the other two developed both infection and hepatitis. A single placebo control monkey was infected but did not develop hepatitis following challenge.

In a subsequent study, seven cynomolgus monkeys were immunized with four 25-μg doses of HEV cDNA vaccine, three monkeys by gene gun application and two monkeys by intradermal inoculation.[124] Two cynomolgus monkeys received placebo by gene gun. All three monkeys that received vaccine by gene gun had progressively higher titres of anti-HEV following each administration of vaccine. In contrast, anti-HEV was not detected in the serum of the two monkeys that received vaccine intradermally. Following challenge with 10 000 $MID_{50}$ of the heterologous Mexican strain of HEV, all three monkeys vaccinated by gene gun were protected from infection, although one had repeated liver enzyme elevations following challenge. Both monkeys that were vaccinated intradermally were infected with HEV following challenge, but neither had significant liver enzyme elevations. Both monkeys that received placebo were infected and one had liver enzyme elevations. Thus, administration of DNA vaccine by gene gun yielded significantly better results than administration of the same vaccine intradermally or than administration of a four times higher dose of vaccine delivered intramuscularly.

### *Preclinical and clinical trials*

Although hepatitis E vaccines consisting of 62-kDa (Genelabs) or 56-kDa (NIH) ORF2 proteins were both immunogenic and protective, the superior stability of the 56-kDa protein vaccine resulted in its selection by GlaxoSmithKline for clinical evaluation. A lot of vaccine suitable for administration to humans was prepared by Novavax, Inc., under the sponsorship of GlaxoSmithKline. The preparation of the vaccine was essentially as described previously.[101,112] The vaccine preparation contained purified 56-kDa capsid antigen derived from the HEV strain Sar-55 and expressed from baculovirus as recombinant protein in vaccine-acceptable SF9 insect cells. The formulations of the vaccine were 1 μg, 5 μg, 10 μg, 20 μg and 40 μg plus alum adjuvant in a volume of 0.5 mL.

Preclinical testing was carried out in 44 rhesus monkeys.[124] Two formulations of the vaccine, 1 μg and 10 μg, and two vaccination schedules (two doses of 1 μg or 10 μg at weeks 0 and 4, one dose of 10 μg at week 0) were compared in 12 monkeys for each regimen. GlaxoSmithKline's Havrix hepatitis A vaccine served as the placebo and was administered to eight monkeys. Both vaccine formulations were highly immunogenic, and there was little difference in the level of antibody following two doses of vaccine, regardless of the formulation. The antibody response to the single 10-μg dose was only approximately one-tenth of that of the two-dose regimens.

Following vaccination, the groups of monkeys were further divided and challenged at week 8 with one of three HEV strains: the Sar-55 strain from Pakistan (genotype 1), the Mex-14 strain from Mexico (genotype 2) or the US-2 strain from the United States (genotype 3). HEV genotype 4 had not been discovered at the time of the study.

Each challenge virus was diluted to deliver 10 000 $MID_{50}$ intravenously per monkey. None of the animals that received two doses of vaccine developed hepatitis, regardless of the challenge virus, whereas 17% of the monkeys that had received a single dose of vaccine developed hepatitis. In contrast, 75% of the monkeys receiving placebo developed hepatitis. Similarly, only 26% of monkeys that received two doses of vaccine were infected, whereas 75% of those that received a single dose of vaccine were infected. All eight of the placebo recipients became infected following challenge. Thus, the two-dose regimens had a protective efficacy of 100% (confidence intervals: 65–100%), whereas the single-dose regimen had a protective efficacy of 78% (confidence intervals of 29–94%). Protection against infection and against hepatitis was inversely related to the titre of anti-HEV at the time of challenge. Thus, as in previous studies, protection correlated with levels of antibody.[113]

### *Clinical trials*

Phase I clinical trials of the vaccine were carried out by the US Army at the Walter Reed Army Institute of Research.[125] The vaccine was found to be safe and immunogenic in 88 American volunteers, aged 18–50 years. It was administered in 1-, 5-, 20- or 40-μg formulations: each formulation was administered intramuscularly to 22 subjects at 0, 1 and 6 months. The seroconversion rate was 67% for the 1-μg formulation and 89–95% for those receiving the other formulations, but the serological test for measuring such antibody was different from that used in the preclinical trials, and a direct comparison cannot be made.

Based on these results, a further phase I evaluation was performed in Nepal, where hepatitis E is endemic. Three doses of formulations of 5 μg or 20 μg were injected intramuscularly into 22 Nepalese volunteers each at 0, 1 and 6 months. By the second month, 43 of the 44 volunteers had seroconverted, and by the seventh month the remaining volunteer had also developed antibody to HEV. Thus, the vaccine was well tolerated and immunogenic in the Nepalese volunteers.

A phase II/phase III trial of the vaccine was carried out by the US Army in members of the Nepalese military (Robert Kuschner, personal communication). Two thousand volunteers stationed in the Kathmandu valley of Nepal received 20 μg of the vaccine or a placebo at 0, 1 and 6 months and were followed for an additional 2 years. Although there was some initial concern that there would not be sufficient cases of hepatitis E to provide a statistically significant outcome, in fact, massive flooding in Nepal resulted in multiple epidemics of hepatitis E in the monitored population. Consequently, there were many more cases of hepatitis E than the minimum number initially predicted for statistical significance. To date, the code has not been broken for this field trial of hepatitis E vaccine, so its protective efficacy cannot be ascertained.

Other events almost derailed the study: most of the royal family was massacred by another family member and a Maoist uprising in the western frontier required shifting troops, including vaccinees, to the war zone during the course of the trial. At least one vaccinee was killed by enemy fire, an unusual untoward reaction in a vaccinee.

### *Prospects for the future*

Thus, a hepatitis E vaccine appears to be feasible. Although experience with recombinant vaccines produced in insect cells is limited, they appear to be safe and well tolerated, and purification of candidate vaccine is straightforward, yielding a preparation that is relatively free of insect proteins.[101] Based on *in vivo* and *in vitro* studies, the vaccine appears to protect against all four recognized genotypes of human HEV. Thus, only one vaccine will be needed for worldwide protection. It appears that three doses of vaccine will be necessary for optimum protection and, as the half-life of anti-HEV appears to be shorter than that of antibodies against other viruses, such as HAV, periodic booster immunizations may be necessary. Nevertheless, it should be possible to manufacture and market an economically viable hepatitis E vaccine.

A larger problem is the market for such a vaccine. The greatest populations at risk reside in developing countries where the cost of even the most essential vaccines can be prohibitive. The market for a hepatitis E vaccine in industrialized countries is relatively small and consists of military personnel and civilian travellers to developing countries. However, one industrialized country, Japan, has discovered that hepatitis E is more common than previously suspected, and that one source of such infections is the ingestion of raw or undercooked pork and venison. Whether the incidence of hepatitis E in Japan is sufficiently high to warrant vaccination programmes is yet to be determined.

Finally, if vaccination programmes are to be implemented, especially in developing countries, it will be necessary to consider universal vaccination, preferably of children between birth and adolescence, as most disease occurs in older children and young adults and as the most severe disease occurs in pregnant women. Attempts to halt epidemics, once they occur, by mass vaccination is unlikely to be effective because most exposures to the virus will probably have occurred by the time the epidemic is recognized, and because studies in monkeys have questioned the efficacy of post-exposure vaccination. Thus, a universal vaccination programme that would fit into WHO vaccination schedules, preferably with a vaccine that combines a hepatitis E vaccine with other vaccines in the Expanded Programme on Immunization, would appear to be the most feasible. However, it remains to be seen if any manufacturer will deem it in their interest to accept the challenge of manufacturing a hepatitis E vaccine.

# Section VIII
# Clinical Aspects of Viral Liver Disease

# Chapter 43
# Aetiology of fulminant hepatitis

Kittichai Promrat, Jack R Wands

## Introduction

Acute liver failure (ALF) or fulminant hepatic failure is characterized by severe and sudden onset of liver injury leading to coagulopathy and hepatic encephalopathy in previously healthy persons with no known underlying liver disease.[1] It can rapidly progress to coma and death from cerebral oedema and multi-organ dysfunction. There are an estimated 2000 cases of ALF in the United States yearly, representing 6% of liver-related deaths.[2] ALF is a clinical syndrome that represents a final common pathway for a wide variety of diseases that rapidly produce severe liver injury. There are numerous causes of ALF including drugs, viruses, toxins and miscellaneous disorders.[3] Patients with ALF can be classified into hyperacute, acute or subacute liver failure depending on the rapidity of development of encephalopathy from the first appearance of jaundice or symptoms.[4] Studies have shown that patients who had a more rapid onset of hepatic coma had a paradoxically better chance of spontaneous recovery. The mortality of ALF remains high, and the overall transplant-free survival rate varies greatly from 5% to 70% depending on the aetiology of liver injury.[5] In a recent large series of ALF cases from the USA, patients with acetaminophen overdose, hepatitis A virus (HAV) infection, shock liver or pregnancy-related acute liver failure, short-term survival without transplantation was 50% or greater,[6] while patients whose liver disease was of indeterminate cause or was presumed to be related to drugs other than acetaminophen, hepatitis B virus (HBV) infection, autoimmune hepatitis, Wilson's disease, Budd-Chiari syndrome or cancer had lower rates of short-term transplant-free survival (<25%).[6] Medical therapy of ALF is critical in management of the complications of ALF including infections, haemodynamic abnormalities, brain oedema, renal and pulmonary failure, and coagulopathy. Liver transplantation has been used increasingly with reasonably good outcome in the management of patients for whom spontaneous recovery is deemed to be unlikely.[2]

The aetiology of ALF varies greatly worldwide (Tables 43.1 and 43.2). Currently, the most common cause of ALF in the United States[6] and the UK[7] is drug-induced liver injury (most commonly acetaminophen toxicity). Viral hepatitis, once the most common cause of ALF in the USA,[8,9] now comprises only one-eighth of all ALF cases in a recent multi-centre study.[6,10] Similarly, there has been a decline in the proportion of ALF cases from viral hepatitis in the UK from 19% (1973–1990) to only 5% in a more recent study (1991–1997).[7] In developing countries, however, viral hepatitis remains the most common cause of ALF.[11,12] HAV infection is seen sporadically worldwide. In areas where HBV infection is endemic, exacerbation of chronic hepatitis B, either spontaneously or on withdrawal of immunosuppressive therapy, is the major cause of ALF.[11] Hepatitis E virus (HEV) infection is the main causative agent of ALF in the Indian subcontinent, especially among pregnant

women.[13,14] Less frequent viral causes of ALF include hepatitis C virus (HCV), hepatitis D virus (HDV), cytomegalovirus (CMV), herpes simplex virus (HSV) and Epstein-Barr virus (EBV) infections. In most series, a significant proportion of patients (10–44%) were classified as indeterminate or cryptogenic despite extensive history taking and serological evaluation.[6,15,16] Some may represent suicidal or toxin ingestions that are not reported because of fear of discovery or obtundation on admission to hospital. Others may represent environmental or bacterial toxins or viruses not yet identified.

In this chapter, viral causes of ALF (fulminant hepatitis) will be discussed (Table 43.3).

## Hepatitis A virus (HAV)

HAV is a positive-strand RNA virus classified within the family of Picornaviridae. Its genomic organization is similar to that of other picornaviruses, including important human pathogens in the genera Enterovirus (e.g. poliovirus) and Rhinovirus. HAV infection causes an acute, usually self-limited necroinflammatory disease of the liver. The infection is spread mainly by faecal-oral transmission and remains a public health problem throughout the world. In the USA, the incidence of hepatitis A has declined steadily since the introduction of HAV immunization, and in 2001 (the most recent available data) it was the lowest ever recorded (4.0/100 000).[17] The decline in rates has been greater among children and in the states where routine childhood vaccination is recommended, suggesting an impact of childhood vaccination.[17] However, large community outbreaks of hepatitis A associated with mortality have been observed sporadically throughout the USA.[18]

Fulminant hepatitis is an uncommon but severe complication of hepatitis A, causing about 100 deaths annually in the USA.[2] The case-fatality rate in acute symptomatic hepatitis A is low and probably is <0.1% overall.[2] HAV is not a common aetiology of acute liver failure in developed countries. In the USA, the proportion of ALF cases from HAV infection has been relatively small (0–7%) and has not changed over the past 25 years despite a declining overall incidence of hepatitis A.[9,10,15,16] In the observation period from 1998 to 2001, 16 (4.5%) of 354 patients with ALF admitted to 19 academic medical centres in the USA had hepatitis A infection as the aetiological factor.[10] Similarly, hepatitis A was implicated in 46 (4.9%) of 943 cases of ALF seen at the Liver Failure Unit at King's College Hospital in UK from 1973 to 1990.[19] Even in developing countries where hepatitis A is endemic, the observed rates of HAV infection as

the cause of ALF have been relatively modest and have varied from 1.7 to 10.6%.[13,20] In Pune, India, there has been an increase in the prevalence of hepatitis A among adults who developed ALF (from 3.5% in 1978–1981 to 10.6% in 1994–1997).[20] This may be due to a change in epidemiology of hepatitis A rendering more individuals susceptible to infection in early adulthood. Hepatitis A remains a frequent cause of ALF requiring liver transplantation among children in endemic areas.[21–23]

In general, most cases of fulminant hepatitis A have a favourable outcome in comparison with other types of fulminant viral hepatitis.[6,15,19] Most series have documented a higher rate of spontaneous recovery and lower rate of liver transplantation among hepatitis A patients in comparison with patients with hepatitis B-related ALF.[10] Data from the Acute Liver Failure Study Group showed a 69% spontaneous survival rate among patients with hepatitis A, while only 19% of patients with hepatitis B had spontaneous recovery.[10] Liver transplantation rate was 62% among patients with hepatitis B in comparison to 19% among patients with hepatitis A.[10] The reason for these differences does not appear to be the severity of hepatic dysfunction at the time of clinical presentation but seems to be an inherent feature of the disease. An alternative explanation for higher transplant rate among patients with HBV-related ALF is a bias among physicians towards transplanting patients with hepatitis B because of reports of poorer survival among these patients.

The risk of ALF due to HAV infection increases markedly among persons older than 40 years[24,25] and patients with pre-existing chronic liver disease.[26] In a study from Italy,[26] patients with chronic hepatitis C with HAV superinfection had exceedingly high rates of ALF (41%) and death (35%). Interestingly, in this study such a severe manifestation of HAV superinfection was not observed in patients with underlying chronic hepatitis B.[26] Previous studies, however, have shown an increased mortality rate among hepatitis B surface antigen (HBsAg)-positive individuals in comparison with HBsAg-negative individuals during outbreaks of hepatitis A.[27,28] Therefore, all patients with chronic liver disease should be considered for immunization against hepatitis A. The cost-effectiveness of this practice remains controversial.[29,30]

The diagnosis of acute hepatitis A is made on the basis of the detection of HAV IgM antibody in the serum. During HAV-related ALF, the HAV RNA level may be very low or undetectable, suggestive of excessive host immune-mediated lysis of virally infected hepatocytes similar to what has been observed in HBV-related ALF.[31] Interestingly, low or undetectable HAV viral load has been shown to be independently associated with fulminant course and death or transplantation in patients with acute hepatitis A.[31] To date, few studies have been published on viral factors and clinical severity of hepatitis A.[32,33] Investigators from Japan sequenced the 5′ non-translated region (5′ NTR) of the HAV genome, which has an internal ribosomal entry site and is important in cap-independent translation of the viral message, from patients with fulminant hepatitis A.[33] Fewer nucleotide substitutions in the central portion of the 5′ NTR were noted among patients with a fulminant course. The authors concluded that nucleotide variations in the central portion of the 5′ NTR of HAV might influence the severity of hepatitis A. Thus far, no apparent associations between disease severity and HAV genotype have been documented.[31,34] A case of recurrent hepatitis A after orthotopic liver transplantation for fulminant hepatitis A has been reported.[35]

## Hepatitis B virus (HBV)

HBV is a partially double-stranded DNA virus of approximately 3.2 kilobase pairs that is classified within the family of Hepadnaviridae. HBV infection is a major public health problem worldwide. Approximately 2 billion people or one-third of the world's population have serological evidence of past or present HBV infection, and 350 million people are chronically infected. HBV is transmitted by percutaneous and mucous membrane exposure to infectious blood or body fluids. Hepatitis B infection can lead to a variety of clinical presentations including acute self-limited hepatitis, fulminant hepatitis, chronic hepatitis and hepatocellular carcinoma (HCC). In the USA and Western Europe, there has been a significant decline in the incidence of acute hepatitis B during the past decade since the implementation of a routine immunization programme.[36] In HBV endemic areas such as Taiwan, the universal hepatitis B vaccination programme has been shown to be highly beneficial. The incidence rates of chronic HBV infection and HCC among children younger than 15 years have been markedly reduced as a result of this mass vaccination programme.[37]

Fulminant hepatitis is an uncommon but potentially fatal clinical manifestation of acute hepatitis B. The case-fatality rate of acute hepatitis B is approximately 0.4–1.0%.[2,38] In the USA, the proportion of cases of ALF from hepatitis B has declined significantly over the past three decades, from 34% in the 1970s,[9] and 18–19% in the 1980s,[16,39] to 10% in the early 1990s[15] and to 7% in the most recent series from 1998 to 2001.[6] A similar trend has been observed in the UK.[7] This decline may simply reflect the reduction in the overall incidence of acute hepatitis B in these countries. Another contributing factor may be the increase in other aetiologies of ALF, particularly acetaminophen toxicity, which is now the most common cause of ALF in Western countries.[5,7] However, HBV remains a common cause of ALF in endemic areas.

Infection with HBV is the most prevalent cause of ALF in the Far East, France and many other southern European countries. For instance, HBV infection accounted for 80% and 63% of the cases of ALF in Hong Kong and Taiwan, respectively.[40,41] In India, HBV was found to be an aetiological agent in 28% of ALF cases, the second most common after HEV.[13] The importance of HBV infection in ALF in endemic areas is further illustrated by the decline in the mortality associated with fulminant hepatitis in infants in Taiwan after the implementation of the mass HBV immunization programme.[42]

The diagnosis of fulminant hepatitis B can be difficult. Typical serological markers of acute hepatitis B may not be measurable by the time of clinical presentation of acute liver failure.[3,43] One-half or two-thirds of patients have lost HBsAg by or within a few days of presentation. This relatively short course of hepatitis B surface antigenaemia is thought to be due to intense immune-mediated clearance of infected hepatocytes in an attempt to clear the virus. In some cases, the diagnosis of HBV-related ALF may depend solely on the presence of serum anti-hepatitis B core immunoglobulin M (anti-HBc IgM). However, anti-HBc IgM can also be detected during spontaneous flares of chronic hepatitis B,[44] thus the presence of anti-HBc IgM in patients with fulminant hepatitis does not exclude an underlying chronic HBV infection. Several studies reported that some patients with HBV-related ALF lacked serological evidence of HBV infection (negative for both HBsAg and anti-HBc IgM) but had detectable HBV DNA in the serum or liver using polymerase chain reaction (PCR) assays.[45–47] The prevalence of this occult form of hepatitis B infection in patients with ALF with no apparent cause has been reported to vary from 0–4%[48–52] to as high as 50%[46,47] (Table 43.4). The currently available data on the prevalence of occult HBV infection among patients with ALF are conflicting and based on studies with a relatively small number of patients.[45–54] It appears that occult hepatitis B infection associated with fulminant hepatitis is more prevalent in geographic locations where hepatitis B is endemic such as the Far East (Japan, Taiwan). Whether occult HBV infection plays a direct pathogenic role in causing ALF in these cases remains to be proven. A more recent study from a large series of ALF patients in the USA found no evidence of occult HBV infection among ALF patients with indeterminate aetiology.[55] However, it will be important to revisit these cases with ultrasensitive PCR-based diagnostic techniques that identify <10 viral particles/mL of blood and liver tissue before firm conclusions may be reached.

Fulminant hepatitis B can occur in the setting of acute *de novo* infection or in the setting of reactivation of chronic infection either as a spontaneous flare or after withdrawal of immunosuppressive therapy. This latter presentation appears to be a more common form of HBV-related ALF in the Far East (Hong Kong and Taiwan).[11] Spontaneous flares most frequently occur during the immune clearance phase of chronic HBV infection and precede clearance of the virus and hepatitis B e antigen seroconversion to anti-HBe.[56] Thus, severe flares leading to hepatic compensation may be observed in previously asymptomatic inactive HBV carriers. Withdrawal of immunosuppressive therapy also could lead to fulminant hepatitis in patients with chronic HBV infection.[57,58] Most reported cases occur after withdrawal of cytotoxic immunosuppressive chemotherapy for haematological malignancy or solid tumour.[59–61] Another well-described and increasingly recognized condition associated with reactivation of HBV is engraftment of bone marrow transplantation.[62–64] The mechanism of severe liver injury associated with withdrawal of immunosuppression or engraftment of bone marrow transplantation is thought to be a two-stage process.[11] The first stage occurs during intense immunosuppressive therapy, which leads to enhance viral replication and widespread infection of hepatocytes. The second stage develops during or soon after the withdrawal of immunosuppressive therapy, in which the recovery of

*Cases of fulminant hepatitis with no serological evidence of HAV or HBV infection.

the immune system produces an intense immune-mediated destruction of the HBV-infected hepatocytes. A high pretransplant HBV DNA level has been shown to be a predictive factor of hepatitis B exacerbation in bone marrow transplant recipients.[65] Pre-emptive therapy with a nucleoside analogue such as lamivudine in bone marrow[66] or renal allograft[67] transplant recipients or patients undergoing chemotherapy[68,69] with underlying HBV infection has been shown to significantly reduce the incidence of exacerbation of hepatitis B.

Various mutations of HBV genome have been implicated in the aetiology and pathogenesis of fulminant hepatitis B. In the majority of cases, HBV mutations that affect HBeAg expression have been reported.[70–73] To date, mutations in the precore and core promoter regions have been most extensively evaluated. HBV variant with a mutation in the precore region of the HBV genome (G to A change at nucleotide 1896, G1896A) has been detected in several case series and outbreaks of fulminant hepatitis B from Israel,[71] Japan[72–75] and southern Europe.[76] This mutation creates a stop codon at codon 28 and leads to premature termination of the precore/core protein, thus preventing the production of HBeAg.[72,74] The precore stop codon mutation is much more prevalent in specific HBV genotypes (D>A) because genotype-specific nucleotide difference upstream of the stop codon mutation is involved in critical base-pairing with the mutation in the secondary structure of the HBV encapsidation signal.[77] Therefore, in areas where HBV genotype A is predominant such as the USA and France, the precore stop codon variant has been found at lower frequency in patients with fulminant hepatitis B.[78–80] Subsequent studies have identified additional mutations in the core promoter region in patients with fulminant hepatitis B.[81,82] Two mutations in the core promoter region have been noted in most studies: an A to T change at nucleotide 1762 (A1762T) and a G to A change at nucleotide 1764 (G1764A). Unlike precore variants, core promoter variants can be detected in both HBeAg-negative and HBeAg-positive individuals.[83] An association between core promoter variants and fulminant hepatitis B has been observed in Japan[82] and Germany[84] but not in the United States.[85] The pathogenesis of fulminant hepatitis associated with HBeAg-negative HBV mutants may involve viral factors that lead to enhanced viral replication and widespread infection of hepatocytes during acute infection. In support of this view, an HBV strain implicated in an outbreak of fulminant hepatitis B was shown to exhibit the phenotype of enhanced replication in tissue culture.[86] Specific naturally occurring mutations in the HBV core promoter (C1766T and T1768A) were found to be responsible for the enhanced replication of this particular variant via increased viral encapsidation of pregenomic RNA into the core particles.[87,88] A more common core promoter variant (A1762T/G1764A) has also been demonstrated by many investigators to moderately enhance viral replication.[89] Interestingly, additional mutations in the neighbouring nucleotides of the core promoter region (C1766T, T1768A, T1753C) have been shown to further enhance viral replicative capacity and alter HBeAg expression.[90] Taken together, these data suggest that multiple mutations may contribute to an increase in viral replication fitness implicated in the pathogenesis of fulminant course of hepatitis B.[91,92] In addition to viral factors that enhance viral replication, the lack of HBeAg production may also play an important role in the immunopathogenesis of fulminant hepatitis B. The absence of HBeAg, which has immunoregulatory property, may result in an exclusively Th1-like, proinflammatory response in the context of acute infection.[93,94] Furthermore, by sharing antigenic epitopes with the core protein, secreted HBeAg may downregulate the inflammatory response directed at the HBcAg by serving as a decoy to buffer anti-core protein immune response. In summary, a vigorous and extensive immune response in conjunction with enhanced viral replication may then lead to massive liver injury and ultimately fulminant hepatic failure.[93]

In addition to mutations affecting HBeAg production, other mutations in the HBV genome associated with fulminant hepatitis B have included HBV variants encoding changes in the core protein,[95] the pre-S2 gene[96] and S gene.[97,98] The role of HBV genotypes in fulminant hepatitis has recently been investigated. A study from Japan found an increase in frequency of HBV genotype B among patients with acute hepatitis B with a fulminant course.[99] Preliminary data from the US Acute Liver Failure Study group noted a higher prevalence of HBV genotype D among patients with HBV-related acute liver failure in comparison with the background distribution (32% vs 16%).[100] These viral factors, either alone or in various combinations ,and the interaction between the virus and host immune response are probably important in the development of fulminant hepatitis B.

## Hepatitis C virus (HCV)

HCV is an RNA virus of the Flaviviridae family and is the sole member of the genus Hepacivirus. It has a single-stranded RNA genome that is approximately 9.6 kilobases in length and encodes a single, large polyprotein of about 3000 amino acids. Hepatitis C infection is the most common chronic blood-borne infection in the USA with an estimated prevalence of 1.8%. HCV transmission occurs primarily through exposure to infected blood (injection drug use, blood transfusion before 1992, transplantation of solid organs from infected donors, unsafe medical practices, birth to an infected mother, sex with an infected partner). Transmission from blood products and organ transplants was virtually eliminated by the introduction of a more sensitive test for antibody to HCV (anti-HCV) in mid-1992. The incidence of

HCV infections declined sharply in the late 1980s. Currently, approximately 35 000 new HCV infections are estimated to occur each year. Most (68%) newly acquired cases of hepatitis C are related to injection drug use.[101] Only about one-third of adults with acute HCV infection develop clinical symptoms and jaundice.[102] Acute hepatitis C can be severe and prolonged but is rarely fulminant. Two deaths (0.1%) were observed among the 1536 cases of acute hepatitis C from 1995 to 2000 in Italy.[38] In a study involving 308 consecutive patients with ALF admitted to 17 tertiary care liver centres in the USA from 1998 to 2001, no cases of fulminant hepatitis C were identified.[6] In addition, HCV infection does not appear to play an important causative role in patients with fulminant hepatitis of indeterminate cause in the USA and Europe.[49,103–107] In several case series from Europe and the USA, HCV RNA was rarely detected in serum or hepatic tissue of patients with ALF of presumed viral origin but with no markers of HAV or HBV (non-A, non-B fulminant hepatitis). The prevalence of anti-HCV or serum HCV RNA among cases of non-A, non-B fulminant hepatitis from the USA and Europe is approximately 2% (range 0–12%)[49,103–107] with one exception: a study conducted in California reported a prevalence of 60% associated with low socio-economic status and Hispanic ethnicity.[108] In contrast, HCV infection appears to play a more prominent role in fulminant hepatitis in the Far East. Antibodies against HCV (anti-HCV) or serum HCV RNA were found in 40–60% of patients with non-A, non-B fulminant hepatitis in Japan and Taiwan.[109–111] Whether these discrepancies reflect geographic differences in the epidemiology of HCV infection or the pathogenicity of the prevalent viral strains is not known.

Dual infection with HBV and HCV has been observed in patients with fulminant hepatitis. A study from France[49] found that eight of seventeen (47%) patients with HBV-related fulminant hepatitis also had evidence of HCV infection. Some patients appeared to have acute HBV and HCV co-infection, while others were chronic HBV carriers with HCV superinfection. The findings of HCV RNA in the serum and liver tissue with negative results for anti-HCV among cases of HBV-related fulminant hepatitis indicated the presence of acute HCV co-infection or superinfection. A study from Taiwan also noted HCV superinfection in nine of forty-six (20%) chronic HBV carriers who presented with fulminant hepatitis.[111] Fulminant hepatitis due to reactivation of hepatitis C after withdrawal of chemotherapy has been reported among patients with underlying chronic HCV infection in Italy.[112] This presentation has been observed rarely and is far less common than reactivation of hepatitis B after withdrawal of chemotherapy.

Detection of serum HCV RNA is the earliest marker for the diagnosis of fulminant hepatitis C. In acute hepatitis C, HCV RNA can be detected in the serum in most cases within 1–2 weeks after exposure.[102] Anti-HCV is not a reliable test in the diagnosis of acute hepatitis C and is often negative in fulminant hepatitis C, possibly due to the extremely rapid course of the disease. In contrast to fulminant hepatitis B where HBV replication is barely detectable, fulminant hepatitis C is characterized by high levels of viraemia.[113] Viral factors and host immune response may play an important role in the pathogenesis of fulminant hepatitis C. Analysis of HCV isolates from patients with fulminant hepatitis C showed a remarkably low degree of genetic diversity, whereas in those who evolved into chronic hepatitis C, there was considerable diversity.[114] These data suggest that in fulminant hepatitis C, there is a trend to preserve the unique fitness of a particular viral variant, which supports the hypothesis that the inherent virulence of a specific HCV strain may lead to massive hepatocellular injury.[114] A case report of an unusual HCV strain causing two episodes of fulminant hepatitis in a single patient and severe acute hepatitis in a chimpanzee after inoculation by serum from the index patient also supports this view.[115]

## Hepatitis delta virus (HDV)

HDV is a negative-strand RNA virus that depends on a DNA virus, HBV, for propagation. It is the sole member of the genus Deltavirus of the Deltaviridae family. The HDV virion particle is a unique subviral pathogen made of circular HDV RNA and hepatitis D antigen (HDAg) coated by HBsAg. Three major genotypes have been characterized and associated with different geographic locations and clinical phenotypes.[116] HDV genotype III is associated with a severe and fulminant course of hepatitis D in countries in northern South America (Columbia, Venezuela, Peru and Ecuador).[117,118] HDV is spread in the same ways as hepatitis B, through parenteral or sexual exposure to blood or body fluids. Delta hepatitis has a worldwide distribution, but areas of dramatically high endemicity associated with severe clinical outcomes have been identified in the Amazon basin, Central Africa, and parts of Eastern Europe.[119–122] Most cases of acute icteric HDV infection among indigenous people in the Amazon basin of South America appear to be HDV superinfection in chronic HBV carriers rather than HDV and HBV co-infection. Prevention of hepatitis B will also prevent hepatitis D. In a triumph of public health, increasing vaccination rates for hepatitis B are contributing to the decline in HDV incidence in developed countries. In Italy, the prevalence of anti-HDV among HBsAg carriers has declined steadily from 23% in 1987 to 14% in 1992 and 8.3% in 1997.[123] Consequently, cases of fulminant hepatitis from HDV infection are becoming less common in southern Europe. The clinical presentation of severe acute hepatitis D that rapidly progresses

to liver failure commonly observed in southern Europe in the 1970s appears to be extremely rare in recent years. The majority of current HDV cases are those who were infected years ago and are now left with chronic mild liver disease, or those who rapidly advanced to cirrhosis but subsided with stable clinical conditions for more than a decade.[124]

Both co-infection with HBV and HDV and superinfection with HDV in individuals with pre-existing HBV infection have been associated with development of fulminant hepatitis.[125] The diagnosis of HBV/HDV co-infection relies on the presence of HBsAg, anti-HBc IgM and antibody to HDV IgM. HDV RNA can be detected in serum very early in the course of infection and quickly disappears with resolution of disease. Superinfection usually results in overt hepatitis in inactive HBsAg carriers and may rapidly lead to liver failure in carriers with pre-existing chronic hepatitis B.[43] The diagnosis is based on the early presence of HDV viraemia and presence of both IgG and IgM forms of antibody to HDV, while anti-HBc IgM is usually absent or present in low titres.[126] In acute HDV superinfection in tropical countries, hepatic histology may include intense microvesicular steatosis associated with conspicuous eosinophilic necrosis of the hepatocytes.[127,128] This pattern of liver injury has been rarely observed in Western countries.[129]

## Hepatitis E virus (HEV)

Hepatitis E, previously known as enterically transmitted non-A, non-B hepatitis, is a distinct clinical entity that was first recognized in the 1980s. HEV is a non-enveloped, 32–34-nm diameter RNA virus with a single-stranded, 7.5-kb RNA. HEV is responsible for large epidemics of acute hepatitis and a proportion of cases of sporadic hepatitis in the Indian subcontinent, south-east and central Asia, the Middle East, parts of Africa and Mexico. The virus is excreted in faeces and is transmitted by faecal-oral route. Most reported outbreaks have been related to the consumption of faecally contaminated drinking water.

The clinical manifestations of acute hepatitis E are similar to those of acute infection with other hepatitis viruses. In a small proportion of cases, disease is more severe and can rapidly progress to fulminant hepatic failure and death. The case-fatality rate of acute hepatitis E has ranged from 0.5% to 4%.[130] In endemic areas, HEV infection is an important cause of fulminant hepatitis. HEV infection is the most common aetiological agent in sporadic cases of ALF in India.[14,20] In a series of 180 patients with ALF from Kashmir during an observation period from 1989 to 1996, hepatitis E virus was found to be the causative agent in 79 (43.9%) patients.[14] In another series from a different region in India, among 264 patients with ALF who had no serological evidence of HAV or HBV infection (non-A, non-B fulminant hepatitis), HEV could be implicated as the causative agent in 62%.[13] HEV infection either alone or in combination with HAV is also an important cause of ALF among children in India and accounts for 60–90% of fulminant hepatitis cases in some areas.[20,131] In Western countries, HEV has occasionally been implicated in a relatively small number of sporadic cases of non-A, non-B fulminant hepatitis.[107,132] In some cases, no risk factor such as recent travel to endemic area could be identified.

Interestingly, pregnant women, particularly those in the second and third trimesters, are more frequently affected during hepatitis E outbreaks and have a worse outcome. This similar pattern has also been observed in sporadic cases of HEV infection.[133] A significant proportion of pregnant women with acute hepatitis E (up to 70%) progress to ALF with a short pre-encephalopathy period, rapid development of cerebral oedema and high occurrence of disseminated intravascular coagulation.[133] The mortality rate for acute HEV infection among pregnant women is high and has ranged from 15% to 25%.[134–137] The reasons for the high prevalence rate of HEV among pregnant women in endemic areas with particularly rapid and fulminant course remain largely unknown.

## Putative new hepatitis viruses

### GB virus C/hepatitis G virus

GBV-C/HGV belongs to the family of Flaviviridae and consists of a linear, positive, single-stranded RNA molecule comprising about 9500 nucleotides. GBV-C/HGV is globally distributed and the presence of viral RNA in healthy blood donors varies widely by geographic region, ranging from 0.6% to 11%. The prevalence is 1–2% among US blood donors. GBV-C/HGV is transmitted through blood transfusion. An association between HGV and fulminant hepatitis has been reported in earlier studies.[138–140] A study from Germany noted a specific strain of GBV-C/HGV associated with fulminant hepatitis.[140] A correlation between serum levels of GBV-C RNA and the serum ALT levels in three patients with fulminant hepatitis has also been documented in a study from Japan.[141] However, despite these intriguing observations, most subsequent studies have failed to demonstrate an association between GBV-C/HGV infection and fulminant hepatitis.[142–146] It has been shown in several studies that the finding of HGV RNA in serum from these patients is likely related to the administration of blood product transfusion after the onset of fulminant hepatitis.[146] Therefore, GBV-C/HGV does not appear to be causally related to non-A to E fulminant hepatitis.

### TT virus (TTV)

The TT virus subfamily consists of small, non-enveloped, single-stranded, circular DNA viruses in the Circoviridae family. TTV was discovered in 1997 by representational difference analysis performed in Japan on samples obtained before and after hepatitis from five patients with transfusion-associated hepatitis.[147] TTV can be transmitted by both parenteral and faecal-oral routes. It is now known that TT viraemia is very common in apparently healthy persons throughout the world. To date, no convincing evidence has been found that TTV plays a pathogenic role in humans. TTV does not appear to cause acute hepatitis or fulminant hepatitis.[148–152]

### SEN virus (SENV)

SENV is a small, non-enveloped, single-stranded, circular DNA virus, which belongs to the Circoviridae family and appears to be related to the TTV family. Two SENV variants (SENV-D and SENV-H) have been studied most extensively. In the National Institutes of Health (NIH) prospective study of transfusion-associated hepatitis,[153] SENV-D and -H were found in nearly 2% of US blood donors and were unequivocally transmitted by transfusion and frequently persisted. SENV was demonstrated in 11 (92%) of 12 cases of acute transfusion-transmitted non-A to E hepatitis. However, the vast majority of SENV-infected recipients did not develop hepatitis. Whether SENV plays a direct causal role in post-transfusion hepatitis remains uncertain. In a recent study,[154] two SENV variants (SENV-D and SENV-H) were detected by PCR amplification in 1706 patients and control subjects from different geographic locations (the USA, Europe and Asia). SENV was detected in 54 (22%) of 248 patients with acute or chronic non-A to E hepatitis, 9 (35%) of 26 patients with hepatitis-associated aplastic anaemia, and none of 17 patients with cryptogenic acute liver failure, compared with 150 (24%) of 621 control subjects with liver disease and 76 (10%) of 794 healthy control subjects. When controlling for geographic region, the prevalence of SENV among case and control subjects was not significantly different. Therefore, currently there is no evidence to indicate that SENV is a cause of fulminant hepatitis, hepatitis-associated aplastic anaemia, or cryptogenic chronic liver disease.

## Non-hepatotropic viruses

### Herpes simplex virus (HSV)

Hepatitis secondary to infection with HSV is a rare, frequently fatal disease with less than 100 reported cases in the literature.[155] HSV hepatitis can present during primary or recurrent HSV infection. Either type 1 or type 2 HSV can cause fulminant hepatitis, usually as part of disseminated infection. Most adults with fulminant HSV hepatitis are either immunosuppressed or pregnant, although cases of HSV hepatitis in immunocompetent adults have been reported.[155,156] Underlying conditions typically associated with fulminant HSV hepatitis include renal or bone marrow transplantation, use of corticosteroids, autoimmune disorders or pregnancy, usually in the second or third trimester.[157–161] The clinical features of HSV hepatitis are non-specific and the diagnosis is often delayed.[155–157] The diagnosis of HSV hepatitis was made *ante mortem* in fewer than 25% of published cases. Fever is present in 75% of cases. Other symptoms include anorexia, nausea, vomiting and abdominal pain. Typical mucocutaneous lesions may be absent in 31–67% of patients. Leukopenia is present in 43–67% and thrombocytopenia in 45–90%. Disseminated intravascular coagulopathy is frequent. Despite markedly elevated serum aminotransferase levels, most patients (up to 90%) are anicteric.[155–157] A diagnosis of HSV hepatitis should be considered in patients with ALF who present with fever, leukopenia and marked elevation of serum aminotransferase levels with minimal hyperbilirubinaemia in the absence of any other obvious cause of fulminant hepatitis.[155–157]

The definitive diagnosis of HSV hepatitis is based on liver biopsy. Histological findings include irregular zones of confluent haemorrhagic necrosis and characteristic viral inclusions and nuclear changes in hepatocytes surrounding the necrotic areas.[155–157] HSV can be demonstrated in the liver tissue by immunohistochemical staining with antibody against HSV protein.[160] HSV may also be identified in other sites (blood and mucocutaneous lesions) by a PCR assay and viral culture. As tests for IgM antibody against HSV may be negative in patients with reactivated infection and early primary infection, serological findings may be used to support the diagnosis but cannot be used to exclude it. Thorough examination of mucocutaneous tissues and testing of suspicious-appearing lesions and use of liver biopsy will likely lead to early diagnosis and increase the likelihood of survival. In most case series, a high index of suspicion and early use of antiviral therapy (acyclovir) have been shown to improve survival.[161,162] Without antiviral therapy, the mortality rate from fulminant HSV hepatitis exceeds 80%. Successful orthotopic liver transplantation in cases of fulminant HSV hepatitis has been reported.[163,164]

### Cytomegalovirus (CMV)

CMV hepatitis occurs as part of disseminated CMV infection. It occurs mainly among liver or kidney transplant recipients or immunosuppressed persons,[165,166] although cases of CMV hepatitis in immunocompetent hosts have

been reported.[167,168] It is the most frequent manifestation of CMV tissue invasive disease after liver transplantation.[165,169] The incidence of CMV hepatitis after liver transplantation is approximately 2%,[169] much lower than in an earlier report.[165] The frequency of systemic CMV infection is higher in CMV-seronegative recipients of CMV-seropositive grafts, after OKT3 treatment and HLA-DR matched livers.[169] Liver biopsy is required to establish the diagnosis of CMV hepatitis.[170] Antiviral treatment with intravenous gancyclovir is an effective therapy for disseminated CMV infection.[165,168,169] CMV has not been found to be a common aetiological agent in cases of fulminant hepatic failure of indeterminate cause.[54,171]

## Epstein-Barr Virus (EBV)

Liver function test abnormality is common in infectious mononucleosis. Serum aminotransferase values are usually mildly elevated in the range of two to three times the upper limit of normal.[172] Mild elevation of bilirubin level is noted in approximately 45% of cases, although frank jaundice occurs in only about 5%.[172] Severe or fulminant EBV hepatitis is rare and can occur in both immunocompromised and immunocompetent hosts.[173–176] Clinical manifestations include high fever, sore throat, lymphadenopathy, malaise and atypical lymphocytosis, which is usually more pronounced than in other types of viral hepatitis. The diagnosis can be established by a positive heterophile antibody test (Monospot test) or demonstration of EBV-specific antibodies. Detection of EBV DNA in liver tissue of patients with non-A, non-B fulminant hepatitis has been reported. However, the prevalence is not different to control samples from patients undergoing transplantation for other reasons.[54]

## Varicella zoster virus (VZV)

Varicella, usually a benign infection of childhood, is known to be associated with more serious complications, especially in adults and immunocompromised patients. Of these, varicella pneumonitis is the most common. Elevation of serum aminotransferases without clinical hepatitis is commonly observed in children with uncomplicated varicella.[177] However, clinical hepatitis is uncommon and has been infrequently reported among adults with primary varicella and pneumonitis. All cases of fatal varicella hepatitis have been described in immunocompromised patients[178–180] with only one reported case in an immunocompetent individual.[181] Most fatal cases of varicella hepatitis presented with typical generalized maculopapulovesicular rash with other visceral organ involvement.[178–181] Liver histology revealed multiple coagulative necrosis with haemorrhage. Intranuclear viral inclusions and multinucleate giant cells may be seen around necrotic areas.[181] Successful therapy with acyclovir in a patient with fulminant varicella hepatitis has been reported.[182] An unusual case of fulminant varicella hepatitis caused by reactivation of VZV infection has been described.[183]

## Parvovirus B19

Parvovirus B19 has been suggested as a possible cause of fulminant hepatitis[184,185] and hepatitis-associated aplastic anaemia.[186,187] Aplastic anaemia is a rare but well-recognized complication of acute hepatitis and ALF, especially among children who undergo liver transplantation for fulminant non-A, non-B hepatitis. In a study from the USA,[188] aplastic anaemia developed in six of eighteen (33%) children and one of nineteen (5%) adults who underwent liver transplantation for fulminant non-A, non-B hepatitis. In another study from the UK,[189] bone marrow failure occurred in 10.7% of children with acute liver failure. Among eight patients who had evidence of bone marrow failure, two had parvovirus B19 and six had non-A, non-B, non-C hepatitis. The role of parvovirus B19 in the pathogenesis of fulminant hepatitis and hepatitis-associated aplastic anaemia remains controversial. In a more recent study,[190] parvovirus B19 was detected in some liver tissue samples from patients with fulminant hepatitis (four [27%] of fifteen patients), but not at a significantly higher prevalence than in hepatic tissue from patients with non-viral liver disease (three [14%] of twenty-two patients). A confirmatory test was performed in a second group of liver tissues. Parvovirus B19 was present in eight (35%) of 23 liver tissue samples from patients with fulminant hepatitis and in ten (33%) of thirty livers from patients with known HBV and/or HCV infections. Importantly, parvovirus B19 viral transcripts were not detected in any of the parvovirus B19-positive liver tissues, arguing against the presence of active viral replication. Therefore, parvovirus B19 may be an innocent bystander and play no direct causal role in the development of fulminant hepatitis.[190]

## Other viruses

Fulminant hepatitis due to *adenovirus* has been reported as part of disseminated infection in bone marrow or liver transplant recipients.[191,192] As there is no specific antiviral therapy, mortality rate remains high.[193] Histologically, adenovirus hepatitis is characterized by small or large areas of coagulative necrosis with no particular zonal distribution. Inflammatory response is usually sparse or absent. Intranuclear viral inclusions with smudgy appearance and chromatin margination are characteristic.[194] Immunohistochemical examination of a liver biopsy and culture of liver tissue and blood can help confirm the diagnosis.[194] *Enterovirus* (Coxsackie vi-

rus, echo virus) infection can cause fulminant hepatitis in neonates.[195,196] It is associated with coagulopathy and in some cases, myocarditis[197] and carries high morbidity and mortality. *Human herpes virus-6* (*HHV-6*)-associated fulminant hepatitis has been described.[198,199] Some cases of fulminant non-A, non-B, non-C hepatitis may be caused by HHV-6. In a study from Finland, HHV-6 was found in 12 (80%) of 15 explanted livers of patients with ALF of unknown cause. Most of these patients (10/12) also demonstrated HHV-6 antigenaemia.[200] In another study, HHV-6 was detected in 7 (64%) of 11 Japanese paediatric patients with fulminant non-A, non-B, non-C hepatitis.[171] However, HHV-6 was not detected in any of the liver tissue samples from liver transplant recipients with fulminant non-A, non-B, non-C hepatitis from North America.[54] Other viruses implicated as aetiological agents in fulminant hepatitis include *toga virus-like particles*,[201,202] *paramyxoviruses*[203–205] and other *flaviviruses* (*yellow fever virus*, *dengue virus*).[206,207]

# Chapter 44
# Treatment of fulminant hepatitis

Kinan Rifai, Hans L Tillmann, Michael P Manns

## Definition of fulminant hepatitis

Fulminant hepatic failure (or acute liver failure) is a rare, but dramatic clinical syndrome associated with a high mortality. Diagnosis of fulminant hepatic failure is based on three criteria that have to be met to fulfil its definition.[1,2]

**1** Acute disturbance of liver function with coagulopathy and jaundice.
**2** Exclusion of chronic liver disease.
**3** Presence of hepatic encephalopathy.

Hepatic encephalopathy distinguishes fulminant hepatic failure from *fulminant hepatitis* which is defined as a severe form of acute hepatitis. In the past, several authors used the term fulminant hepatitis as a synonym for fulminant hepatic failure. However, the distinct definitions are relevant for the spontaneous prognosis that is excellent in severe acute hepatitis and unfavourable in most cases of fulminant hepatic failure.

Exclusion of chronic liver disease is important, as three principal differences in the management of fulminant hepatic failure and acute-on-chronic liver failure exist.

**1** A different diagnostic approach, as acute decompensation of chronic liver disease can be triggered by other factors (e.g. spontaneous bacterial peritonitis).
**2** A different monitoring, as patients with fulminant hepatic failure develop other complications than those with acute-on-chronic liver failure (e.g. cerebral oedema).
**3** A different therapeutic approach, as only patients with fulminant hepatic failure are eligible for emergency liver transplantation (depending on the allocation system).

Depending on the interval between onset of jaundice and onset of hepatic encephalopathy, various definitions of liver failure with a different prognosis are used. In general, a shorter interval is associated with a better prognosis for the patient. According to the most widely used definition, *fulminant hepatic failure* has an interval of <2 weeks between onset of jaundice and encephalopathy.[3,4] *Subfulminant hepatic failure* is present if hepatic encephalopathy develops >2 weeks after the appearance of jaundice.

Another definition was introduced by O´Grady *et al*. and differentiates more precisely between *hyperacute liver failure* (interval jaundice to encephalopathy <7 days), *acute liver failure* (interval 7–28 days) and *subacute liver failure* (interval >4 weeks).[5] Recently, the International Association for the Study of the Liver (IASL) recommended another modified definition differentiating between *acute* (interval <4 weeks) and *subacute hepatic failure* (interval 4 weeks to 6 months).[5a]

Table 44.1 gives an overview of the different types of liver failure with their main clinical characteristics.

## Aetiology of fulminant hepatitis

Different aetiologies for fulminant hepatic failure are described in more detail in Chapter 43. They deserve to be mentioned briefly because specific treatments are discussed for certain aetiologies (see Table 44.2).

Several viruses are capable of inducing a fulminant liver disease, especially the hepatitis viruses A, B, D and E. There have been reports of fulminant hepatitis in relation to hepatitis C virus (HCV) infection. In recent times, non-viral factors have become more frequent while the incidence of viral fulminant hepatitis has decreased due to a wider distribution of vaccinations and other preemptive measures like the use of condoms.

### Hepatitis A virus

Hepatitis A virus (HAV) infection is mostly a harmless infection when acquired in childhood, with mortality increasing with patient's age and leading to death in approximately 2.5% of patients aged over 49 years.[6] However, vaccination against HAV could prevent both infection and disease.

### Hepatitis B virus

Although hepatitis B virus (HBV) infection is on the de-

**Table 44.1** Clinical characteristics of different types of liver failure

| Clinical charcteristics | Fulminant hepatitic failure | Subfulminant hepatitic failure | Fulminant hepatitis | Acute-on-chronic liver failure |
|---|---|---|---|---|
| Chronic liver disease | – | (+) | (+) | +++ |
| Hepatic encephalopathy | +++ | ++ | – | ++ |
| Interval from jaundice until HE | <2 weeks | >2 weeks | No encephalopathy | Different |
| Cerebral oedema | +++ | ++ | – | + |
| Infections | +++ | ++ | (+) | ++ |
| Renal failure | ++ | +++ | (+) | ++ |
| Circulatory failure | +++ | +++ | – | ++ |
| Respiratory failure | ++ | +++ | – | ++ |
| Hypoglycaemia | +++ | ++ | + | ++ |
| Survival without OLT | Bad | Very bad | Very good | Bad |

HE, hepatic encephalopathy; OLT, orthotopic liver transplantation.

cline, it is still a major factor in the aetiology of fulminant hepatitis.[7] Infection with HBV could be prevented by active immunization, which should be available to everyone. However, active vaccination programmes vary geographically.

## Hepatitis C virus

The hepatitis C virus (HCV) is found in most cases of non-A, non-B acute or chronic hepatitis. However, its role in fulminant hepatitis is still controversial (see Chapter 25). Cases have been reported from Japan[8] but very rarely from Western countries. In >300 patients treated for fulminant hepatitis in northern Germany, no HCV infections were observed.

## Hepatitis delta virus

Hepatitis delta virus (HDV) infection requires ongoing HBV infection. Co-infection and superinfection with HDV can both lead to fulminant hepatic failure.[9]

## Hepatitis E virus

Apart from rare cases, hepatitis E virus (HEV) infection on its own is not widespread in the Western world, nor is HEV-induced liver failure. However, it always has to be kept in mind for differential diagnosis in hepatitis A–D. A particular problem is the high rate of fulminant hepatitis in cases of HEV infection during pregnancy.[10,11]

## Other viral infections reported in relation to fulminant hepatitis

Herpesviridae have been associated with hepatitis, but are rarely found in fulminant hepatitis.[12] However, herpes virus simplex I and II (HSV-1, HSV-2) as well as cases of Epstein-Barr virus (EBV), varicella zoster virus (VZV) and human herpes virus 6 (HHV-6) infection have been described.[13–16] Additionally, adenovirus infections have been attributed to fulminant hepatitis, especially in immunosuppressed or paediatric patients.[17,18] In neonates,

**Table 44.2** Types of viral infections in fulminant hepatitis

| Types of virus | Main characteristics |
|---|---|
| Hepatitis A | More frequent with higher age |
| Hepatitis B | Still the most frequent viral cause of fulminant hepatitis |
| Hepatitis C | More frequent in Asia than in Europe and North America |
| Hepatitis D | Requires HBV co-infection |
| Hepatitis E | Especially severe in pregnancy |
| Herpesviridae | Rare |
| Coxsackie virus | Rare, in neonates |
| Adenovirus | Rare, in immunosuppressed patients |
| Parvovirus B19 | Might be associated with aplastic anaemia |
| Haemorrhagic fever viruses | Rare |

Coxsackie virus B infection may present itself as fulminant hepatitis.[19] The role of parvovirus B19, previously reported in relation to fulminant hepatitis,[20] has recently been questioned.[21] Finally, the haemorrhagic fever viruses such as dengue, Lassa, Ebola and yellow fever may also induce fulminant hepatitis. However, fulminant hepatitis is usually not the most important clinical factor in these diseases.

Two viruses presumed to be associated with viral hepatitis, the TTV (transfusion-transmissible virus) and the GB virus C (also known as hepatitis G virus) are not associated with fulminant hepatitis or with hepatitis at all.[22] Even though initial studies suggested a role of GB virus C in fulminant hepatitis,[23,24] this was not confirmed in subsequent larger studies.[25–27]

There is no available evidence reporting cases of acute liver failure in cytomegalovirus (CMV) infection, even though it is a well-known hepatotropic virus. On the other hand, other unknown viruses might be involved in cases of cryptogenic fulminant hepatitis when no known virus can be detected.[22]

### Non-viral factors

Non-viral factors contributing to fulminant hepatitis are mainly paracetamol (acetaminophen) intoxications due to intentional but also unintentional overdosing. It is now the most frequent cause of fulminant hepatitis in developed countries. Furthermore, Wilson's disease, intoxication of *Amanita phalloides* as a result of mushroom poisoning, fatty liver during pregnancy, acute Budd-Chiari syndrome, ischaemic liver failure, autoimmune hepatitis and a number of drugs such as halothane and isoniazid have been implicated in the aetiology of fulminant hepatitis. Finally, general sepsis, hyperthermia, malignant infiltration of the liver and Reye's syndrome may, in rare cases, resemble the clinical spectrum of fulminant hepatitis.

## Complications in fulminant hepatitis

Basically, prognosis of fulminant hepatitis depends on halting further cell damage and on the replication capacity of hepatocytes. However, extrahepatic complications frequently determine the prognosis of patients with fulminant hepatitis.[28] Organ involvement depends on the dynamics and aetiology of liver failure. Host defences are compromised as a consequence of increased toxic substances in the blood due to liver dysfunction and hepatocyte necrosis. This enables infections with activation of immune mechanisms (e.g. cytokine release) further worsening tissue hypoxia. The consequence is damage to a number of organs resulting in multi-organ failure.

Strategies to avoid complications include close monitoring and prophylactic treatment as well as unspecific and, if feasible, specific therapeutic interventions. An overview of the main complications with their pathophysiological basis, the recommended monitoring and potentially beneficial therapy is given in Table 44.3.

### Hepatic encephalopathy and cerebral oedema

Cerebral oedema is the main cause of death in fulminant

**Table 44.3** Complications in fulminant hepatitis

| Complication | Pathophysiology | Monitoring | Therapeutic possibilities |
|---|---|---|---|
| Hepatic encephalopathy, cerebral oedema | Circulating toxins, blood-brain barrier dysfunction, loss of autoregulation of cerebral blood flow | Clinical grading, EEG, cranial CT scan, epidural ICP catheters | Mannitol, hyperventilation, hypothermia, lactulose, gut lavage, ornithine-aspartate, barbiturates, flumazenil, ranitidine, phenytoin |
| Coagulopathy | Reduced hepatic biosynthesis, platelet dysfunction | Coagulation profiles | Fresh frozen plasma, AT III, acid suppression |
| Infections | Reduced hepatic clearance, fibronectin deficiency, use of synthetic catheters | Microbiological surveillance | Intestinal decontamination, broad-spectrum antibiotic and antimycotic prophylaxis |
| Renal failure | Hypovolaemia, parenchymal ischaemia, direct nephrotoxicity, acid-base disturbances | CV catheter, electrolytes, blood pH, base excess | Volume control, electrolytes, renal replacement therapy, bicarbonate infusion |
| Circulatory failure | Splanchnic vasodilatation, low systemic blood pressure | CV catheter, PAC or PiCCO | Volume control, catecholamines |
| Respiratory failure | Pulmonary shunting, oedema, ARDS, pneumonia, aspiration | X-ray, blood gas analyses | Oxygen, antibiotics, volume control, mechanical ventilation |
| Metabolic abnormalities | Hypercatabolism, reduced hepatic metabolism | Blood glucose test, serum triglycerides | I.v. glucose, parenteral and enteral nutrition |

ICP, intracranial pressure; CV, central-venous; PAC, pulmonary artery catheter; PiCCO, pulse-induced contour cardiac output system; ARDS, adult respiratory distress syndrome; AT III, antithrombin III; EEG, electroencephalogram; CT, computed tomography.

hepatic failure. It can be found in 80% of patients with advanced hepatic encephalopathy. Encephalopathy differentiates fulminant hepatic failure from severe acute hepatitis. The pathophysiological basis is multifactorial and includes various circulating toxins that impair neuronal function and damage the blood-brain barrier.[29,30] Among them, ammonia plays a crucial role. In fulminant hepatic failure, increased ammonia levels induce astrocyte swelling by glutamine accumulation which cannot be compensated as in chronic liver failure.[31] Only at the initial stage, astrocyte swelling is partially balanced by a reduction of intracranial cerebrospinal fluid. Later on, cerebral perfusion is impaired by a loss of its autoregulation[32] and by progressive cerebral oedema with increasing intracranial hypertension. Finally, brainstem herniation and death of the patient may follow.

Hepatic encephalopathy is graded according to the West Haven criteria shown in Table 44.4.[33] Clinical signs of cerebral oedema are systemic hypertension, increased muscle tone which may progress to decerebrate postures, pupillary abnormalities and seizures. In fulminant hepatic failure, subclinical seizure activity is increased.[34] Therefore, systematic electroencephalography (EEG) controls are recommended for all patients, not only in those presenting seizures or requiring mechanical ventilation.

To exclude cerebral bleeding, a cranial computed tomgraphy (CT) scan may be necessary. Even though it is helpful to detect cerebral oedema, indication for a CT scan should be carefully evaluated. It has to be considered that any procedure that includes moving the patient could potentially increase intracranial pressure.

Direct quantification of intracranial pressure (ICP) can be best performed by epidural ICP monitoring catheters.[35] However, their use is associated with specific risks such as bacterial infection (especially gram-positive strains) or intracranial bleeding.[36] To date, no controlled clinical trials have been published demonstrating a beneficial effect of epidural catheters. Therefore, they are only recommended for patients waiting for liver transplantation with hepatic encephalopathy of at least grade III. In addition, cerebral oxygen supply can be estimated by jugular bulb oxygen saturation measurement.[37]

Therapy of hepatic encephalopathy aims to ensure a sufficient cerebral perfusion and avoid brainstem herniation. Cerebral perfusion pressure (CPP) should be kept above 50–60 mmHg and is calculated by subtracting intracranial pressure (ICP) from mean arterial pressure (MAP). Therapeutic measures to decrease intracranial pressure are indicated at an ICP >20 mmHg. A poor neurological outcome is associated with a sustained ICP of >40 mmHg.[36,38]

Basic measures involve establishing a quiet environment with minimal interventions. Degree of head elevation is controversially discussed. Some authors recommend only up to 20°, others found a 30° posture preferable.[39,40]

The osmotic diuretic mannitol is the first-line treatment (1–2 g per kg body weight i.v.). It can be given as repeated boluses as long as serum osmolality does not exceed 320 mosmol/L.[41] In patients with renal failure, mannitol should be used with caution and sufficiently haemofiltrated.

Therapeutic hyperventilation leads to cerebral vasoconstriction in ventilated patients. It can be used in incipient cerebral oedema if CPP is maintained at sufficient levels. In advanced cerebral oedema, hyperventilation improves acute intracranial hypertension only for a short period of time.[42,43] Prolonged hyperventilation can aggravate cerebral hypoxia and should be avoided.

Mild hypothermia (body temperature of 32–33 °C) has recently shown positive effects on cerebral oedema that need further confirmation in larger patient series.[44,45]

Lactulose or retention enemas are commonly used to minimize bacterial translocation, but lack supporting controlled data. L-Ornithine-L-aspartate can decrease circulating ammonia levels, but prevention of brain oedema has not been proven.[46,47] Other therapeutic measures without sufficient evidence comprise thiopental that reduces cerebral metabolism and flumazenil that antagonizes endogenous GABA-like toxins.[48,49] If seizure activity is increased, therapy with phenytoin is indicated. Its prophylactic use in encephalopathy of grade III–IV is under discussion, as one study has shown a reduction of cerebral oedema.[34]

Hepatectomy is the *ultima ratio* in desperate situations of patients awaiting liver transplantation. Removal of the 'necrotic liver' can improve cerebral oedema and circulatory parameters.[50,51] However, total loss of liver function after hepatectomy is fatal if liver transplanta-

**Table 44.4** Grades of hepatic encephalopathy

| Grade | Symptoms | Survival |
|---|---|---|
| I | Disturbed sleep, altered personality, reduced concentration capability, asterixis | 70% |
| II | Drowsiness, inappropriate behaviour, dysarthria, temporal and spatial disorientation | 60% |
| III | Arousable stupor, agitation and aggression possible | 40% |
| IV | Coma without response to painful stimuli | 20% |

tion is not performed in time (i.e. during the next few hours to days).

## Coagulopathy

Disturbed hepatic protein biosysnthesis of the majority of coagulation factors and platelet dysfunction cause a severe deterioration of blood coagulation with significant risk of bleedings. In addition, reduced levels of coagulation inhibitors result in an imbalance of coagulation profiles that resembles disseminated intravascular coagulation.[52,53] Up to one-third of patients without substitution of coagulation factors develop spontaneous bleedings. Intracerebral and intra-abdominal bleedings are particularly feared. Even though no supporting data have been published to date, many centres perform a prophylactic substitution of coagulation factors.[54] In every case, correction becomes necessary at the time when overt bleeding develops or before invasive procedures. To avoid a dysequilibrium of the different factors, fresh frozen plasma (FFP) should be used instead of factor concentrates. Only antithrombin III (AT III) is selectively administered to disrupt disseminated intravascular coagulation.[55,56] For prevention of upper gastrointestinal bleeding, consequent acid suppression therapy is recommended.[57]

## Infections

Infections contribute greatly to mortality in fulminant hepatic failure. These patients have an increased infection rate as a consequence of different pathophysiological changes that impair cell-mediated and humoral immunity. The hepatic barrier and clearance function are disturbed, resulting in increased bacterial translocation. Reduced complement levels and especially reduced opsonization caused by a deficiency of fibronectin predispose to infections as well.[58] Furthermore, monitoring and therapy of fulminant hepatic failure require the use of synthetic catheters that are a well-known source of infections.

Bacterial infections can be found in up to 80% of patients with fulminant hepatic failure, in most cases gram-positive strains.[59] As a consequence, systemic inflammatory response syndrome (SIRS) may develop and contribute to intracranial hypertension.[60] The probability of infection is dependent on the length of stay in the intensive care unit.[61] Fungal infections typically appear late in the clinical course, but can be found in up to 30% of patients (especially *Candida* species).[62] They are associated with a high mortality (about 50%). Most infections affect the lungs (50%), other manifestations are solitary bacteraemia, urinary infections and colonization of catheters.[59] Even after liver transplantation, the infection rate in patients transplanted for fulminant hepatic failure is higher than in those transplanted for chronic liver failure.[63]

In many patients, infectious complications remain asymptomatic (30%), i.e. they develop neither fever nor leucocytosis.[59] Therefore, systematic microbiological surveillance is mandatory including chest X-rays and cultures taken from all available body compartments (e.g. blood, urine, sputum).

Because of the high incidence of infections in fulminant hepatic failure, different prophylactic antibiotic combinations have been evaluated in the past. A selective intestinal decontamination (e.g. with paromomycin) can reduce the frequency of infections by bacteria of the intestinal flora.[64] The additional benefit of a selective intestinal decontamination is questionable if systemic antibiotics are administered in parallel.[61] An early broad-spectrum antibiotic prophylaxis reduced the incidence of infections to 20%, and progression of hepatic encephalopathy to advanced cerebral oedema was also significantly reduced.[59] Enteral administration of amphotericin B resulted in reduction of fungal infections to 4%.[61] Prophylactic administration of fluconazole has proven to be effective in the prevention of mycosis.[65]

Even though no survival benefit could be demonstrated to date, antibiotic prophylaxis for all patients with fulminant hepatic failure is recommended. The specific regime should be chosen according to the local microorganism spectrum and resistances.

## Renal failure

Acute renal failure can be observed in nearly half of the patients with fulminant hepatic failure.[66] Those with additional intoxification of acetaminophen (paracetamol) are particularly at risk. The main causes are relative hypovolaemia, parenchymal ischaemia and acute tubular necrosis by direct nephrotoxicity. Metabolic acidosis can be aggravated by acetaminophen toxicity or lactic acidosis resulting from tissue hypoxia and reduced hepatic clearance.

Volume status should be controlled by continuous monitoring with central venous catheters to avoid an increase of intracranial pressure due to volume overload. Electrolyte levels have to be carefully controlled and corrected as well. Especially in case of hypophosphataemia, rapid parenteral substitution is needed. Hyponatraemia is likely to play a role in the development of cerebral oedema and should be avoided.

In case of incipient renal failure, early renal replacement therapy is indicated. Continuous veno-venous haemofiltration (CVVH) seems to be better tolerated and should therefore be preferably used.[67,68] Anticoagulation with heparin should be administered with caution because of the increased risk of bleeding.[69] Novel

dialysis procedures are described in more detail below in the section on extracorporeal liver support devices.

### Circulatory failure

Splanchnic vasodilatation is characteristic of fulminant hepatic failure. As a result, septicaemia is mimicked by increased cardiac output, reduced systemic blood pressure, reduced systemic vascular resistance and reduced vascular filling pressures such as central venous pressure.[70,71] Relative hypovolaemia plays a pathophysiological role in the aetiology of other complications like renal failure. On the other hand, intracranial hypertension can cause an increase of systemic blood pressure.

There are no published data regarding optimal management of volume status in patients with fulminant hepatic failure. Still, monitoring of central venous pressure is mandatory to manage volume replacement therapy. In case of progressive circulatory failure, extended monitoring is provided by pulmonary artery catheters or PiCCO systems (pulse-induced contour cardiac output).

Beside volume replacement therapy with electrolyte solutions, colloid fluids can be administered. They can sometimes be spared in patients receiving fresh frozen plasma to stabilize coagulation. Therapy of peripheral vasodilatation essentially consists of catecholamines. Usually, dopamine is the preferred catecholamine. If it is not sufficient to maintain an acceptable systemic blood pressure, noradrenaline must be administered even though it can further compromise tissue oxygenation.[72]

### Respiratory failure

In patients with fulminant hepatic failure, respiratory failure is often part of multi-organ failure. Usually, it does not develop prior to advanced hepatic encephalopathy. Respiratory failure is associated with a very high subsequent mortality.[73] Arterial hypoxaemia can be caused by intrapulmonary shunting, adult respiratory distress syndrome (ARDS), pneumonia, aspiration, intrapulmonary haemorrhage and pulmonary oedema.[74]

The only therapeutic option is artificial ventilatory support. Elective intubation to prevent aspiration is recommended for patients with hepatic encephalopathy grade III–IV.[71] In case of mechanical ventilation, sedation should be performed with propofol, as it seems to reduce intracranial pressure itself.[75]

### Metabolic derangements

Few controlled data are available regarding nutritional support in fulminant hepatitis. Therefore, it should be performed according to pathophysiological concepts. In contrast to patients with chronic liver diseases, only a minority of patients with fulminant hepatitis do initially present signs of malnutrition. As a result of intracranial hypertension, increased production of endogenous corticosteroids and catecholamines induces a hypercatabolic state with an increased resting energy expenditure.[76] In addition, impaired liver function limits intrahepatic substrate metabolism.[77] On the other hand, reduced gluconeogenesis and depletion of glycogen stores can result in hypoglycaemia. Therefore, repeated tests of blood glucose levels are mandatory.

Blood glucose should be maintained at levels of about 5–10 mmol/L by continuous infusion of 10% or 20% glucose. Lipids and amino acids should additionally be given if parenteral nutrition is necessary for >3 days. Energy supply is recommended for around 30 kcal per kg body weight per day. As a consequence of encephalopathy, amino acids should be administered with caution (0.4–1.0 g/kg/day). The rest of the calculated energy expenditure should be equally divided between glucose and lipids.[78] Lipids can be administered as long as the triglyceride levels remain below 4.0 mmol/L. Hypertriglyceridaemia can also result from overdosing of glucose because of impaired lipid utilization. This may induce acute hepatic steatosis, further worsening disturbed liver function.

Adaptive amino acid solutions were introduced to improve the disturbed amino acid patterns in fulminant hepatitis. They contain a higher proportion of branched chain amino acids and a reduced proportion of aromatic amino acids. Even though successful tests were accomplished in animal models,[79] no controlled studies on the effects of adaptive amino acids in patients with fulminant hepatitis exist.[80]

Enteral nutrition to prevent villous atrophy and to reduce the risk of bacterial translocation is recommended as long as paralytic ileus does not develop. Positive effects of immunonutrition (e.g. with glutamine) are not proven.

## Specific therapy in fulminant hepatitis

Whenever there is evidence for a specific therapy for fulminant hepatitis (see also Table 44.5), this should be initiated as early as possible in addition to standard treatment options for fulminant hepatitis.

A main problem in establishing any specific treatment is the rarity of certain aetiologies of fulminant hepatitis on one hand and the severity of the disease on the other hand. Once there is evidence for a potentially life-saving treatment option with little or no toxicity, a placebo-controlled trial might not be feasible owing to ethical constraints.

**Table 44.5** Specific therapy of viral infections in fulminant hepatitis

| Type of virus | Specific therapy |
|---|---|
| Hepatitis A | No specific therapy available; in case of liver transplantation HAV immunoglobulins should be given to prevent recurrence of hepatitis |
| Hepatitis B | Lamivudine likely to be effective; in case of liver transplantation combination prophylaxis of HBIg and lamivudine should be administered to prevent recurrence of hepatitis |
| Hepatitis C | No specific therapy available |
| Hepatitis D | No specific therapy available |
| Hepatitis E | No specific therapy available |
| Herpesviridae | Acyclovir |
| Coxsackie virus B | No specific therapy available |
| Adenovirus | No specific therapy available |
| Parvovirus B19 | No specific therapy available |
| Haemorrhagic fever viruses | Ribavirin |

## HAV

No specific therapy has been established for HAV infection. The outcome of fulminant hepatitis A was reported to be related to HAV viral load.[81] Therefore, antiviral therapy might be an option in the future, when an effective antiviral against HAV will be available. As there have been reports of persistence of hepatitis A after liver transplantation,[82,83] these patients could benefit from HAV immunoglobulins.

## HBV

For chronic hepatitis B infection, a number of different therapies have been established. The first was interferon (IFN)-α (see Chapter 20), followed by lamivudine and more recently adefovir dipivoxil and entecavir. There is good evidence for an overwhelming immune response in the pathogenesis of fulminant hepatitis B.[84–86] Thus, IFN-α can be dangerous in fulminant hepatitis B due to its immune-stimulating properties.

In contrast, the oral nucleoside analogue lamivudine inhibits hepatitis B viral replication with an immediate decline of serum HBV DNA. Lamivudine has been first reported to successfully prevent death in a few case reports of patients who developed acute decompensation of chronic hepatitis B, and thus were not eligible for high urgency transplantation.[87–91] In addition, one patient series in renal transplant recipients has been published.[92] Even though death was not universally prevented, mortality was lower in treated than in untreated patients. Importantly, these series also indicate that early start of lamivudine therapy appears to be essential.

Based on these reports and on the favourable safety profile of lamivudine, treatment with lamivudine was started in patients presenting severe acute hepatitis B at risk of developing hepatic failure. Treatment was initially aimed at preventing HBV reinfection after liver transplantation. However, only one of nine patients required liver transplantation compared with 16 of 20 from an historic control ($p = 0.002$).[93] All patients cleared HBsAg and normalized liver enzymes. In addition, a recent report showed prevention of further deterioration of liver impairment in three patients with severe acute hepatitis.[94]

In summary, lamivudine appears to be safe in patients with severe acute or fulminant hepatitis B, and may have the potential to prevent liver failure when administered early. It is therefore recommended to start lamivudine within prospective studies in these patients once prothrombin time deteriorates. No data on adefovir dipoxivil or entecavir are available yet.

## HCV

In contrast to acute hepatitis C infection, there are currently no data on any specific treatment option in fulminant hepatitis C. While IFN-α leads to a transaminase peak in hepatitis B, this is rarely seen in HCV infection. Thus, IFN-α might be a theoretical option in fulminant hepatitis C. However, data in relation to immune activation in fulminant hepatitis C are currently lacking. In the future, potent antiviral agents such as proteinase inhibitors or polymerase inhibitors are likely going to play a role. If they could drop the hepatitis C viral load within days, this could be an attractive option. Ribavirin, which is helpful in increasing the response to IFN in chronic infection, has shown little effect when given alone (see Chapter 34). Thus, ribavirin probably would be of very limited help, if any, in case of fulminant HCV infection.

## HDV

There is currently no highly efficient therapy available for chronic hepatitis delta. The only option with limited effect is high dose IFN (see Chapter 38), which again appears to be dangerous in cases of fulminant hepatitis D. Thus, in this disease, supportive care appears to be the

only treatment option beside liver transplantation. Adding lamivudine is not likely to cause any adverse event, and might have a positive effect in increasing clearance of HBsAg, but no such data exist at present.

### HEV

As for HAV infection, there is no established therapy for HEV infection (see Chapter 42). Whether emergency delivery is of any benefit, has not been investigated. Effective antiviral agents are currently unknown.

### Herpesviridae

In case of HSV infections, early diagnosis is required, as in any other cause of fulminant hepatitis. Probably only early intervention with acyclovir holds some promise to alter the course of herpesviridae-associated disease.[16] Otherwise, the diagnosis can often be made only after the patient has died.[95] Likewise, in case of EBV, VZV or HHV-6 infection, therapy with acyclovir probably is a theoretical option, even though clear data are missing to date.

### Specific therapy for non-viral causes of fulminant hepatitis

#### *Paracetamol intoxication*

N-acetylcysteine (NAC) for treatment of paracetamol (acetaminophen) intoxication was the first drug to show a beneficial effect in any cause of fulminant hepatitis.[96] Importantly, it has been shown that early administration is crucial.[97] Currently a dose of 140 mg/kg is given i.v. within 1 hour followed by 70 mg/kg/h.[98]

In addition, paracetamol may contribute to fulminant hepatitis in other causes of acute hepatitis, as patients frequently take paracetamol for their unspecific complaints prior to the clear onset of fulminant hepatitis. Thus, addition of NAC might improve patient survival in general. But prior to a final recommendation, a currently ongoing multicentre trial in the US should be awaited. Nevertheless, most centres currently administer NAC to patients with fulminant hepatitis, especially when there is anamnestic evidence for paracetamol intake prior to the onset of liver disease.

#### *Amanita intoxication*

Therapy with silibinin and penicillin has been established as an antidote for *Amanita phalloides* intoxication. If given in time, silibinin (20–50 mg/kg/day i.v.) and penicillin (300 000–1 000 000 IU/kg/day i.v.) can be curative treatment options to prevent the need for liver transplantation.[99,100]

#### *Wilson's disease*

Wilson's disease is a hereditary failure of copper excretion through the bile, leading to copper overload with subsequent damage to hepatocytes resulting in either chronic liver disease (cirrhosis) or acute liver failure. For patients with chronic Wilson's disease, treatment with d-penicillamine has been proven effective in halting disease progression. One recent report suggests that this medication might also ameliorate the course of fulminant Wilson's disease, circumventing the need for liver transplantation.[101] This has not been confirmed in any other study so far.

#### *Autoimmune hepatitis*

In patients with presumed autoimmune genesis of fulminant hepatitis, steroids may lead to a dramatic improvement, circumventing the need for liver transplantation .[102]

#### *Budd-Chiari syndrome*

Patients with Budd-Chiari syndrome may require treatment with portal decompressive surgery or liver transplantation. Transjugular intrahepatic portosystemic shunt (TIPS) represents a new treatment alternative. Early reports indicate that the procedure can help at least to bridge until liver transplantation.[103,104] In the future, it could help to circumvent the need for transplantation. However, anticoagulation is also required in these patients.

### Specific therapies for rare causes of fulminant hepatitis

Steroids may be helpful in giant cell hepatitis. When malaria falciparum leads to fulminant hepatitis, antimalarials are required. Immediate delivery ameliorates the course of disease in fatty liver of pregnancy. If heart failure leads to ischaemia, recompensation of cardiac function may also restore liver function. In case of malignant infiltration of the liver, chemotherapy is the only causal option.

## Prognosis, liver transplantation and alternative procedures

### Prognosis

Fulminant hepatic failure has a high spontaneous mortality. The likelihood of recovery depends on many factors such as aetiology, age, complications and duration of illness. To estimate survival, two main prognosis

**Table 44.6** Scoring systems for estimation of prognosis in fulminant hepatitis

| Criteria of King's College London | |
|---|---|
| *Paracetamol intoxication* | *Other aetiologies* |
| Arterial pH <7.3 | PTT >100 s (INR >6.7) |
| or all of the following: | Or three of the four following criteria: |
| PTT >100 s | age <10 or >40 years |
| creatinine >3.4 mg/dL | jaundice >7 days before onset of encephalopathy |
| hepatic encephalopathy 3–4° | bilirubin >17.4 mg/dL |
| | unfavourable aetiology (non-A-non-B-hepatitis, drug-induced) |
| French criteria (Clichy)[105] | |
| Factor V <20% and patient age <30 years | |
| Or | |
| Factor V <30% and hepatic encephalopathy 3–4° | |

PTT, prothrombin time; INR, international normalized ratio.

scores were introduced: the King's College Criteria[28] and the French Criteria[105] (detailed in Table 44.6). Both scoring systems aim to predict patients with an estimated mortality of >80%. In these patients, emergency liver transplantation becomes necessary. Specificity of both scores is good, but clinical evaluations have shown a low sensitivity. As a result, many patients who do not fulfil transplant criteria take a fatal course.[106–109] Therefore, more accurate indicators for assessing the prognosis are necessary and several others have already been studied. For instance, unfavourable outcome is indicated by an APACHE II score >15 points or an arterial lactate level of >3 mmol/L.[110,111]

The role of liver biopsy is still controversial.[112–114] As a consequence of coagulopathy, it has to be performed via the more complicated transjugular access. Histological assessment of parenchymal necrosis can be helpful for predicting prognosis and for decisions as to indications for transplantation. Additionally, liver biopsy may be necessary to exclude chronic liver disease or to clarify the aetiology of fulminant hepatitis in unknown cases.

## Orthotopic liver transplantation

Conventional orthotopic liver transplantation (OLT) is the only proven therapy for patients with a severe course of fulminant hepatitis.[115–118] According to the European Liver Transplant Registry (ELTR; http://www.eltr.org), 9% of all liver transplantations in Europe are performed for acute liver failure. This proportion doubles in patients with an age below 45 years.

Correct timing is crucial for indication of liver transplantation in fulminant hepatitis. On one hand, transplantation should be avoided in patients with a realistic possibility of hepatic regeneration. On the other hand, transplantation has to take place before irreversible complications like brainstem herniation develop. To prevent unnecessary loss of time, every patient with fulminant hepatitis should be discussed with a specialized centre for liver transplantation. As mentioned above, transplantation is indicated in patients with an estimated mortality of >80%. Contraindications are irreversible brain damage, fulminant sepsis, AIDS, advanced co-morbidities or a malignant disease. Patients with fulminant hepatitis have a higher priority for liver transplantation than those with chronic liver disease, resulting in short waiting periods of just a few days.

Outcome after transplantation is fair (ELTR: 5-year survival 60%) and depends greatly on pre-transplant

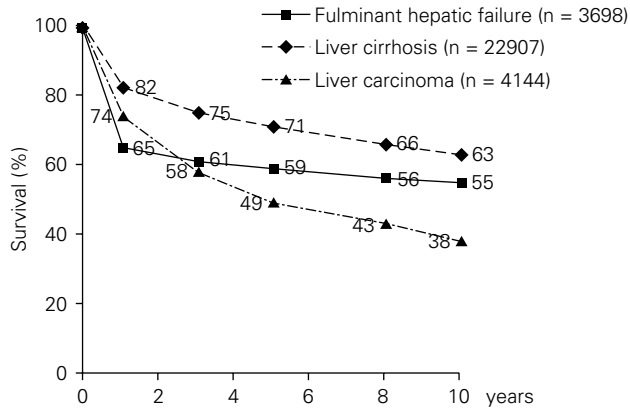

**Figure 44.1** Patient survival after orthotopic liver transplantation for fulminant hepatitis. Survival rates after liver transplantation of patients with fulminant hepatic failure (n = 3698) in comparison with patients transplanted for liver cirrhosis (n = 22 907) or carcinoma (n = 4144). All data were collected from the European Liver Transplant Registry from January 1988 to December 2001 (http://www.eltr.org). Survival in patients with fulminant hepatic failure was significantly worse in the first year after liver transplantation followed by a nearly stable survival curve in the long-term follow-up.

morbidity. A high mortality early after transplantation is characteristic and can be mainly explained by the sequelae of cerebral oedema and the increased infection rate. If the patient is able to survive the first months after OLT, the long-term prognosis is comparable to or even better than in patients transplanted for chronic liver disease.[119] Fig. 44.1 depicts patient survival after liver transplantation for fulminant hepatitis in comparison with other indications.

## Split liver transplantation

Conventional cadaveric transplantation is limited by the shortage of available organs. As a result, other options besides whole organ transplantation are being developed. Grafting only part of the liver is one of these options.[120] To provide enough functional liver parenchyma, the weight of the graft should be >1% of the recipient´s body weight. Therefore, it is usually necessary to transplant the right hepatic lobe in adults. The procedure is associated with a higher risk of complications such as biliary leakage.

## Living related donor transplantation

The concept of split liver transplantation was adopted to transplantation from living related donors. Apart from ethical aspects, the donor must be aware of the risk of morbidity and even mortality. In practice, it can be difficult to find and evaluate a suitable living donor in the short period of time available before severe complications develop.[121,122]

## Auxilliary liver transplantation

In fulminant hepatitis, chronic liver disease is absent by definition. Even in the case of total parenchymal necrosis, the patient's liver has the potential for full recovery. Therefore, technical variants of liver transplantation were introduced, allowing the patient´s own liver to remain in place. In auxilliary partial orthotopic liver transplantation (APOLT), the patient´s left hepatic lobe is resected and replaced by a split liver graft to bridge the period of liver dysfunction. After regeneration of the patient´s own liver, the procedure is completed by surgical graft removal or by withdrawal of immunosuppression resulting in graft atrophy.[123] Controlled data have shown a comparable survival to conventional liver transplantation even though APOLT seems to have an increased complication rate.[124,125] The proportion of patients who achieve successful withdrawal of immunosuppression is between 30% and 70%.[126,127] In practice, APOLT is rarely used, as only a few patients and grafts present optimal conditions with prospect of hepatic recovery.

## Hepatocyte transplantation

The transplantation of hepatocytes is an experimental procedure. Administration of freshly isolated, cryopreserved or cultivated hepatocytes has been performed in animal models and in a few human patients.[128–131] The necessary amount of hepatocytes seems to be much higher in patients with fulminant hepatitis than in therapy of hereditary metabolic diseases. Unsolved principal problems are the extraction of a sufficient amount of hepatocytes, establishing an optimal route of application, avoiding possible complications (e.g. pulmonary embolism) and evaluating the extent and type of immunosuppression.[132] In animal experiments, promising results were found with encapsulated hepatocytes that need confirmation in humans. Furthermore, studies in rabbits suggest a positive influence of induced transient ischaemia on efficacy of hepatocyte transplantation.[133]

## Xenotransplantation

After the initial euphoria about transplantation of xenogenous organs, progression in this field is much slower than expected. Immunological risks of complement-mediated, hyperacute rejection seem to be controllable by genetic engineering (e.g. removal of GAL-epitope on porcine endothelial cells). But the variety of donor species is limited, as organ size, metabolic pathways and export proteins must resemble the human model as much as possible. Therefore, primates and pigs are the main candidates for potential donor species. In addition, the possibility of transmission of zoonoses (e.g. porcine endogenous retrovirus; PERV) is controversially discussed.[134] To date, only three xenotransplantations in patients with acute or chronic liver failure have been performed and these took place several years ago. Maximum patient survival was 70 days.[135]

## Extracorporeal liver support devices

Three main types of extracorporeal liver support devices exist: bioartificial liver systems containing hepatocytes in bioreactors, mechanical detoxification systems (e.g. albumin dialysis) and extracorporeal liver perfusion. Recent meta-analyses could not find any survival benefit in patients with fulminant hepatitis regardless of the device.[136–138] Therefore, no general recommendation for the use of extracorporeal liver support devices can be given outside of clinical trials. An overview of all extracorporeal systems is given in Table 44.7.[139–161]

### *Bioartificial livers*

These systems ('bio livers') aim at providing enough functional liver cell mass to bridge the critical period

**Table 44.7** Extracorporeal liver support systems

| Procedure | Principle | References |
|---|---|---|
| Extracorporeal liver perfusion (ECLP) | | 103, 138 |
| Blood from the patient is purified while being guided through an explanted liver (human or xenogenous) in a sterile chamber | | |
| Bioartificial devices | | |
| Modular Extracorporeal Liver Support (MELS) | Human hepatocytes | 139–141 |
| HepatAssist | Porcine hepatocytes | 142–144 |
| Bioartificial Liver (BAL) | Porcine hepatocytes | 145 |
| Bioartificial Liver Support System (BLSS) | Porcine hepatocytes | 146 |
| Extracorporeal Liver Assist Device (ELAD) | Hep G2 cell line | 147 |
| Mechanical procedures ('liver dialysis') | | |
| Haemodialysis, plasmapheresis, haemadsorption | Classic dialysis | 148–152 |
| Biologic-DT | Classic dialysis | 153,154 |
| Single-Pass Albumin Dialysis (SPAD) | Albumin dialysis | 155 |
| Molecular Adsorbent Recycling System (MARS) | Albumin dialysis | 156–159 |
| Prometheus | Albumin dialysis | 160, 161 |

of liver dysfunction until transplantation takes place. Hepatocyte cultures are kept in a special matrix in a bioreactor with capillaries that contain the circulating blood of the patient. A functioning bioreactor requires the capability to maintain hepatocyte cell function as well as an effective bidirectional transport of nutrients, metabolites and toxins. Depending on their origin, three principal types of hepatocytes can be differentiated: hepatocytes from humans (allogenous) or animals (xenogenous) or cell culture lines (immortalized cells or tumour cell lines). Different bioreactors exist for all cell types, and all are associated with distinct management problems, as described below.

**1** Human hepatocytes. The only published system is the Molecular Extracorporeal Liver Support System (MELS; formerly called BELS on the basis of porcine hepatocytes).[139,140] It includes a cell module with human hepatocytes, a detox module for Single-Pass Albumin Dialysis (SPAD; see below) and a dialysis module for continuous veno-venous haemofiltration (CVVH). The required amount of human hepatocytes for support of one patient is comparable to the size of an entire liver.[141]

**2** Xenogenous hepatocytes. These have the same risks as xenotransplantation such as transmitting a zoonosis or creating immunological problems. Furthermore, biochemical compatibility must be sufficient. Examples with porcine hepatocytes are HepatAssist,[142–144] the Bioartificial Liver (BAL)[145] or the Bioartificial Liver Support System (BLSS).[146]

**3** Cell culture lines. The functional capacity of immortalized cell lines is impaired. Theoretically, tumour cell lines could enter the patient's circulation and induce neoplasia. A clone of C3A cells of the HepG2 cell line is used for the Extracorporeal Liver Assist Device (ELAD).[147]

A promising perspective is the use of human stem cells that are currently not available. Providing some kind of biliary efflux and the composition of the extracellular matrix are other important problems of the bioreactors. At present, hepatocyte function is limited outside the complex system of liver architecture and its adoption into clinical practice has therefore not been completely successful. Available data show a good biocompatibility and an improvement of detoxification, but no replacement of hepatic synthetic function and, especially, no survival benefit. The future of bioartificial livers will depend on the availability of functional and safe hepatocytes in a system that keeps the cells alive without losing clinical practicability.

### *Mechanical devices*

These devices use filtration techniques to support hepatic detoxification without substitution of liver synthesis ('liver dialysis'). Established nephrological procedures mainly remove water-soluble substances. Haemodialysis, exchange transfusion, plasmapheresis and haemadsorption with charcoal, alone or in combination, have brought about some biochemical and clinical improvements in fulminant hepatitis without affecting survival.[148–152] BiologicDT is a system that combines haemodialysis and haemadsorption.[153,154]

For effective detoxification, additional removal of protein-bound substances is inevitable. Therefore, novel concepts aim to remove both types of substances, water-soluble and protein-bound ('albumin dialysis'). The technical realization of albumin dialysis is quite similar in the Molecular Adsorbent Recycling System (MARS) and Single-Pass Albumin Dialysis (SPAD). The blood of the patient is purified over an asymmetric, non-al-

bumin-permeable membrane against albumin in a secondary circuit. In contrast to SPAD,[155] the MARS device recycles the 'loaded' albumin by two adsorbers and low-flux dialysis.[159] Controlled data regarding survival in patients with fulminant hepatitis are not available.[156,157] However, haemodynamic parameters improved in eight patients with fulminant hepatitis and MARS therapy in comparison with five controls.[158]

The Prometheus device is based on the concept of fractionated plasma separation and adsorption (FPSA).[160] In contrast to MARS, the plasma is separated through an albumin-permeable filter into the secondary circuit where it is directly purified by adsorber. This is followed by conventional high-flux haemodialysis. For the moment, the only available data are from patients with acute-on-chronic liver failure, showing a significant improvement of several biochemical parameters.[161]

### *Extracorporeal liver perfusion*

In extracorporeal liver perfusion (ECLP), the patient's blood is guided through a freshly explanted liver that is kept in sterile chambers outside the body. This organ is of xenogenous nature or a human liver that is otherwise not suitable for transplantation. First trials >40 years ago were not continued because of the increasing success of conventional liver transplantation. Recently, ECLP has regained interest as a result of progress in xenotransplantation and the increasing shortage of available human organs. If xenogenous organs are used, the immunological and infectious risks equal those in xenotransplantation, even though contact in ECLP is only temporary. Until now, neither hyperacute rejections nor xenogenous infections have been reported, and anaphylactic reactions were sporadic. In fulminant hepatitis, extracorporal xenoliver perfusion was feasible for up to 36 hours, indicating that hyperacute rejection might be limited due to impairment of the complement cascade in fulminant hepatitis.[162] However, two recently published meta-analyses could not demonstrate an improvement in patient survival or hepatic encephalopathy. All systems seemed to be safe, but use of human or baboon livers was associated with significantly better results than use of porcine livers.[137,138]

## Conclusion

Fulminant hepatic failure is an acute severe impairment of liver function including hepatic encephalopathy and jaundice in the absence of chronic liver damage.

The main viral agents are the classical hepatitis viruses (A to E). There are no specific treatments currently established for any of these viruses. However, early lamivudine therapy seems to ameliorate the course of fulminant hepatitis B. If there is evidence for herpesviridae as a cause of fulminant hepatitis, acyclovir should be given. In case of haemorrhagic fever virus infection, ribavirin is recommended.

Extrahepatic complications include cerebral oedema, coagulopathy with risk of bleeding, bacterial and fungal infections, changes in metabolism and multi-organ failure (especially renal failure). Because these complications highly determine survival, therapy should begin early and should be aggressive. However, despite significant improvements in intensive care medicine, spontaneous mortality still remains high. The patient's prognosis can be predicted by clinical scores. However, the scores have a low sensitivity. In patients with an estimated fatal course, conventional liver transplantation still represents the treatment of choice. Therefore, early contact with a transplantation centre is mandatory. In selected cases, living-related transplantation or auxilliary partial transplantation can be useful. Hepatocyte transplantation and xenotransplantation are experimental procedures that could become more important in the future. Likewise, controlled trials of extracorporeal liver support with bioartificial or mechanical devices that show an improvement of survival are lacking to date. Any therapeutic approach aimed at circumventing the need for liver transplantation should be initiated as early as possible.

# Chapter 45
# Hepatitis and haemophilia

Christine A Lee

Two types of haemophilia, A and B, are identical in their clinical manifestations and sex-linked recessive inheritance patterns. In haemophilia A, the common variety, bleeding is caused by a deficiency of factor VIII in the blood. In haemophilia B, factor IX is deficient. Patients with severe disease (<1 U/dL) suffer repeated, spontaneous and painful bleeding into muscles and joints, which if untreated, rapidly leads to crippling. Uncontrolled bleeding in other sites, such as the brain, causes premature death. Patients with haemophilia have developed hepatitis as a result of treatment with blood and blood products. Thus, hepatitis may also occur as a result of transfusion treatment in the less common clotting factor deficiencies (e.g. factors XI, VII, V and X deficiencies, as well as von Willebrand's disease).

Although the first report of blood transfusion to treat haemophilia was as early as 1840,[1] effective therapy for the condition has become widely available only during the last 25 years. As recently as 1937, Birch[2] described 113 patients with haemophilia, of whom 82 died before the age of 15 years, often as a result of trivial injury. During the 1950s and 1960s, fresh frozen plasma improved the management of the condition and was the main treatment.[3,4] The introduction of clotting factor concentrates in the late 1960s revolutionized the treatment of haemophilia, making possible a near-normal life for many patients.

The discovery that cryoprecipitate was rich in factor VIII was made in 1955 by Remigy,[5] and the description of a method of production of a high-potency concentrate of anti-haemophilic globulin in a closed bag system (cryoprecipitate)[6] made home treatment possible. Although cryoprecipitate has the advantage of simplicity of manufacture and therefore remains the mainstay of treatment for the less economically developed parts of the world, it has been superseded in most Western countries by lyophilized clotting factor concentrates and increasingly by recombinant products which are now recommended for treatment in economically well resourced countries.[7]

Large-pool clotting factor concentrates are manufactured on an industrial scale, from plasma pools to which many thousands of donors have contributed.

Patients with haemophilia were at high risk of contracting hepatitis because of both a large donor exposure from a single pool of blood products and the use of unsterilized lyophilized blood products from many thousands of donors. The development of virucidal methods and their application since 1985 to clotting factor concentrates have largely, but not completely, stopped transmission of viruses causing hepatitis.[8]

Transfusion-associated jaundice was first described in the 1940s,[9,10] and became increasingly recognized as a complication of haemophilia treatment following the introduction of plasma product therapy in subsequent years.[11,12] By the 1970s, overall estimates of the rate of symptomatic acute hepatitis with jaundice in haemophilic individuals ranged from 2% to 6% of treated patients per year, being particularly recognized in those patients who had previously received little or no treatment with blood products.[11,13]

## Hepatitis A

Hepatitis A virus (HAV) is only rarely transmitted by transfusion[14,15] and has formerly not been recognized as a problem for the recipients of blood product therapy. However, in 1992–1993 a number of outbreaks of HAV were reported from Italy,[16] Germany,[17] the Republic of Ireland[18] and Belgium.[19] All cases were associated with the use of a high purity product, factor VIII sterilized by solvent detergent (Octa VI, Octapharma). In the German outbreak between 1988 and 1992, 17 patients demonstrated HAV seroconversions, 13 had high HAV IgM seroconversions and 10 had clinical symptoms.[20]

In the Italian outbreak, 52 cases were identified during the years 1989–1992. Most cases were identified because jaundice developed in 42 of 52 patients. It was possible to identify HAV sequences in five of twelve lots of factor VIII tested, indicating that viral contamination occurred relatively frequently. A case-control study found a strong correlation between the occurrence of hepatitis and the use of a high purity factor VIII concentrate, manufactured in Italy, which was similar to concentrates produced in Austria and Germany and was

administered to patients with haemophilia in Germany, Ireland and Belgium in whom hepatitis A developed.[21] All concentrates were produced by ion-exchange chromatography and contained little immunoglobulin and were virally inactivated by solvent detergent. The products differed in that the Italian product was manufactured from plasma obtained in the United States from paid plasmapharesis donors, whereas the German, Irish and Belgian products were manufactured from plasma of local unpaid donors. The epidemiological association of the factor VIII lots with the transmission of HAV together with the detection of the identical sequences in the factor VIII and the corresponding patients' serum samples in two cases strongly supported the conclusion that HAV was acquired from the factor VIII.

It is likely that HAV-infected plasma units contaminated the pools used to prepare the concentrates. The attack rate of HAV infection is decreasing in all Western countries.[22,23] Therefore, more susceptible patients with haemophilia now comprise the population of clotting factor recipients. Also, individuals susceptible to HAV infection are more likely to reach the age at which they might donate plasma during the asymptomatic viraemic phase of HAV infection. Furthermore, if a contaminated plasmapharesis unit entered a pool for fractionation, the content of specific neutralizing antibodies (which is decreasing because of the changing epidemiology of HAV infection) may not be sufficient to neutralize HAV. It is also possible that virus–antibody complexes might dissociate during the manufacture of the concentrate as an effect of the solvent detergent.

A further outbreak of HAV has been associated with solvent detergent-treated factor VIII (Alphanate) among patients with haemophilia in the United States.[24] As a result of this outbreak, which also involved a factor IX concentrate (AlphaNine), the manufacturers decided to add another virucidal step: heating at 80 °C for 72 hours.

Because HAV is non-enveloped, it is not inactivated by solvent detergent alone. Therefore, a double inactivation process is necessary.

It is also possible to protect susceptible patients against hepatitis A. There is accumulating evidence that haemophilic patients respond well despite the need to give the vaccine by the subcutaneous route, apart from those who are immunocompromised with human immunodeficiency virus (HIV) infection.[25,26]

## Hepatitis B and delta infection

The discovery in the mid-1960s of the Australia antigen, against which multi-transfused patients with haemophilia developed precipitating antibodies, led to the identification of several specific markers that are now available for the characterization of hepatitis B virus (HBV) infection and the recognition that HBV infection was a major cause of transfusion-transmitted disease. The majority of intensively treated older patients with haemophilia have serological evidence of previous HBV infection.[27] Advances made in blood donor screening and concentrate sterilization have largely stopped HBV transmission to haemophilic patients. However, because such patients are at higher risk of receiving unsterilized whole blood, hepatitis B vaccination is mandatory.

Hepatitis D virus (HDV, delta agent) requires the presence of HBV for its propagation. Superinfection with HDV can occur in chronic HBV infection and co-infection in acute hepatitis B. It has been shown that among individuals who receive multiple transfusions of blood and blood products, haemophilic patients have the greatest risk of acquiring infection with HDV.[28,29] Anti-HDV prevalence of 34% among 79 hepatitis B surface antigen (HBsAg)-positive haemophilic patients who had received commercial clotting factor concentrates in western Europe and the United States was reported.[29] However, there was no evidence of HDV infection among 24 HBsAg-positive haemophilic patients from Brazil, Germany (former GDR) and Australia who had received factor concentrate prepared locally.[29] In another study, anti-HDV was detected in 35 (9.1%) of the HIV-positive patients, with 10/35 (29%) also having IgM anti-HDV indicating active infection.[27] In the HIV-negative patients, 13 (4%) had anti-HDV and only one patient had IgM anti-HDV.

It was found that HDV markers were most prevalent in type B haemophilia after controlling for disease severity ($p$ <0.02.) These data suggest that in the past, factor IX concentrates have been more heavily contaminated than factor VIII concentrates. It could be that the different manufacturing techniques could have resulted in a higher level of factor IX contamination in the past by HBV and HDV.

An interesting phenomenon of suppression of hepatitis C virus (HCV) by replication of HDV has been demonstrated.[30] Eight chronic carriers of HBsAg from a cohort of 99 patients with haemophilia co-infected with HIV and HCV were tested for antibody to HDV and quantitatively for HIV RNA, HCV RNA and HDV RNA. HCV RNA was detected in only one of five patients with HDV infection. In contrast, all three without HDV had high levels of HCV RNA. This represents viral interference, a well-known, but poorly understood, phenomenon in hepatitis infections.

## Hepatitis C

The natural history of HCV in haemophilia has been reviewed.[31,32] People with haemophilia who received non-virucidally treated large-pool clotting factor before 1986 were infected with HCV, previously referred to as non-

A, non-B hepatitis. A few patients were infected from single donor cryoprecipitate, particularly those receiving regular treatment with this product. Thus, on average people with haemophilia have been infected with HCV for more than two decades and also in many cases have received a large viral burden.

The large-pool clotting factor used to treat patients was obtained from plasma donors in northern Europe and the United States, where the prevalent genotypes were 1, 2 and 3. The most common genotype to be found in haemophilic patients is genotype 1. It is not clear why a particular genotype becomes the dominant genotype in any one haemophilic patient. The prevalence of type 1 may reflect the immune response at the time of infection, perhaps the greater replication competence of type 1 or the prevalence of this genotype among blood donors at the time of infection.

In haemophilic patients in Edinburgh, the distribution of genotypes was similar to that found in Scottish blood donors[33] (Fig 45.1). These investigators found that over 10 years, there was a change in genotype and serotype in nine of 29 patients.[34] The distribution of genotypes in haemophilic patients compared with the US population is shown in Table 45.1 and there was a much higher proportion of genotype 3 in the haemophilic individuals.[35] Furthermore, changes in genotype over time occurred in 58%, and this was more common in the presence of HIV.

In a study in Belgium, HCV genotype 1b was found to be predominant in both haemophilia patients and the general population, but in the haemophilic patients double infection with two genotypes occurred, as well as a relatively high infection with types 2 and 3.[36]

It is interesting that in Japan, where patients with haemophilia have been treated with concentrates derived from US donors, the predominant genotype in patients with haemophilia was la, whereas for the general population of Japanese patients type 1b was the most common.[37]

## Natural clearance

Approximately one-tenth of patients with haemophilia who were infected with HCV have been shown to clear the infection naturally as demonstrated by the presence of antibody to HCV in the face of persistent negative HCV RNA.[38–40] The majority of these patients had non-severe haemophilia and therefore infrequent treatment with clotting factor concentrate. Patients who cleared HCV were also young at first exposure, and therefore it is possible that their immune response at the time of infection was more effective. Of patients who became infected with HIV from clotting factor concentrate, most would also have been infected with HCV either at the same time or earlier. Thus, it is remarkable that there are reports of individuals co-infected with HIV and HCV, and that there has been clearance of HCV naturally.[40]

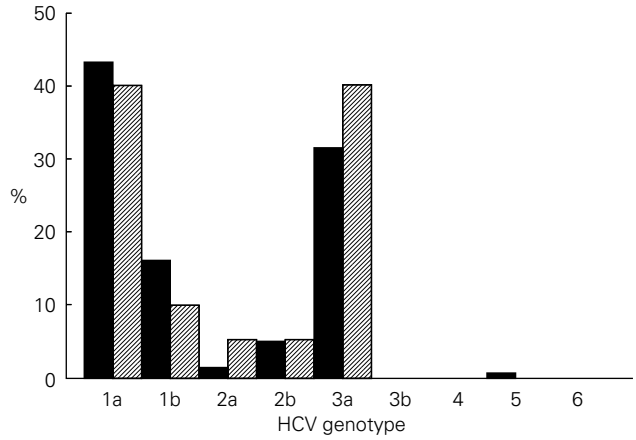

**Figure 45.1** HCV genotype in blood donors and haemophilia recipients. From Jarvis *et al*.[33]

## HCV mono-infection

Studies of the natural history of HCV in haemophilia are few in number. It is important to review the natural history of singly infected individuals separately from those co-infected with HIV. A cohort of 102 HCV-infected haemophilic patients who had been exposed to the virus for 15–34 years from three centres in Italy showed that 14% had cleared the virus naturally; 86% were HCV RNA-

**Table 45.1** Chronic HCV patients from Florida, Missouri and California

| | Prevalence of genotypes | | | |
|---|---|---|---|---|
| Results | HIV-positive (n = 17) | HIV-negative (n = 14) | Total (n = 31) | US population estimates (n = 139) |
| 1a | 6 (35%) | 4 (29%) | 10 (32%) | 37.4% |
| 1b | 2 (12%) | 2 (14%) | 4 (13%) | 37.4% |
| 2 | 1 (6%) | 1 (7) | 2 (6.5%) | 10.8% |

From Eyster and Hatzakis.[35]

positive and of these 69% had non-progressive liver disease, and only 7% showed cirrhosis.[41] The authors conclude that that there is slow progression of HCV infection in HIV-negative haemophilic patients. In a study of 4865 men and boys with haemophilia in the UK, it was shown that mortality from liver disease was 16.7 times higher than in the general population. However, the cumulative risks for those infected with HCV alone was relatively lower at 1.4% (all ages) compared with 6.5% for those co-infected with HIV.[42] A further study also has demonstrated that HCV singly infected individuals show only slow progression.[40] Thus, after all patients in a cohort of 310 would have been infected with HIV (125) the Kaplan-Meier progression rate to death from liver failure was 3% after 25 years of infection with HCV (Fig. 45.2). Overall, the time course of HCV mono-infection appears to be very slow.

## Age

Many studies have reported an influence of age on progression. Thus, in a Cox proportional hazards model the relative hazard of death for individuals co-infected, compared to infection with HCV alone, was 0.9, 3.5 and 9.7 for the age groups at infection of 10–19, 20–29 and >30 years, respectively.[40] A large study from the UK has also shown a strong influence of the age at infection and progression of liver disease. However, the influence of age may be reflecting time since infection.[42]

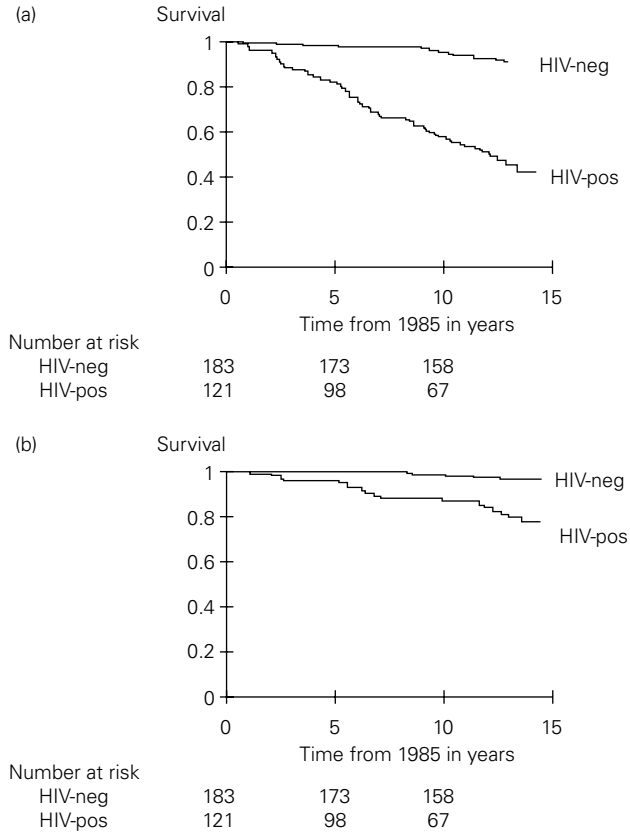

**Figure 45.2** Kaplan-Meier progression rate to death in HIV-positive and -negative patients: (a) all cause death, (b) liver death. From Yee *et al*.[40]

## Co-infection with HIV and HCV

Co-infection in haemophilia has been reviewed recently.[43] There have been several studies in haemophilia which have considered co-infection with HCV and HIV. Among 151 patients with haemophilia (85 HIV-positive and 72 HIV-negative) the rate of end-stage liver disease was greater among HIV-positive than HIV-negative individuals (relative risk 3.72).[44] In the study of 310 patients from London,[40] 125 were co-infected with HIV and of the patients who died 77% (20/26) were also infected with HIV. The Kaplan-Meier rates to death and liver-related death were increased in co-infected individuals (Fig. 45.2). Furthermore, using Cox proportional hazard models, the adjusted relative hazard of death for individuals co-infected with HIV compared with those infected with HCV alone was 19.47.[40] The study amongst haemophilic patients infected with HCV in the UK also showed higher mortality from liver-related disease in co-infected patients than those infected with HCV alone.[42]

More recently, a study in a cohort of 383 co-infected Spanish haemophilic patients showed that 18 (5%) died of end-stage liver disease – this represented 19% deaths before 1988, 4% during 1988–89, in 1990–1991 and 1992–1993, 2% in 1994–1995, 10% in 1996–1997 and rising to 33% in 1998–2001. Thus, the reduction in death attributable to highly active retroviral therapy for HIV has accounted for an increasing proportion of deaths from end-stage liver disease in this cohort in recent years[45] (Fig. 45.3).

The way in which HIV infection, which occurred 10 years after HCV infection in the haemophilic population, influences the progression of HCV is unclear. HCV viral loads have been shown to be higher in HIV-infected individuals.[46,47] The viral load is a reflection of the rate of viral replication and the rate of viral clearance in the infected host. HCV is an RNA virus with a high mutation rate leading to the generation of quasi-species. The high viral loads found in the face of HIV infection suggest that there is difficulty in containing the virus in the face of immunosuppression. It has been postulated that the progressive fall in CD4 counts, defective CD4 proliferation and CD4 apoptosis may weaken the lim-

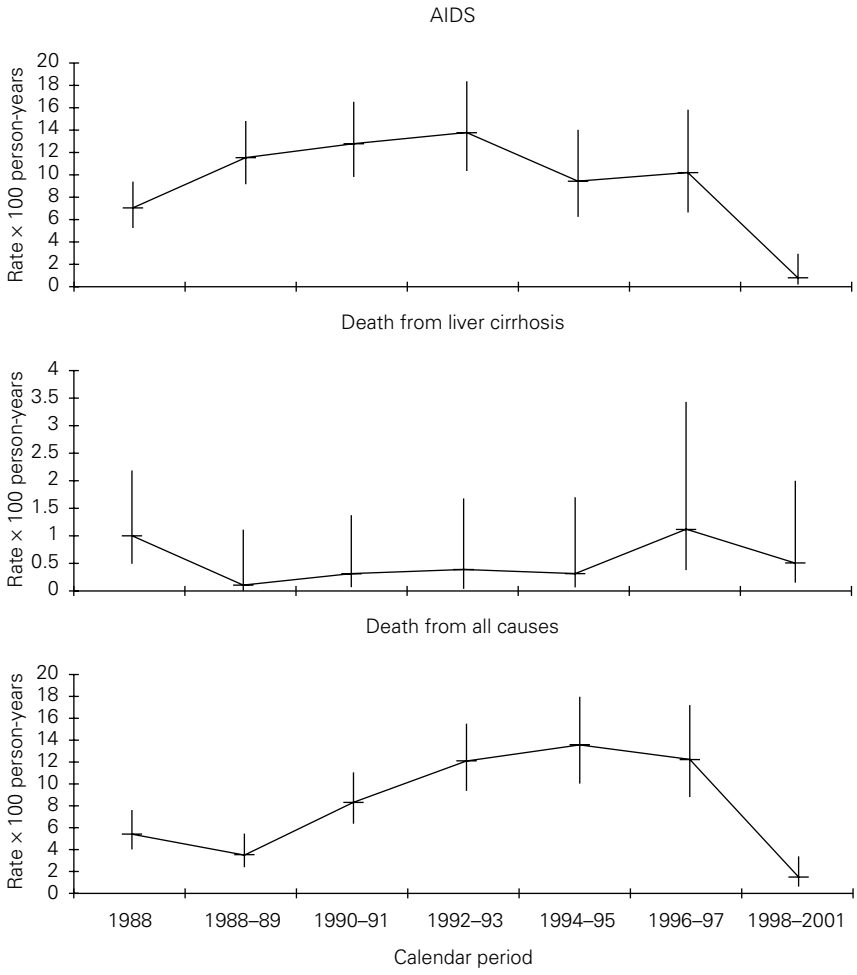

**Figure 45.3** Crude incidence rates per 100 person-years by calender period in HIV-positive haemophilic individuals. From Quintana *et al*.[45]

ited immune response to HCV.[48] HIV is also a potent activator of the immune response through the production of cytokines which are known to promote liver fibrosis.

HCV genotype 1 has been shown to be associated with more rapid progression to cirrhosis than other genotypes.[40,41] In one study, the adjusted relative hazard of death was 2.7 for genotype 1 when compared with other genotypes,[40] and in another study genotype 1 was associated with more advanced liver disease.[41] Interestingly, genotype 1 has also been shown to hasten the progression of HIV disease.[49]

## Cryoglobulinaemia

An association between HCV and cryoglobulins has been shown in both haemophilic and non-haemophilic patients with HCV. Serum cryoglobulins have been detected in 19–55% of patients. In the study reported from Italy, 24% of patients developed cryoglobulins after an average 14 years with clinical symptoms in 17%. Type 1 HCV was more commonly associated with cryoglobulins.[41] An anecdotal case report showed symptomatic cryoglobulinaemia with vasculitis, nephritis and arthritis at the time of HCV serocoversion in a patient with haemophilia.[50]

## Hepatocellular carcinoma

HCV infection is recognized as a risk factor for the development of hepatocellular carcinoma (HCC). This was first described in haemophilic patients in 1991 when a worldwide survey showed the incidence to be 30 times greater than the normal population.[51] Two cases were reported in a population of 102 who were infected on average for 25 years.[41] Five deaths were reported in the UK haemophilic population occurring over a period from 1969 to 1985. This represented a mortality from liver cancer 5.6 times greater than for the normal population.[42] In the study from London, 3 of 310 patients had developed HCC a median 22 years from time of HCV infection.[40] It is clear that the risk increases with the time from HCV infection.[42] It is likely that with the widespread use of antiviral agents for the treatment of HCV this end-stage complication will be overcome.

### Sexual transmission of HCV

Sexual transmission of HCV is an important issue for haemophilic patients, their families and those involved in their health care. Studies on HCV-infected patients and their partners indicate that transmission has been uncommon (Table 45.2).[52–59] Although 13 partners showed infection, seven of 13 had other risk factors. The transmission of HIV was also higher. There was an increased risk of transmission of HCV if the index case was infected with HIV. HIV has been shown to increase the risk of HCV transmission in non-haemophilic individuals.[60] Thus, the present evidence suggests that the transmission of HCV does occur between partners but is a rare event, compared with the transmission of HIV. The sexual route is the most likely route, although this has not been proven. Transmission is much more likely in prolonged relationships and in the presence of advanced liver disease and HIV infection where the viral load is often high. Many haemophilic couples have used barrier methods of contraception for years because of fear of HIV and, therefore, this may have also limited the transmission of HCV.

## Multiviral infections and interference

It is clear from many international studies that the likelihood of multiple infection depends on a number of factors, including national transfusion and treatment programmes, prevalence of infection among donor populations, when donor screening and exclusion policies were introduced, the use of virus attenuated blood products, and the vaccination of recipients. This was illustrated in a multicentre study in which 74% of HIV-infected patients with haemophilia had serological evidence of HBV and HCV infection, whereas only 31% of HIV-negative patients were similarly affected. The former group included patients who were older and who were exposed to untreated concentrate.[27]

Multiple infection by hepatotropic viruses may lead to complex viral interactions and has the capacity to complicate the diagnosis and management of chronic hepatitis in patients with haemophilia. Data suggest that some viruses may inhibit the replication of another virus and ameliorate the severity of the hepatitis. This is the phenomenon of interference and it has been reviewed in the context of haemophilia.[61] An anecdotal report described viral interference in a haemophilic patient co-infected with HCV, HBV and HDV. The initial infection with HCV resulted in a delay in the appearance of markers of HBV (Fig. 45.4).[61a]

In a further study of 60 haemophilic patients: 42 had anti-HCV by enzyme-linked immunosorbent assay (ELISA); 33 of 42 were positive for HCV RNA. In the

nine patients who were HCV RNA-negative, there were five individuals with HBsAg. In contrast, none of the patients who were positive for HCV RNA showed HBsAg. These studies in a small population suggest that active replication of HBV may suppress HCV.[62]

## Liver biopsy in haemophilic patients

As in other patient groups, a liver biopsy is indicated where there is doubt regarding the aetiology of the liver disease. However, the decision to perform a liver biopsy should be balanced against the cost and side-effects of the procedure. Transjugular liver biopsy using ultrasound by an experienced operator is the safest route, but this must be supported by treatment for the coagulation disorder, as shown in Table 45.3. Treatment by continuous infusion is also an option.[63]

The role of liver biopsy has been reviewed recently.[64] Since the publication of a large series of 126 biopsies in 1985,[65] where there were two deaths, this recent review summarizes the details of a number of small case series (range 6–103) representing a total of 387 biopsies. There were no fatalities and the calculated complication rate was 0.33% – similar to that in non-haemophilic patients. However, the numbers biopsied in haemophilia remain small in comparison to non-haemophilic individuals.

In the UK, national guidance has been issued on the use of ribavirin and interferon (IFN) by NICE (National Institute for Clinical Excellence). This now includes the statement 'those in whom liver biopsy poses a substantially increased risk (such as patients with haemophilia) may be treated on clinical grounds without histology'.[66]

Clearly, for individuals with type 2/3 HCV where there is >90% chance of cure with pegylated IFN and ribavarin, biopsy is redundant. It could also be argued that for type 1 patients, a trial of treatment could be initiated without the need for prior liver biopsy. Failure of response at 3–6 months using monitoring with transaminases and HCV PCR would require cessation of treatment.

Thus, although liver biopsy can be performed safely in haemophilic patients, where necessary, for diagnostic purposes, the vast majority of patients can be treated and monitored effectively without biopsy.

## Liver transplantation

The ultimate treatment for liver failure is liver transplantation, and for patients with haemophilia this results in cure of the inherited coagulopathy. The Pittsburgh group performed the first liver transplantation in a patient with haemophilia A and end-stage liver disease in 1985.[67] Post-transplant normal circulating factor VIII levels were sustained following discontinuation of FVIII concentrate supplementation at 18 hours. This was followed in 1987 by successful transplantation in a patient with haemophilia B.[68] In 1988, details of 26 haemophilic patients who were known to have been transplanted in Europe and the United States between 1985 and 1996 were reported.[69] The 3-year survival in HIV-negative and HIV-positive patients was 83% and 33%, respectively. At the time of this report, overall five of twenty HIV-negative and five of the six HIV-positive patients had died.

More recently, liver transplantation has been reported in 11 haemophilic patients treated at a single UK centre.[25] This report describes in detail 11 of 16 patients referred between 1990 and 2001 (Table 45.4). The mean age of the patients was 46, nine had haemophilia A and two had haemophilia B. Factor concentrate was administered using a continuous infusion regimen following initial bolus dosing. Concentrate infusion was stopped at a median of 36 hours (range 24–72 hours) post-transplant. Nine patients survived for a median of 5 years (6 months to 11 years). One patient died 6 years post-transplant of myocardial infarction and another of liver failure secondary to HCV infection following a second transplant because of HCV cirrhosis. Overall, five further patients developed HCV post-transplant.

It is significant that the HIV-positive patient who was transplanted was well with continued suppression of circulating HIV load on anti-retroviral triple therapy.[70] The authors conclude that the outcome of liver transplantation in haemophilic patients is good and is associated with relatively little morbidity.

## Prevention of hepatitis

Selection of low-risk donors and the screening of blood

**Table 45.3** Treatment regimen for liver biopsy in haemophilic patients

| | |
|---|---|
| Day 0 | |
| Pre-biopsy dose | Give calculated dose of VIII/IX to increase factor VIII/IX to 1.0 U/mL (100%) |
| Dose 2 – pm | (Factor VIII.) Further infusion to increase factor VIII to 1.0 U/mL (100%) |
| Day 1 | |
| Assay factor VIII/IX | Give calculated dose of VIII/IX to increase factor VIII/IX to 1.0 U/mL (100%) |
| Day 2 | |
| Assay factor VIII/IX | Give calculated dose of VIII/IX to increase factor VIII/IX to 0.5 U/mL (50%) |

From Makris *et al.*[63]

donations are important measures to minimize the risk of blood-borne viruses and must be implemented and continually improved. However, these measures are not sufficient to abolish viral transmission because a few infected donations will escape the screening process. Even though the fractionation procedures currently used to produce high purity coagulation factor concentrates improve safety by mechanically removing some of the viral burden, they are not sufficient to abolish transmission. Virucidal methods are now obligatory for the licence of concentrates in many countries. There are three main virucidal methods: (1) terminal heating of the lyophilized products at 80 °C (dry-heating), (2) heating in solution at 60 °C (pasteurization) in the presence of stabilizers or in moisture with hot vapour under high pressure, and (3) adding a solvent/detergent mixture during the manufacturing process. The risk of transmission of the hepatitis viruses has been markedly lowered but not completely eliminated. These methods are quite effective against HBV and HCV, but HAV can be transmitted rarely because solvent detergent is not effective against this virus (Tables 45.5 and 45.6).[8]

## Vaccination

The immunization of patients with bleeding disorders differs from that of the normal population with respect to the risk of haematoma formation at the vaccination site and the unusual risks associated with the potential and past exposure to blood products. Thus, it is recommended that vaccinations should be given subcutaneously.[71] Individuals should be tested for hepatitis immunity prior to vaccination due to previous community-acquired hepatitis A or hepatitis B infection through the use of non-virus-inactivated clotting factor concentrates.

### Hepatitis A vaccination

It is important to protect recipients of plasma-derived coagulation factor concentrates, because there have been several outbreaks of hepatitis A among recipients of

**Table 45.4** Liver transplantation in haemophilia: patient characteristics

| Patient | Haemophilia diagnosis | Age at transplant (years) | Date of transplant | Child Pugh status at transplant | HCV genotype | Acute rejection | Comments/post-transplant progress |

contaminated factor VIII.[16–19] Also patients with chronic hepatitis C may develop severe (decompensated) liver disease if they are co-infected with hepatitis A.[72] The hepatitis A vaccine is only licensed for use in patients over 1 year of age, and as hepatitis A is rarely symptomatic below the age of 8–10 years it is advised to wait for the patient's first birthday. It has been shown that children and adults react well to vaccine given subcutaneously.[26,73] However, in a study which included HIV-infected individuals the immune response was related to CD4 count.[74]

## Hepatitis B vaccination

Despite the advances that have been made in blood donor screening and concentrate sterilization, haemophilic patients continue to be at higher risk of acquiring HBV infection. For this reason, HBV vaccination is recommended. Hepatitis B vaccine is conventionally given intramuscularly, but subcutaneous vaccination has been shown to be effective in haemophilic patients to avoid the risk of haemorrhage.[75–77] Most vaccines use recombinant technology. An accelerated vaccination schedule can be used at 1, 2 and 6 weeks with good effect.[73]

Those infected with HIV respond to vaccine with a lower titre of antibody and may lose antibody much earlier.[77–79]

There is currently debate on the need to monitor anti-HBs levels and give booster hepatitis B vaccinations.[71] It is likely that once a person has been vaccinated and documented to have a good response (i.e. anti-HBs >100 IU/dL) a booster should be given every 5 years.

# Chapter 46
# Occupational aspects of hepatitis

Will Irving, Kit Harling

## Compensation for occupationally acquired infection

Virus infections may be transmitted in the workplace through precisely the same routes of infection as occur in the wider community at large. However, recognition that a virus (or indeed any other) infection is a particular risk of certain occupational groups raises the issue of compensation due to workers who acquire infections through exposure at work. The Industrial Injuries Scheme in the UK provides a benefit that can be paid to an employed earner because of an industrial accident or prescribed disease contracted through work. The benefit is non-contributory and 'no-fault', and is administered by the Department for Work and Pensions: the Department is advised in these matters by the Industrial Injuries Advisory Council (IIAC). The IIAC was established in 1948 under the Industrial Injuries Act 1946 and has advised the government ever since.

The most recent legislation, the Social Security Contributions and Benefits Act 1992, states that the Secretary of State may prescribe a disease where he is satisfied that the disease:

**1** ought to be treated, having regard to its causes and incidence and any other relevant considerations, as a risk of the occupation and not as a risk common to all persons; and

**2** is such that, in the absence of special circumstances, the attribution of particular cases to the nature of the employment can be established or presumed with reasonable certainty.

In other words, a disease may only be prescribed if there is a recognized risk to workers in a particular occupation, and the link between disease and occupation can be established or reasonably presumed in individual cases. In determining whether a particular disease should be prescribed, the IIAC considers whether the risk for a particular occupational group has been doubled or whether there are other factors which allow attribution in particular cases to be made.

Viral hepatitis was first prescribed in 1975 and the arrangements were revised in 1984. The current list defines Prescribed Industrial Disease (PID) 8 as 'viral hepatitis' linked to an occupation that involves contact with either (1) human blood or human blood products, or (2) a source of viral hepatitis. This would clearly apply to most health-care workers (HCWs) but does require that the infected person demonstrates that their work does involve exposure to blood or blood products or some other source of the virus.

In 2003, the IIAC recommended to the Secretary of State that the description of viral hepatitis should be amended, by dividing PID8 into two and by making the illnesses more specific.[1] Hence, PID8a would be hepatitis A linked to jobs involving exposure to raw sewage, whilst PID8b would be hepatitis B or C linked to work involving contact with human blood or blood products, or a source of hepatitis B or C virus. Other hepatitis viruses would not be considered to be prescribed for the purposes of access to state benefit. These proposed changes simply bring up to date the details of the prescribed industrial disease to match what is known about occupational transmission.

## Hepatitis A

Hepatitis A virus (HAV) is transmitted by the faecal-oral route. Person-to-person spread is the most common method of transmission, although consumption of contaminated food or water will also result in infection. The introduction of a safe and effective vaccine in the 1990s has raised the question of who should be vaccinated, and in the context of occupationally acquired infection, this has resulted in a number of studies looking at seroprevalence rates in different occupational groups. Perhaps the most obvious group of workers with potentially increased risk of acquisition of HAV infection are those who come into contact with raw sewage. Studies in Singapore, France and the USA have reported seroprevalence rates in sewage or wastewater workers more than double those of non-occupationally exposed popu-

lation groups,[2–4] and outbreaks of HAV infection have been reported in sewage workers.[5]

HCWs are another potential risk group. Nosocomial outbreaks of HAV infection involving HCWs have been reported in neonatal and paediatric intensive care units, and other ward settings.[6–9] However, seroprevalence studies in HCWs have generated conflicting data. Increased rates were reported in general HCWs,[10] physicians and dentists,[11] dental workers,[12] and nurse aides.[13] However, others found no increase for physicians[13] or nurses.[11] Staff who work with children, e.g. in day-care centres and kindergartens, may also be at risk.[11]

It is relatively straightforward to protect individuals from HAV infection by vaccination. HAV vaccine is offered selectively to those subgroups of the population at risk. However, the UK guidelines for HAV vaccination[14] for occupationally at-risk workers recommend vaccination for very few occupational groups, reflecting the uncertainties as to who is or is not at increased risk of infection indicated by the seroprevalence data discussed above. Immunization is recommended only for laboratory workers who are working directly with the virus. Routine immunization of HCWs in general is not recommended. Immunization may be indicated for staff and residents of institutions for people with learning disabilities dependent on a local risk assessment. Within child day-care centres, immunization is only recommended in the specific instance of a local community outbreak of HAV infection. Whilst immunization is not recommended for all sanitation workers, it should be considered for those who come into contact with raw untreated sewage.

## Hepatitis B and C viruses

In the particular context of viral hepatitis within occupational settings, most attention has been focused on the potential spread of the blood-borne members of the group – hepatitis B and C viruses (HBV and HCV). It is not difficult to construct a list of occupations where there is at least a theoretical risk of acquisition of one or both infections. This will comprise those whose work practices bring them into contact with blood, tissues and bodily fluids, or with inanimate objects contaminated with the same. The most obvious and largest occupational group at risk are therefore HCWs, but there are others, including paramedics, emergency responders, police and fire-fighters. Much effort has therefore been expended to devise appropriate strategies to protect such workers from occupational exposure to, and acquisition of, HBV and HCV. However, in the heath-care setting, just as it is possible for HCWs to acquire infection from their patients, there has been an increasing realization that virus may travel in the opposite direction, i.e. patients are at risk of acquiring infection from their HCWs. The remainder of this chapter will therefore deal with the issues of prevention of spread of HBV and HCV from patients to HCWs, and also from HCWs to patients.

## Occupational acquisition of HBV by workers

### Evidence of risk in different occupational groups

A number of serosurveys performed prior to the widespread adoption of HBV vaccination demonstrated convincingly an increased prevalence of markers of HBV infection in workers exposed to blood and bodily fluids. In the USA, an overview of published data concluded that the overall risk to persons employed in health-related fields was four times that of the general adult population. In particular subgroups of such workers, the risk was even higher – five to ten times for physicians and dentists, and more than 10-fold for surgeons and laboratory workers having frequent contact with blood samples.[15] Similar findings were reported for emergency physicians[16] and oral surgeons.[17]

In 1990, the Centers for Disease Control and Prevention in the United States estimated that 6500–9000 new HBV infections occurred among HCWs. Extrapolating from the known natural history of infection, this equates to the generation of 350–950 chronic carriers, with a prospective 100–150 deaths from cirrhosis and 25–40 from hepatocellular carcinoma.[18]

Surveillance of acute hepatitis B infections in the UK reveals a similar story. Whilst the average annual rate of infection in men in the whole population between 1975 and 1979 was 4 per 100 000, this rose to up to 36 per 100 000 for HCWs. Comparative rates in the years 1980–1984 were 6 and 37 per 100 000, respectively.[19,20] Again, surgeons and laboratory workers were the subgroups with the highest rates of infection.

Occupations allied to health care may also carry a risk of HBV infection. Embalmers, who commonly give a history of needle-stick injuries at work, were reported to have twice the frequency of markers of HBV infection as blood donors.[21] Other groups include staff and specialized teachers in schools for those with learning disabilities,[22] and emergency ambulance staff and paramedics.[23–25] Studies of police officers, prison officers and firemen on the whole have failed to find a significant increased risk.[26–29] Amongst professionals unrelated to health-care or emergency service workers, outbreaks of infection have been reported in butcher's shops, presumably arising through spread from an infected employee to colleagues from cuts sustained at work,[30,31] and inapparent parenteral infection arising from dermatitis and small cuts from scissors was suggested to account for an excess of HBV markers in hairdressers in Scotland.[32]

### Modes of occupational transmission of HBV to workers

The most obvious potential route of occupational transmission of HBV is via inoculation of infected blood either by needle-stick injuries (stab injuries with blood-contaminated needles), or sharps injuries (cuts with blood-contaminated scalpel or other sharp instruments). A number of studies have documented the risk of HBV transmission after accidental inoculation of infected blood. All find a significantly higher risk of clinical hepatitis (19–31%) if the source patient was hepatitis B 'e' antigen (HBeAg)-positive compared with 1–6% for HBeAg-negative sources.[33–36] Data to allow estimates of the risk of HBV transmission after other types of exposure are not available. By analogy with HIV, there must also be at least a theoretical risk of transmission by exposure of mucous membranes to blood splashes, although it is likely that this will be lower than for inoculation injuries. There are no reports of transmission of HBV via blood contact with intact skin.

Other body fluids may contain infectious viral particles, and therefore, potentially at least, pose a risk for transmission of hepatitis B. These include amniotic, pericardial, peritoneal, pleural, synovial and cerebrospinal fluids, and semen and vaginal secretions. Exposures to non-blood-stained faeces, nasal secretions, sputum, sweat, tears, urine and vomitus are not thought to pose a risk of infection.[37,38] Hepatitis B transmission has been reported following human bites,[39–41] presumably related to inoculation of the biter's blood-stained saliva. This sort of exposure may be experienced by workers with mentally disturbed or subnormal patients or by police and prison officers.

Whilst percutaneous injuries are the most obvious route of exposure to HBV, in reality, many infections acquired by HCWs result from direct or indirect blood or body fluid exposures that inoculated HBV into cutaneous scratches, abrasions, burns, other lesions or on mucosal surfaces.[42] HBV has been demonstrated to survive in dried blood at room temperature on environmental surfaces for at least 1 week.[43]

### Magnitude of risk

The risk to HCWs of acquiring HBV infection at work will depend on the prevalence of HBV carriers among the patient population, the frequency of needle-stick/sharps injuries, the risk of transmission per exposure (considered above), and the immune status of the HCW population in regard to HBV (see below, under prevention).

The prevalence of HBV carriers in the patient population will vary widely according to the population under study. The UK is a low prevalence area with an estimated hepatitis B surface antigen (HBsAg) carriage rate of 0.1%. Elsewhere, carriage rates may exceed 20%. Rates may vary within identifiable population subgroups – e.g. in the UK, in hospitals for those with learning disabilities, prevalence rates between 1 and 12% have been reported.[44]

Blood exposure incidents are, unfortunately, all too common in a hospital setting, the most obvious occurrences being during operative procedures. Studies of sharps injuries in operations report rates of 1–7%.[45–48] Risk factors include long procedures, high blood loss, major operations and wound closure with staples. Other potential exposures include glove tears and perforations,[49–51] and eye splashes with blood and other bodily fluids.[52–54] Other HCWs, including nurses, laboratory, domestic and portering staff also suffer blood exposures.[55] Widely differing rates are reported in different studies, and there may be considerable inaccuracies due to under-reporting.[56–58]

In an Italian national surveillance programme of occupational exposures to blood-borne pathogens, only 13% of exposures to a known infected source were to HBV. There were 1155 exposures to known HBsAg-positive sources in the period 1986–1998.[59] No HBV seroconversions were observed, even in 158 known susceptible HCWs, 117 of whom received post-exposure prophylaxis (PEP). The Communicable Disease Surveillance Centre of the Health Protection Agency in the UK has been running an active surveillance scheme of needle-stick injuries in HCWs, in collaboration with over 200 occupational health departments in England, Wales and Northern Ireland. In this study, incidents of HCW exposure to HBV were a small minority compared with HCV and HIV.[60] No HBV seroconversions were reported after 219 HBV exposure incidents in the period 1997–2002.

### Prevention of occupational acquisition of HBV

The principal strategies for the prevention of occupationally transmitted HBV infection are (1) vaccination of at-risk personnel, (2) institution of appropriate infection control policies, and (3) institution of appropriate policies for management of exposure incidents.

## Hepatitis B vaccine

Recombinant surface antigen-based vaccines for prevention of HBV infection have been in routine use for some years. They are demonstrably safe and efficacious, although protection from vaccination is not 100% (see below). The key issues surrounding vaccination policies are (1) who should be vaccinated, (2) what is a protective response to vaccine, (3) what is the need for boosters, and (4) how should non- or hypo-responders to vaccination be managed?

## Who should be vaccinated?

It is the recommended policy of the World Health Organization (and also of the European Union) that HBV vaccine be adopted as a universal vaccine of childhood, and this is now the case in the majority of countries around the world.[61] However, the UK currently operates a selective vaccination policy – that is, vaccine is targeted only at those subgroups of the population deemed to be at significant risk of exposure to HBV. In occupational terms, the official UK guidance[14] explicitly identifies 'Health-care workers including students and trainees', 'staff and residents of residential accommodation for those with severe learning disabilities', and a catch-all 'other occupational risk groups' including morticians and embalmers, certain sections of the police, ambulance, fire and rescue services, and prison service staff in regular contact with prisoners. With a selective policy, there is always going to be a grey area as to precisely which individuals within an organization do or do not require vaccination. In the past, this has led to considerable discussion and division. Hopefully, the experience accumulated over a number of years has now led to the adoption of more inclusive policies, rather than yet more attempts to justify withholding vaccine from certain subgroups of individuals, and the controversies over who to vaccinate have now become a non-issue.

Mandatory vaccination policies are more effective than voluntary ones. A recent Canadian report has demonstrated that between 10 and 60% of all exposure-prone procedure (EPP)-performing HCWs were not vaccinated under a voluntary system.[62] However, mandatory policies are difficult to implement, and therefore most countries rely on highly recommending HBV vaccination to HCWs, whilst reserving the right to determine the infection status of individuals who refuse vaccination.

## What is a protective response to vaccination?

The initial trials of plasma-derived vaccine demonstrated that protection acquired from vaccination was directly proportional to the level of anti-HBs achieved. Importantly, vaccinees who did not generate any detectable anti-HBs response were as susceptible to HBV infection as placebo recipients, and there is no evidence to suggest that such vaccinees may somehow be protected by non-humoral mechanisms (e.g. T-cell immunity) generated by the vaccine. However, a matter of some debate is precisely how much anti-HBs is required in order to be confident of protection. There is a strong lobby in favour of 10 IU/L as being a cut-off level above which the individual is deemed to be protected, and this is the official policy in the USA.[42] Certainly, there are vanishingly few reports of acquisition of either symptomatic acute HBV infection, or of the development of chronic hepatitis B infection in vaccinees who have attained this level of anti-HBs, although asymptomatic anti-HBc seroconversion, indicative of infection, is more common.[63] In the UK, a more cautious approach has been taken, whereby an antibody level above 100 IU/L is considered to be protective, and responses in the range 10–100 IU/L are regarded as suboptimal. One concern that led to this approach was the specificity/reliability of the anti-HBs detection assays operating at close to their lower limits of detection. A second concern is that on its own, a low level of anti-HBs may not represent a protective response to vaccination – chronic carriers of HBV frequently have low levels (i.e. <100 IU/L) of anti-HBs in their sera.[64,65] The importance of this latter phenomenon is discussed in more detail in the section concerned with prevention of HCW-to-patient transmission of HBV.

## What is the need for booster doses of vaccine?

The anti-HBs level in vaccines shows an inexorable decline over time since the last dose of vaccine. Thus, even individuals who make respectable levels of anti-HBs (>100 IU/L), as assessed 2 months after the last dose of vaccine, will eventually become anti-HBs-negative in the absence of further antigenic stimulation. Given that the degree of protection against infection is proportional to the level of anti-HBs achieved, this observation raises the possibility that protection will be lost over time as anti-HBs levels decline. Thus, initial vaccination policies built in stipulations for booster doses at various time intervals following the initial vaccination course. Some regimens tried to take into account individual variations in the half-life of anti-HBs, and therefore tailored the timing of booster doses according to serial measurements of anti-HBs, with boosters only being given as an individual's anti-HBs level declined below the 10 IU/L mark. Such policies proved to be very difficult to implement in practice, and a more pragmatic approach of universal boosting at specified time intervals, e.g. 5 years, became more commonplace. This accepted the fact that some individuals would dip below the magic 10 IU/L before receiving their booster, whilst others would still have protective levels of anti-HBs at the time of boosting, but the overall gain in efficiency of implementation of fixed interval policies outweighed these considerations. However, there is now a solid body of evidence that the immunological memory induced by the initial course of vaccination will protect against infection even if the serum anti-HBs levels have declined below the limit of detection at the time of a subsequent exposure. The exposure itself will provide a potent antigenic stimulation, leading to the induction of protective anti-HBs within 3–5 days, well within the prolonged 4–12 week incubation period of HBV infection.[66] The European Consensus Group on Hepatitis B Immunity (ECG on HBI) has

therefore argued that, for individuals who have made a demonstrably protective level of anti-HBs in response to a primary course of vaccination, there is no need for any subsequent boosters.[67] This is now the official policy in the USA.[42] In the UK, the extant guidance remains that issued in 1996,[14] which recommends a single booster dose 5 years after completion of the primary course.

## Management of non- and hypo-responders to vaccination

For almost all prophylactic vaccines in current use, no attempt is made to confirm the induction of immune responses to vaccination, even though it is known that most vaccines do not induce protection in 100% of vaccinees. However, in the specific context of HBV vaccine used as prophylaxis against occupational exposure, there is a need to check the immune response to vaccination. About 10% of otherwise healthy adults do not see the currently licensed surface antigen vaccines as immunogenic, and mount no detectable anti-HBs response. A further 10% make somewhat suboptimal responses in the range 10–100 IU/L. As non-response equates with non-protection, it is important that such individuals are aware of their non-immune status. Provided that the exposure incident is reported appropriately, they can still be offered passive protection with hepatitis B immunoglobulin (see below). The issue as to whether hypo-responders to vaccination are really at risk of acquiring HBV infection was discussed above. One possible explanation for a non- or suboptimal response to vaccination is, of course, that the vaccinee is already a carrier of HBV. This has important implications for the individual's own state of health, and for their fitness to practise within the health-care service (i.e. whether they may perform EPPs or not, see below). Thus, the need for anti-HBc or HBsAg testing must be discussed with the individual concerned.

The management of these individuals, apart from ensuring that they are aware of their status and its implications, centres around how to improve their anti-HBs levels. One obvious strategy is to offer more doses of vaccine. UK and USA recommendations are for non-responders to receive a complete second course of vaccine, and hypo-responders to receive an immediate booster dose.[14] Around 30–50% of non-responders can be coaxed into making a detectable anti-HBs by a second course of vaccine, although it is unlikely that titres will be very high.[68,69] Beyond these blanket recommendations, whether or not to continue with multiple further doses in those who still fail to mount a response is a decision which needs to be made on an individual basis. For instance, if the non-responder is a surgeon, there may be a greater degree of motivation to try to generate some anti-HBs than, say, for a psychiatrist.

A variety of strategies have been tried, mostly on a small scale, to improve anti-HBs responses to current vaccines.[70] These include the use of the intradermal (i.d.) route of vaccine administration, the addition of various immunostimulants given at the same time as vaccine doses, and the development of more immunogenic vaccines.

Large-scale prospective studies have demonstrated satisfactory anti-HBs responses to vaccine administered i.d. in comparison to the standard intramuscular route.[71–73] A number of small-scale studies have reported impressive results with the use of the i.d. route of administration in HCWs known to be non-responders to conventional courses of vaccination (see Table 46.1).[74–78] However, despite these promising results, it should be emphasized that current vaccines are not licensed for use in this way.

The effect of a variety of immunostimulants administered at the same time as vaccine has been studied, but results are generally disappointing. Addition of recombinant interleukin-2 to a booster dose of hepatitis B vaccine in previously non-responsive uraemic patients failed to improve response rates.[79] The response to i.d. vaccine of patients with end-stage renal failure was slightly augmented by the addition of erythropoeitin.[80] Interferon (IFN)-α given at the same time as a booster dose of vaccine in healthy non-responders failed to produce a sig-

**Table 46.1** Use of intradermal vaccination in healthy non-responders to intramuscular vaccine

| Reference | Intradermal regimen | n | Results |
|---|---|---|---|
| 74 | 3 doses 2.5 μg 2–3 weeks apart | 17 | 16 seroconverted, mean titre anti-HBs >100 IU/L |
| 75 | 4 doses 5 μg every 3 weeks | 25 | 22 seroconverted |
| 76 | 2–5 doses 20 μg | 9 | 8 achieved anti-HBs >100 IU/L |
| 77 | 5 μg every 2 weeks up to 5 doses | 31 | 29 achieved anti-HBs >10 IU/L |
| 78 | 5 μg every 2 weeks up to 4 doses | 6 | 6 seroconverted |

nificant increase in response rates.[81] There is a report of enhancement of anti-HBs responses by use of granulocyte-macrophage colony stimulating factor, but this was a very small trial (15 patients) with no control group.[82]

A hope for the future is that more immunogenic vaccines will appear, generating such solid responses that all issues relating to non- and hypo-responders will disappear. Vaccines containing pre-S1 and pre-S2 regions of the HBsAg, in addition to the conventional S region, may circumvent genetic non-responsiveness to the S antigen. One trial of such a triple vaccine demonstrated 70% seroconversion in 100 HCWs who had failed to seroconvert after at least four doses of a licensed HBV vaccine containing the S component only.[83] However, production of that vaccine is technically difficult, and 7 years after the initial trial, there is no sign that it will become widely available. New adjuvant formulations may significantly improve anti-HBs responses to conventional S only vaccines. One such adjuvant, AS04, which contains 3′-deacylated monophosphoryl lipid A and alum, achieved response rates in non-responders (titre <10 IU/L after four doses of conventional vaccine) of over 90% after three further doses, compared with only 68% of those who received further doses of conventional vaccine. More impressively, the titre of anti-HBs reached after the third dose was over a log higher with the AS04 adjuvenated vaccine.[84] New approaches to vaccine development include DNA vaccines. A novel DNA vaccine against HBV has been shown to induce protective levels of anti-HBs in non-responders to conventional vaccine.[85]

## Infection control policies

Approaches to reduction of hazardous exposures to blood-borne viruses (BBV) can be categorized as: (1) the taking of special precautions for patients or specimens known or suspected to be infected, or (2) the adoption of universal precautions to cover all patients and specimens, the principle of which is that the level of precautions taken depends on a risk assessment of the procedures being undertaken, rather than on the patient's infection status. The key elements of universal precautions are hand disinfection after contact with patients, use of barrier precautions (e.g. gloves, gowns, goggles as appropriate), and minimal manipulation and safe disposal of sharp instruments. In recent years, there has been a major shift towards the latter approach, one of the main reasons being that for every patient known to be infected with a BBV, there will be many more in routine clinical practice where this status is not known or even suspected. There is also evidence to suggest that knowledge of a patient's high-risk status may not reduce the risk of blood exposures during surgical procedures,[46] whilst practising universal precautions does reduce the frequency of blood exposures among trained HCWs.[86,87]

Strategies designed to prevent the occurrence of inoculation injuries are essential to reduce the risk of occupationally acquired BBV infection. Possibilities include the development of safer surgical techniques including methods of passing instruments between personnel, avoidance of the use of sharp instruments where alternatives exist (e.g. when suturing), and better training of junior surgeons using surgical rigs.[51,88,89] Other infection control measures include double gloving,[90] spectacles or visors to avoid eye splashes,[52,53] impermeable gowns to prevent skin contamination,[91] effective systems for collecting and disposing of used sharps,[92] and safer needle and syringe combinations that reduce needle handling[93] and automatically protect the needle after use.[94]

## Post-exposure prophylaxis policies

Despite great attention to education and introduction of innovative infection control policies, it is unlikely that the risk of suffering a needle-stick injury will ever be zero. Thus, an important part of any strategy dealing with occupational exposure to HBV is the development of an effective policy for management of exposure incidents. This should include testing the source patient (if known) for HBsAg and HBeAg, establishing the worker's immune status for HBV, and administering HBIg and HBV vaccine as necessary. There should be clear lines of responsibility for the management of exposure incidents, including out-of-hours arrangements.

The risk arising from an exposure will be dependent on the type of exposure, the HBV status of the source, and the HBV status of the person exposed. Guidelines in the UK[95] define a significant exposure as one which is percutaneous (needle-stick or sharps injury, bite), mucocutaneous (non-intact skin, conjunctiva or mucous membrane) if involving blood, or sexual. The HBV status of the source may be known, determinable, or unknown and not determinable. The HBV status of the person exposed is categorizable as known responder to vaccine, known non-responder to vaccine, unknown, or known HBsAg carrier. On the basis of these variables, an algorithm was constructed to indicate the appropriate post-exposure prophylaxis (PEP) needed in different circumstances, a simplified version of which is shown in Table 46.2. The options for action to be taken vary from nothing through to administration of HBV vaccine and HBIg. The efficacy of HBIg given post-exposure in the occupational setting is estimated to be of the order of 75%.[34] The most recent guidelines in the USA are provided by the Public Health Service.[42]

**Table 46.2** HBV post-exposure prophylaxis for reported exposure incidents

| | Significant exposure | | | Not significant exposure | |
|---|---|---|---|---|---|
| HBV status of exposed person | HBsAg-positive | Unknown source | HBsAg-negative | Continued risk | No further risk |
| Not vaccinated or anti-HBs response unknown | Accelerated vaccine course | Accelerated vaccine course | Standard vaccine course | Standard vaccine course | No HBV prophylaxis |
| Known vaccine responder | Booster | Consider booster | Consider booster | Consider booster | No HBV prophylaxis |
| Known vaccine non-responder | HBIg × 1 consider booster | HBIg × 1 consider booster | No HBIg consider booster | No HBIg consider booster | No HBV prophylaxis |

## Transmission of HBV from infected workers

### HBV transmission from infected workers via exposure-prone procedures

There are over 45 reports of HCW-to-patient transmission of HBV in the literature, with over 400 infected patients, and transmission rates of 6–15%.[96] This was first recognized as a problem due to outbreaks of HBV infection occurring in renal dialysis units. In the UK, between 1975 and 1990, there were 12 outbreaks of HBV infection associated with infected HCWs, with 91 infections identified (reviewed in Heptonstall[97]). In 11 of 12 instances, the HCW was HBeAg-positive (the status of the 12th was unknown). In five outbreaks where tracing and testing of exposed patients was performed (i.e. lookback), acute icteric HBV infection occurred in 1–2% of patients, with an overall transmission rate (including asymptomatic cases) of 4–9%. In a report of 20 such outbreaks in the USA involving over 300 infected patients, all 17 surgeons who were tested were HBeAg-positive.[98]

The risk of an infected HCW transmitting HBV is dependent on the type of work performed, with obstetric/gynaecological and cardiothoracic surgeons being the two most frequently implicated in HCW-to-patient transmission of HBV. Within those specialties, there are clearly high- and low-risk procedures. For one obstetrician, a lookback covering 247 patients identified transmission in 19% of 108 high-risk, 1% of 107 medium-risk and 0% of 32 low-risk procedures.[99] The term 'exposure-prone procedures' (EPPs) was coined in 1991 by the Centres for Disease Control and Prevention[98] to describe procedures where there is a risk of percutaneous injury to the HCW, and where, if such an injury does occur, the worker's blood may contact the patient's tissues or mucous membranes. This is more likely when manipulation of needles or other sharp instruments in a body cavity without clear vision or in a restricted space is necessary.

### Magnitude of risk of transmission from infected workers

In the absence of any control measures, this will depend on the prevalence of HBV infection amongst HCWs performing EPPs, and the frequency of virus transmission from such HCWs per EPP. Using an estimate of the latter of 5% for HBeAg-positive surgeons, based on the reported range of 4–9% in UK outbreaks,[97] it is possible to work out the likely number of HBV transmissions by HCWs performing EPPs occurring per year in any country, by feeding into the equation the HBV prevalence band of the country concerned, and the total number of EPPs performed per year in that country. An example of this is given in Table 46.3.[101]

### Prevention of transmission of HBV from workers

The realization that HCWs who are chronic carriers of HBV are a potential infection risk for their patients has resulted in the introduction of a variety of measures to reduce this risk and thereby protect patients. In 1981 in

**Table 46.3** Risk of transmission of HBV by prevalence band of country of origin of health-care worker (HCW)

| Prevalence band | Typical prevalence | Risk per 500 000 EPPs | Approximate risk per EPP |
|---|---|---|---|
| Low (<2%) | 0.3 | 75 | 1 in 7000 |
| Intermediate (2–7%) | 5 | 1250 | 1 in 400 |
| High (≥8%) | 10 | 2500 | 1 in 200 |

EPP, exposure-prone procedure. Estimated transmission during EPP is 5%. Adapted from Department of Health 2002.[101]

the UK, the Advisory Group on Hepatitis (AGH) recommended restriction of the working practices of individuals who had been shown to be associated with the spread of infection, but stopped short of recommending routine screening of staff or patients. This was clearly not sufficient to prevent HCW-to-patient transmission of HBV. The UK guidelines have since been modified at various intervals, with the trend towards the introduction of ever more restrictive guidelines.

The first major revision occurred in 1993.[102] The explicit intention of these new guidelines was to remove HBeAg-positive HBV carriers from the pool of HCWs allowed to perform EPPs, a decision based on the extensive evidence available at that time that HBV-transmitting HCWs were all HBeAg-positive (where HBeAg/anti-HBe testing had been performed). The guidelines stipulated that HCWs performing EPPs should:

> undergo a course of HBV vaccination and have their response checked 2–4 months after completion of the primary course; non-responders to vaccine should, after appropriate counselling and consent, be tested for HBsAg; those found to be HBV carriers should then be tested to determine their HBeAg/anti-HBe status; those found to be HBeAg-positive were then banned from performing EPPs. No restrictions were placed upon infected health-care workers who were HBeAg-negative.

The implementation of this guidance undoubtedly had a profound effect on those surgeons found to be HBeAg-positive, who were faced with the end of their surgical careers. Indeed, in one infamous incident, a surgeon substituted another blood sample for his own to hide the fact that he was HBeAg-positive. He was subsequently struck off the medical register and given a prison sentence, having transmitted infection to 24 patients.[103] There was also a significant effect on the health-care service through the loss of surgical expertise.

In the years since 1993, despite these guidelines, there have been nine HCWs who have transmitted infection to at least 15 patients, three of whom died of fulminant HBV infection (see Table 46.4). This is considerably less than the 75 transmissions per year estimated to arise in the absence of any regulatory guidelines (see Table 46.3 above), but was nevertheless disappointing. In all instances, the guidelines had been correctly instituted. The first eight surgeons in Table 46.4 were known to be anti-HBe-positive HBV carriers (and therefore entitled to perform EPPs), whilst the ninth case was an HBeAg-positive junior house surgeon who did not perform EPPs (and where, presumably, transmission occurred through failure of infection control procedures).

Detailed investigation of all transmission incidents has demonstrated the reason for failure of the guidelines – all the anti-HBe-positive surgeons harboured precore mutants and had high levels of HBV DNA. The first four cases of surgeon-to-patient HBV infection from anti-HBe-positive surgeons have been reported in detail.[104] In the light of these unexpected incidents, the AGH recommended yet further restrictions on HBsAg-positive HCWs wishing to perform EPPs. Clearly, HBeAg/anti-HBe markers are only surrogate guides to the infectivity of an HBsAg-positive individual, the true marker being HBV DNA. Options considered by the AGH included the banning of all HBsAg-positive HCWs, regardless of HBeAg/anti-HBe status, or finding some compromise policy based on HBV DNA levels. The former course of action, whilst perhaps more likely to be acceptable to the general public, was felt to be unfair to those HCWs with very low levels of HBV DNA who were likely to pose very little risk to their patients, and would result in unnecessary loss of surgical expertise. The revised guidelines, published in 2002,[105] therefore contained the following recommendations:

> HCWs found to be HBsAg-positive should have their HBeAg/anti-HBe status determined; there was no change to the guidelines for those found to be HBeAg-positive; HCWs without HBeAg should be further tested for HBV DNA; a cut-off value of $10^3$ copies per mL was set – with HCWs with DNA levels below this level allowed to continue to perform EPPs, subject to annual testing of their HBV DNA levels, and HCWs with DNA levels above this cut-off banned from EPPs.

Given the critical role of the HBV DNA level, procedures were put in place to ensure accurate testing. The assays are performed in only two designated laboratories. Two samples from each HCW are required, taken a few days apart. Each sample is tested twice, and then referred to the other laboratory for testing. The assay used is the same in both laboratories (different commercially available assays may give readings differing by as much as 0.5 $\log_{10}$), and the assays are internally controlled.[106] To date, around 400 anti-HBe-positive HCWs have been

**Table 46.4** HCW-to-patient transmissions of HBV in the UK since the 1993 guidelines

| Surgical speciality | Number infected (number died) | Exposed patients tested |
|---|---|---|
| 1. General | 1 | – |
| 2. O&G | 3 | 92 |
| 3. O&G | 1 | 111 |
| 4. General/urology | 1 | 21 |
| 5. Orthopaedic | 1 (1) | 188 |

HCW, health-care worker; O&G, obstetrics and gynaecology.

tested in this way. Around 60% have DNA levels above the cut-off and have therefore had to stop performing EPPs.

The construction and implementation of this policy has not been without controversy. Two particularly difficult issues are (1) what should the cut-off HBV DNA level be, and (2) should HCWs with DNA levels above the cut-off be allowed to take suppressive drugs such as lamivudine or adefovir, in order to bring their HBV DNA levels into the range which would allow them to carry on their operative careers?

Whatever cut-off level is set, there will always be individuals whose level falls just above. The cut-off level was set taking into account: (1) the levels of HBV DNA in those anti-HBe-positive surgeons known to have transmitted infection – the lowest recorded level was $4 \times 10^4$ copies/mL;[107] (2) the degree of reproducibility of the assays used to measure viral load, where serial testing of the same sample may yield results within a range of half a log about the mean; (3) potential variability in viral load within individuals over time – as a guide, it was estimated that viral load may oscillate by half a log either side of a mean value in a given individual over time, although there are reports that HBV DNA loads may vary by more than this in certain individuals .[108] The agreed level of $10^3$ copies per mL is felt to err on the side of caution. Other countries have opted for different cut-offs, e.g. the Netherlands excludes HCWs with HBV DNA levels $>10^5$ copies/mL.[109] All policies are kept under review, and cut-off values may need to be adjusted to take into account any further transmission episodes should they occur.

The availability of effective and safe antiviral agents capable of suppressing HBV replication creates a new dilemma for policy-makers. If anti-HBe-positive HCWs can maintain their HBV DNA levels below $10^3$ copies per mL by taking lamivudine, adefovir, or even both, then should that individual be allowed to perform EPPs? One concern would be that maintenance of safe levels of HBV DNA would then be dependent on compliance with therapy, something which cannot easily be guaranteed. A second issue is whether long-term suppressive therapy may fail due to the emergence of drug-resistant mutations, resulting in the return of unacceptably high DNA levels. Lamivudine resistance arises in around 15% of patients per year of therapy in both HBeAg-positive[110] and anti-HBe-positive patients,[111] and although current data suggest that adefovir resistance is not as common, there is no doubt that it can occur.[112] The rapidity of emergence of lamivudine resistance is dependent on the initial HBV DNA level.[113,114] Thus, in HCWs with HBV DNA levels in the range, say $10^3$–$10^5$ copies per mL, emergence of resistance may be significantly less likely than the figure quoted above. Also, when resistant mutants do appear, the HBV DNA level rises only gradually, and even then may not return to the pretreatment load. Thus, a persuasive argument can be constructed to allow anti-HBe-positive HCWs to return to EPPs whilst on suppressive therapy, with the built-in safety measures that the pretreatment viral load was no greater than $10^5$ copies/mL, and that the HCW concerned agrees to have regular HBV DNA viral load assays every 3 months. The residual risk of patients acquiring HBV infection under those circumstances must be extremely low. Such a policy would condone the use of antivirals for the sole purpose of allowing a HCW to resume his/her operative career, an indication which is unlicensed. Thus far, no regulatory authorities have adopted a policy allowing HCWs on antiviral therapy to perform EPPs.

One additional 'loophole' arising from the 1993 guidelines has also been dealt with. It is now recommended that HCWs should be screened for HBsAg prior to the onset of vaccination. HBsAg-positive individuals may harbour low levels of anti-HBs.[64,65] Thus, if only non-responders to vaccine are tested for HBV carriage, as was stipulated by the 1993 guidelines, carriers with anti-HBs levels >10 IU/L after vaccination would be allowed to proceed to EPPs without any further testing. There have been several anecdotal reports to the AGH of HBV-infected HCWs with detectable anti-HBs, with some even >100 IU/L. The importance of this loophole is tragically demonstrated by surgeon 8 in Table 46.4. As a low-level apparent anti-HBs responder, this individual received a number of booster doses of vaccine, and at one stage achieved an anti-HBs titre of 252 IU/L. It was only when he was associated with transmission of HBV to a patient that his true carrier status was identified. He was anti-HBe-positive, but with a viral load of $>2 \times 10^5$ copies/mL at the time of transmission.

Policies such as those adopted in the UK and the Netherlands, which allow known HBV-infected HCWs to continue to perform EPPs, should emphasize that any needle-stick or sharps injury to the HCW received whilst performing an EPP must be reported appropriately, regardless of the HCW's HBV DNA level. The transmission risk to the patient is not simply dependent on the HBV DNA load of the HCW – other factors, such as the amount of blood to which the patient is exposed, are important. A risk assessment must therefore be performed to determine whether or not to offer PEP (HBIg and/or HBV vaccine) to the patient.

Infected workers may occasionally pose a risk in other settings. Outbreaks of hepatitis B infection among butchers have been attributed to transmission from an infected worker.[21,115] It is important for workers in any occupation where cuts and other injuries leading to bleeding are common to be trained in proper methods of treating wounds and cleaning up any blood spillages.

## Hepatitis C

### Occupational acquisition of HCV by workers

#### *Evidence of risk in different occupational groups*

As with HBV, HCV is blood-borne. Occupational exposure to HCV infection is therefore likely to occur through the same routes as for HBV, i.e. needle-stick and sharps injuries, and mucosal splashes. Indeed, there are well-documented examples of acquisition of HCV infection by workers through needle-stick injury,[116–119] some of which have been confirmed by molecular evolutionary analysis.[120] One would expect HCWs to be the occupational group most at risk, and most data concerning prevalence of HCV infection in different occupational groups are derived from such individuals. One case-control study[121] found that health-care employment in the UK was associated with a threefold greater risk of acquiring HCV infection. However, most serosurveys report a low prevalence of anti-HCV in this group, higher than the prevalence in blood donors in some[122–124] but not all[125–127] studies, although it should be acknowledged that blood donors are not an ideal control group. Where comparisons are made to seroprevalence rates in other population groups, most reports indicate that HCWs are no more likely to have markers of HCV infection,[54,123,128,129] although there are one or two exceptions to this.[130,131] Similarly, studies that concentrate on markers of HCV infection in dental-care workers report either a slight increase[6,132] or no difference[133–136] in prevalence compared to control populations. Extensive data from the USA derived from emergency responders (including fire-fighters, paramedics and emergency medical technicians) suggest a prevalence of anti-HCV no different to that among appropriate referent groups in the general US population.[137,138] Taken together, the data in Table 46.5,[54,83,122–135,137–153] showing an absence of consistently higher HCV seroprevalence rates in these occupationally exposed groups, make it difficult to conclude that HCWs are more likely than the general population to have markers of HCV infection. This is in marked contrast to the body of evidence discussed earlier in relation to HBV infection, at least before routine HBV vaccination was introduced. One outstanding exception to this reassuring conclusion is a paper demonstrating anti-HCV positivity in 38% of 50 barbers in Sicily who shaved themselves with the same instruments as those used for their customers, as compared with 0% of 50 local blood donors.[153] However, there are no other data relating to this particular occupational group to verify or rebut these alarming data.

#### *Modes of occupational transmission of HCV to workers*

As with HBV, the most obvious routes of occupational transmission of HCV are via needle-stick or sharps injuries. There is also at least a theoretical risk of transmission by exposure of mucous membranes to blood splashes – transmission by a blood splash into the conjunctiva has been reported.[154] There are no reports of transmission of HCV via blood contact with intact skin.

#### *Magnitude of risk*

The risk of transmission of hepatitis C to HCWs depends on the same variables as previously discussed for hepatitis B virus.

(1) The prevalence of HCV infection in the patient population. This will vary considerably. In a London teaching hospital, 8.5% of 200 needle-stick source patients were positive for hepatitis C antibodies between January 1989 and January 1992, compared with 13.9% of 173 source patients tested between January 1992 and June 1993.[155] The HCV infection in one-quarter of the source patients was only discovered as a result of follow-up of the needle-stick injury. None of 102 patients in a UK hospital for patients with learning disabilities was found to have antibodies for hepatitis C.[156] The prevalence of HCV infection in dialysis units is highly variable, e.g. from 0 to 39%.[157] The clientele attending accident and emergency departments may have a high prevalence of blood-borne virus infection – of 2523 patients attending an inner-city emergency department in the USA, 18% were positive for HCV, and 5% were positive for HBsAg.[158] (2) The frequency of blood exposures among HCWs capable of allowing transmission. This was discussed in detail earlier. Published estimates of this frequency vary from annual rates of 0.1 to 5 per surgeon.[59,159] (3) The risk of transmission following an exposure to an infected source. A number of prospective studies have addressed the risk of seroconversion after a needle-stick injury from a source patient with anti-HCV antibodies – these are summarized in Table 46.6.[59,83,139,157,160–180] Adding the data from all reports in the literature, there are 39 acquisitions of HCV infection in HCWs from 2506 (1.6%) needle-stick exposures, although these figures may not be entirely accurate, as it is difficult to rule out double reporting of incidents/transmission events in studies by the same sets of investigators. The Centres for Disease Control and Prevention (CDCP) guidelines in the USA quote an average incidence of anti-HCV seroconversion after accidental percutaneous exposure from an HCV positive source of 1.8%.[181] Many countries have set up long-term surveillance schemes to monitor trends in HCW exposure to and transmission of

blood-borne viruses. In the HPA surveillance study in the UK referred to earlier, in the period 1997–2002, there were 498 HCWs who were known to have been exposed to an HCV-positive source and from whom follow-up data were available. Percutaneous injuries accounted for 70% of exposures, nearly two-thirds from hollow-bore needles. There were 2 seroconversions, although in 62 HCWs, it was not clear whether a 6-month follow-up sample had been tested or not.[60]

In the most recent reports from the Italian Surveillance scheme (SIROH), 41 participating hospitals reported transmission of HCV arising from 12/3076 percutaneous (0.39%, 95% CI 0.20–0.68), 2/557 mucous (0.36%, 0.04–1.29) and 0/473 (0%, 0–0.78) non-intact skin contaminations.[59] In the particular setting of cardiothoracic surgery, a total of 987 percutaneous and 255 mucocutaneous exposures were reported, of which 257 source patients were anti-HCV-positive. No seroconversions were observed.[177] Using estimates of the probabilities that: (1) a HCW might sustain a percutaneous injury during a surgical procedure, (2) the source patient is HCV-infected, and (3) the virus is transmitted to the surgeon after a single exposure, Yazdanpanah *et al.*[159] constructed a mathematical model from which they estimated a risk between one in 1000 and one in 10 000 for a surgeon acquiring HCV infection from an infected patient. These figures equate to between two and twenty surgeons out of a total of 20 000 in France acquiring HCV infection each year.

### *Prevention of occupational acquisition of HCV*

The cornerstone of any strategy to reduce the risk of HCWs acquiring HCV infection from their patients must be the institution of appropriate infection control

measures, including the use of safe practices to reduce hazardous exposures. This topic was discussed earlier in relation to prevention of hepatitis B transmission from patient to HCW, and the comments therein apply equally well to prevention of HCV transmission. Prevention strategies include ensuring adequate education of HCWs about phlebotomy and intravenous cannula insertion, availability of suitable sharps-disposal containers, introducing safety cannulas, reducing unnecessary use of sharps through less invasive techniques, using blunt needles for suturing, wearing double gloves, and using injury-avoidance work practices when handling sharps.[182] However, even the most rigorous set of infection control guidelines will not prevent completely the occurrence of needle-stick accidents and other potential exposures. Thus, there is a need to consider the post-exposure management of a HCW who has suffered an exposure to blood, whether from a patient of known or unknown HCV status. In contrast to the situation with HBV, there is no vaccine for either pre- or post-exposure active immunization. Also, passive protection with pooled gamma-globulin is not recommended,[181] although there are data pre-dating the characterization of HCV that immune serum globulin prophylaxis reduced the risk of post-transfusion non-A, non-B hepatitis,[183] and there is a provocative report of prevention of sexual transmission of hepatitis C by use of intramuscular immune serum globulin.[184] There are now a number of reports of successful treatment of acute HCV infection with IFN therapy.[174,185–187] Rates of virus clearance when treatment is initiated early following infection are very much higher than in patients with chronic HCV infection. A multicentre German study reported viral clearance in 43 of 44 (98%) such patients, including 14 whose route of acquisition of infection was a needle-stick injury.[186] A French study reported that IFN induced clearance of virus in 12 of 13 patients with acute infection.[187] These encouraging data therefore allow construction of a rational approach to the management of HCV-related needle-stick exposures.

The UK recommendations[188] state that a baseline serum sample from the recipients of such incidents should be stored. Where possible, serum from the source patient should be tested for evidence of infectivity (i.e. HCV RNA). Further samples from the recipient should be taken at 6, 12 and 24 weeks, for HCV RNA and anti-HCV testing. If any of these samples are positive, then comparison with the baseline sample will indicate whether the infection arose from the needle-stick injury. As soon as there is evidence of patient-to-HCW transmission of HCV, the HCW should be referred to an appropriate specialist for consideration of early IFN therapy, and the associated high chance of viral clearance. The only management issue that remains difficult to categorize is precisely when therapy should be started. There is at least a 25% chance that an acutely infected HCW will spontaneously clear the infection, thus sparing him/herself 6 months' worth of IFN therapy, with its attendant side-effects and cost. Thus, there may be some benefit in delaying therapy for, say, 3 months after diagnosis, in order to assess whether spontaneous clearance might occur.

These principles of management are broadly in line with those recommended by American[189] and Australian authorities,[182] although details as to the precise timing and frequency of recipient sampling and antibody and HCV RNA testing may vary. In the period following the percutaneous exposure, the current CDC recommendations state that 'health care professionals exposed to HBV- or HCV-infected blood do not need to take any special precautions to prevent secondary transmission during the follow-up period. However, they should refrain from donating blood, plasma, organs, tissue or semen'.[181] Allowing HCWs to continue their normal professional practice is sensible for two reasons. Firstly, the chances of the HCW becoming infected are low, as is the risk of onward transmission from the HCW to patients (see below). Should the HCW become HCV-infected, the identification and appropriate post-exposure management of patients on whom the HCW performed EPPs during the follow-up period would not be difficult. Secondly, it would be totally impracticable to operate any other policy in this regard. The effect of occupational health departments standing down all surgeons post-needle-stick injury until such time as acquisition of HCV infection had been ruled out would be chaotic, given the unpredictable nature of needle-stick injuries and their unfortunate frequency in HCWs. This would also have the effect of discouraging surgeons from reporting exposure incidents.

Guidelines for the post-exposure management of HCWs who suffer blood exposures can only be implemented if the HCW concerned reports the incident to the appropriate authority. As mentioned under hepatitis B, there is evidence that reporting of such incidents is suboptimal, even after high-risk exposures.[56–58]

## Transmission of HCV from infected workers

### *Evidence of HCV transmission from infected workers*

Hepatitis C can be transmitted from infected HCWs to patients during EPPs, in a similar way to hepatitis B. A number of HCW-to-patient transmissions of HCV infection have been reported (see Table 46.7).[30,109,190–192] The UK has the largest number of incidents, with five surgeons having transmitted HCV infection to patients, although only one of these has been published in full thus far.[190] Using the latest data from the five lookbacks available from the Department of Health, there have been 14 or 15

**Table 46.7** Transmission of HCV infection from health-care worker to patient

*Transmission occurred in 1/489 high-risk and 0/1850 low-risk procedures.

†The denominators in these two reports are rounded figures, as exact number of patients studied in lookback is not available.

‡Two lookback patients tested positive for anti-HCV, one being the index case that led to the lookback. It is not clear yet whether the surgeon is thought to be the source for the second case.

§Reported as personal communication from MJ Alter in 109.

¶Listed in Table 7 of ref. 109.

identified transmissions from 6919 patients (0.20–0.21%, see Table 46.7).

The transmission rates for each surgeon are remarkably consistent (Table 46.7), with all except the Spanish cardiothoracic surgeon being <0.5%. Taking all reports together, the best-case transmission rate is 23/10180 (0.23%, assuming only one transmission from the third UK surgeon, and taking into account all procedures performed by the German gynaecologist), and the worst-case rate is 24/8383 (0.29%, counting both cases from the third UK surgeon, and only the high-risk procedures of the German gynaecologist).

In addition to these well-documented surgeon-to-patient incidents, there have been a number of transmissions associated with anaesthetists. The first of these occurred in Australia, where five patients who underwent surgery during the same session were identified as having HCV infection (two presented with acute hepatitis 5 and 7 weeks after surgery, the other three were discovered by lookback). It has been suggested, although not proven, that transmission occurred due to contamination of the reuseable part of the anaesthetic circuitry via coughing up of respiratory secretions from the first HCV-infected patient on the list, who was known to have other risk factors for HCV.[193] A Spanish anaesthetist infected over 200 patients as a result of contamination of the patients' narcotics used by the HCW for self-injection,[194] whilst an Israeli substance-abusing anaesthestist infected over 30 patients by the same mechanism.[195] A German anaesthesiology assistant acquired HCV infection occupationally, and then transmitted this to five other patients through lack of adherence to infection control protocols.[196] More recently, in the USA, an anaesthetist transmitted to a patient (A) 3 days before he himself became jaundiced. A lookback exercise identified 2/348 patients (A+B) treated by him as having the same virus. It appears likely that he acquired HCV infection from patient B and then transmitted it to patient A.[197] An outbreak of HCV infection in attendees of an endoscopy practice in New York City arose from the anaesthetist re-entering a multidose vial with the same needle and syringe. All 12 newly infected patients had procedures that followed one chronically infected patient, over the subsequent 3 days.[198]

### *Modes of occupational transmission of HCV from workers*

In retrospective investigations, it is often impossible to identify the precise mechanism of transmission of a blood-borne virus. The assumption, for the surgeons at least, is that the surgeon suffers a percutaneous injury, perhaps not apparent at the time, leading to recontact of the surgeon's blood with the patient's open wound. The incidents arising from infected anaesthetists, and indeed, well documented nosocomial outbreaks of HCV,[199] serve to illustrate that unspecified breakdowns in infection control procedures are also a major risk factor for HCV transmission.

### *Magnitude of risk of transmission from infected workers*

In the light of proven HCW-to-patient transmission of HCV, Ross and colleagues[200] have constructed a model to determine the risk of occurrence of this adverse event. This was based on the premise that the risk to an individual patient of acquiring HCV infection from an infected HCW during an exposure-prone procedure is the product of the probabilities that (1) the surgeon is infected with

HCV, (2) the surgeon might suffer a percutaneous injury during the procedure, (3) an HCV-contaminated instrument might recontact the wound, and (4) HCV may be transmitted as a result of the exposure. Using published data for each of the parameters, they conclude that for a surgeon of unknown HCV status, the risk of transmission in any one operation is of the order of one in 135 000 to one in 1.2 million. As with any model, the accuracy of the calculated risks is dependent on the accuracy of the underlying assumptions, and the authors acknowledge that their model has certain limitations. However, it does allow comparison of the risk of HCW-to-patient transmission of HCV with that of the risks for HBV and HIV transmissions. For known infected surgeons, the calculated risks per operation are one in 1750 to one in 16 000 for HCV, one in 400 for HBV, and one in 40 000 for HIV.[200] A simpler approach to estimating transmission risk was adopted by the UK Department of Health.[101] On the basis that one in 200 surgeons currently practising in the UK is infected with HCV (i.e. the same prevalence as in the general population), and that an infected surgeon transmits infection in one in 400 (0.25%) operations (a reasonable assumption, see Table 46.7), then the chances of an individual patient acquiring infection from a surgeon of unknown status is one in 80 000. Thus, if half a million exposure-prone procedures are performed annually, somewhere between five and ten patients per year will acquire HCV infection through this route.

### *Prevention of transmission of HCV from workers*

Constructing sensible guidelines for the prevention of HCW-to-patient transmission of hepatitis C is fraught with difficulties. In contrast to hepatitis B, there is no vaccine available for pre-exposure prevention, and no passive immunization for post-exposure protection. A balance must be struck between protecting the patient on the one hand, and safeguarding the rights of HCWs on the other. The two extreme options are as follows.

**1** To take no action. This policy acknowledges that some HCWs are infected with HCV, and therefore there will always be a background rate of HCW-to-patient transmission of HCV. However, the risk to any individual patient undergoing an EPP is low (e.g. one in 80 000 in the UK, see above), and in any case much lower than other recognized surgical complications such as a wound infection or acquisition of methicillin-resistant *Staphylococcus aureus* (MRSA). Given that at least one-quarter of infected patients would be expected to clear virus spontaneously, and that perhaps only 20% of chronically infected patients develop cirrhosis over a period of 20 years, the annual risk of a life-threatening event arising from such acquisition of HCV is extremely small (e.g. one in $10^7$). For the UK, such a policy would amount to an acceptance of 5–10 HCV infections per year arising through this route.

**2** To screen all HCWs who perform EPPs for HCV infection, and exclude all those who are chronically infected. This would result, in the UK, in the removal of one of 200 such HCWs, representing an enormous loss of expertise. The net effect on the nation's health would be far more detrimental than in scenario (1) above, as surgical waiting lists would increase owing to the absence of trained surgeons. Furthermore, in the absence of a prophylactic vaccine, HCWs would be at risk of acquiring HCV infection from their patients (e.g. a one in 1000 annual infection rate).[159] Thus, there would be no alternative but to continue screening all HCWs performing EPPs at intervals, most likely on an annual basis. This raises a sword of Damocles over the career of every such HCW, with the possibility that they may have to end their chosen career at any time, and would undoubtedly have a negative effect on recruitment into EPP-performing specialties. Finally, if all HCWs were being screened for evidence of HCV infection, it is likely that pressure would be brought to bear to introduce screening of all patients. Not only would this be costly, but it would inevitably lead to discrimination against patients found to be HCV-infected.

There are proponents of each of these extreme policies to be found in the literature. In the United States, mandatory testing of surgeons and other HCWs for HCV is not recommended as a measure to protect patients.[201] However, Mele and 43 co-authors from the Italian Association for the Study of the Liver suggest that 'Healthcare workers who directly perform invasive procedures must undergo serological testing and … those … positive for … anti-hepatitis C virus and hepatitis C virus RNA must abstain from directly performing invasive procedures' ,[96] although they then benignly suggest that 'no other limitations in their activities are necessary'.

Suggested alternatives to these two extremes include introducing mandatory tests for HCV in HCWs at enrolment, but not preventing any HCW found to be HCV-infected from performing their duties.[202] A recent European Consensus Group discussed the issues surrounding both HBV- and HCV-infected HCWs.[109] National guidelines for HCV-infected HCWs were identified for only five (Belgium, Germany, Italy, UK, USA) of the 13 countries represented at the meeting. The Group recommended that HCWs who perform EPPs should know their HCV status – ideally before they begin their EPP posts. The report is somewhat opaque as to whether this injuncture should apply to all HCWs currently performing EPPs, or only to those entering an EPP-based career. It is difficult to see how such a policy of 'test but don't ban' might alleviate the problem of HCW-to-patient transmission of HCV, and it creates the additional dilemma of whether a HCW who knows him/herself to be infected

with HCV is required to inform his/her patients of this in advance.

In the UK, the recommendations of the Advisory Group on Hepatitis, subsequently adopted by the Department of Health, represent a traditional compromise.[203] HCWs who are known to be infected with HCV are banned from performing EPPs. There is no recommendation for blanket screening of all HCWs performing EPPs, although any HCW with reason to suspect that he/she might be infected by way of having a risk factor for infection is encouraged to be tested. However, screening is introduced for all HCWs entering training in a specialty which requires them to perform EPPs. The aim of this is to block the recruitment of HCV-infected individuals into the pool of HCWs who perform EPPs. However, for these HCWs, it is clearly an advantage to know their HCV status at this stage, as any infected individuals can then make an informed career choice. Implicit in this policy is the realization that a small number of patients (5–10 per year) will acquire HCV infection from infected HCWs.

## Hepatitis D

Hepatitis D infection is rarely of occupational relevance, except in particular circumstances. Staff who work with animals experimentally infected with hepatitis D should be screened for hepatitis B infection before starting the work and immunized against hepatitis B. This is in order to protect them, indirectly, from hepatitis D infection, which they can contract only if they already have hepatitis B infection, contracted by any means. Staff working with patients who might have hepatitis D infection should in any case be immunized against hepatitis B.

## Hepatitis E

There is little information about occupational associations with hepatitis E infection. It may pose a risk for individuals whose work takes them to areas of endemicity and poor hygiene, as for hepatitis A. An outbreak of acute HEV infection has been described among military personnel in Ethiopia,[204] and in a serosurvey in Brazil, 6 of 97 gold miners from the Amazon region were found to have antibodies to hepatitis E, thought to be related to poor sanitation in the mining camps.[205]

# Chapter 47
# Neonatal and paediatric infection

Deirdre Kelly, Elizabeth Boxall

Viral infections in neonates have a wide clinical spectrum ranging from an asymptomatic carrier to end-stage acute or chronic liver failure. Most of the hepatitis viruses that affect children have been discussed in detail elsewhere in this book. This chapter will highlight the clinical and therapeutic differences in children. Table 47.1 summarizes the important features of all of the viruses associated with hepatitis in children.

## Neonatal viral hepatitis

Neonates who are infected with hepatitis viruses may have been infected *in utero* or perinatally. The clinical presentation includes intrauterine infection, acute liver failure or an asymptomatic carrier.

### Intrauterine infection

The commonest intrauterine infections or congenital infections are the TORCH infections which are due to toxoplasmosis, rubella, cytomegalovirus, herpes or herpes simplex (Table 47.2). Less common infections include human herpes virus 6, herpes zoster or enteric viruses (echoviruses, Coxsackie A and B viruses, adenoviruses).[1]

#### *Clinical presentation and diagnosis*

The clinical presentation of intrauterine infection is similar for all forms of congenital infection which affect the liver. Most infants are small for gestational dates or are born prematurely. Jaundice and hepatosplenomegaly are constant features. Conjugated hyperbilirubinaemia occurs within 24 hours of life. Serum aminotransferases are frequently elevated (2–4 times normal), while alkaline phosphatase and gamma-glutamyl transpeptidase may be normal or only mildly elevated. Blood glucose and serum albumin may be low, particularly if the infant is premature.

Investigations should include an abdominal ultrasound scan, which will demonstrate hepatosplenomegaly. A radioisotope scan is only necessary if biliary obstruction is a feature and will demonstrate poor hepatic uptake with normal biliary excretion in congenital infection with a neonatal hepatitis. Liver histology demonstrates a neonatal hepatitis with multinucleated giant cell transformation and rosette formation. There may be extramedullary haematopoiesis and cholestasis.

#### *Toxoplasmosis*

Toxoplasmosis is not a viral infection but is an important differential diagnosis in this group of children. Infection is likely following maternal infection in the third trimester, and neonatal hepatitis is an important feature associated with central nervous system involvement with chorioretinitis, hydrocephaly or microcephaly. Intracranial lesions lead to convulsions, nystagmus and raised intracranial pressure. Spiramycin therapy may prevent progression of central nervous system and liver disease

#### *Rubella virus*

Rubella is a toga virus which causes a benign infection in older children. Infants of mothers infected in the first trimester of pregnancy are either stillborn or have a number of congenital malformations. Although congenital infection with rubella virus is rare because of widespread immunization, it is still a significant problem in the developing world.[2] The main clinical features include congenital cataracts, hepatitis, hepatosplenomegaly and congenital heart disease – which includes patent ductus arteriosus or pulmonary artery stenosis, mental retardation and sensorineural deafness. The diagnosis is based on the characteristic clinical features, the liver histology, which shows typical giant cell hepatitis, and the presence of IgM antibodies to rubella. The liver disease is usually self-limited, but occasional patients have persistent cholestasis and progress to cirrhosis.

A recent review which evaluated patients 60 years after the initial intrauterine rubella infection found that >80% were still alive. The most prominent persistent problem was mild aortic valve stenosis in 68%, but none of the survivors had persistent liver disease.[3]

**Table 47.1** Infections associated with hepatitis in childhood

| Aetiology | Antecedent history | Diagnostic investigations | Extrahepatic manifestations | Remarks |
|---|---|---|---|---|
| *Primary hepatotropic viruses* | | | | |
| Hepatitis A virus (HAV) | Neonatal intensive care unit epidemics | Anti-HAV IgM | None reported | Usually asymptomatic |
| Hepatitis B virus (HBV) | HBsAg-positive mothers: blood or blood products | HBsAg | Rash, arthritis? | Acquisition of persistent infection usually asymptomatic; rarely acute icteric or fulminant hepatitis |
| Hepatitis C virus (HCV) | Infants of HCV RNA-positive mothers, HIV-positive mothers, and/or intravenous drug abusers | HCV RNA by PCR; demonstration of HCV antigen in the liver; anti-HCV at 1 year | | More common if with high maternal viraemia (>$10^6$ copies/mL) or co-infection with HIV |
| Hepatitis D virus (HDV) | Anti-HDV-positive mothers | Anti-HDV IgM; HDV antigen in the hepatocytes | | Needs co-infection with HBV to manifest the disease |
| Cytomegalovirus (CMV) | Maternal primary or recurrent CMV infection | CMV-specific IgM; viral isolation in urine (PCR) and saliva; cytomegalic inclusion bodies in hepatocytes | Microcephaly; intracranial calcifications; chorioretinitis | |
| Epstein-Barr virus (EBV) | Maternal primary or recurrent EBV infection | Anti-EBV IgM; EBV DNA by PCR in blood | Low birth weight; congenital anomalies | |
| *Systemic viruses* | | | | |
| Rubella virus | Maternal infection, especially in the first trimester of pregnancy | Anti-rubella IgM; viral isolation from pharyngeal secretions, urine, CSF | Blueberry skin lesions; cataract; heart disease | Now uncommon in developed countries due to immunization |
| Herpes simplex virus (HSV) | Maternal HSV, especially in the genitalia | HSV-specific IgM; viral isolation from vesicular fluid, CSF, liver | Skin vesicles; keratoconjunctivitis; encephalitis | |
| Varicella zoster virus (VZV) | Maternal varicella less than 5 days before to 7 days after delivery | VZV-specific IgM, viral isolation from vesicular fluid and liver | Skin vesicles; pneumonitis | |
| Adenovirus | Vaginal delivery; premature rupture of membrane; maternal upper respiratory tract infection | Neutralizing or complement-fixing antibody to adenovirus; viral isolation in the liver | Thrombocytopenia; coagulopathy; pneumonitis | |
| Coxsackie virus | Epidemics of enteroviral disease in the community | Viral isolation in faeces, blood, CSF | Myocarditis; meningoencephalitis; pneumonitis; generalized myositis; thrombocytopenia | |
| Human immunodeficiency virus (HIV) | HIV-positive mothers | HIV proviral DNA in blood, HIV RNA by PCR; IgA anti-HIV; anti-HIV when age >1 year | Lymphadenopathy; intrauterine growth retardation | |

PCR, polymerase chain reaction; CSF, cerebrospinal fluid; HBsAg, hepatitis B surface antigen.

### *Cytomegalovirus*

Cytomegalovirus (CMV) is a DNA virus which is a common cause of congenital infection in humans, affecting 0.2–2.4% of all live-born infants, most of whom are asymptomatic. Severe infection is associated with intrauterine retardation or prematurity.[4] It accounts for 46% of neonatal hepatitis in Taiwan.[5] Seropositivity for CMV increases with age, ranging from 52% in infants aged <1 year to 60% in children between 4 and 7 years old in China. A higher rate of CMV antibodies has been observed among urban than rural children, in those who

**Table 47.2** Intrauterine infection: diagnosis and treatment

| Disease | Diagnostic test | Treatment |
|---|---|---|
| Rubella | IgM-specific antibodies | None |
| Cytomegalovirus | Urine for viral culture/PCR; IgM antibodies | Ganciclovir |
| Herpes simplex | EM/viral culture of vesical scraping | Acyclovir |
| Human herpes virus 6 | Seology, PCR | Acyclovir |
| Herpes zoster | Serology, PCR | Acyclovir |
| Human immunodeficiency virus (HIV) | Anti-HIV, PCR (EDTA blood); CD4 count | Retroviral therapy |
| Parvovirus B19 | IgM antibodies | |
| Syncytial giant cell hepatitis | Giant cell hepatitis on liver biopsy | Ribavarin |
| Toxoplasmosis | IgM-specific antibodies | Spiramycin |

EM, electron microscopy; EDTA, ethylenediaminetetraacetic acid; CD, cluster designation.

were breastfed, and among day-care centre attendees.[6] Acquisition is later in countries with better socio-economic conditions.[7]

### *Transmission*

Primary infection in the second or third trimester is likely to result in symptomatic CMV infection during the neonatal period,[8] while perinatal infection may occur through infected maternal genital secretions, urine, saliva or breast milk.[9] Infected infants excrete CMV for many years in urine and saliva and are a risk to other children and pregnant women. Infected blood products or donor organs may also be a source for CMV transmission of importance to transplant recipients.

### *Clinical features*

All infected infants have intrauterine growth retardation. Clinical features include fetal ascites, jaundice and hepatosplenomegaly and a petechial rash in 60–80%. CMV infection may affect the central nervous system, with microcephaly, intracranial calcification and chorioretinitis. Progressive sensorineural deafness, developmental delay or cerebral palsy may develop later in childhood. It is important to differentiate the neonatal hepatitis secondary to CMV from other causes of neonatal cholestasis, including biliary atresia, particularly as co-infection may exist.[10,11]

Although usually self-limiting, CMV infection may progress to hepatic fibrosis or cirrhosis[12,13] or non-cirrhotic portal hypertension.[14] Persisting neurodevelopmental abnormalities tend to be the most significant problem.[15]

### *Diagnosis*

Diagnosis is made by isolation of virus from any site (urine, saliva, bronchoalveolar lavage, blood, or liver) or by the presence of specific IgM antibody to CMV in the neonate.[16] Samples must be collected soon after birth to eliminate the possibility of post-natally acquired infection. Immunofluorescence staining using monoclonal antibody to detect the early CMV antigen following inoculation into cell cultures is a sensitive method, whereas CMV DNA detection by genome amplification techniques (e.g. polymerase chain reaction; PCR) is the most specific method in the diagnosis of CMV hepatitis, particularly post-transplant.[17] PCR can be performed on EDTA blood, urine and liver biopsies. Liver biochemistry is compatible with neonatal hepatitis syndrome and includes nuclear inclusion bodies and giant cell formation (see above).

Liver biopsy demonstrates giant cell hepatitis with multinucleated giant cell transformation. Hepatocyte necrosis, cholestasis, extramedullary haematopoiesis and fatty infiltration with minimal inflammatory cells are common, but the classic inclusion bodies of CMV are rarely seen in neonatal infection (Fig. 47.1). Occasionally, portal fibrosis and bile duct proliferation may be seen, similar to findings in extrahepatic biliary atresia.[18]

### *Prevention and treatment*

It is not possible to prevent perinatal infection, as vaccination is not available despite attempts to develop an

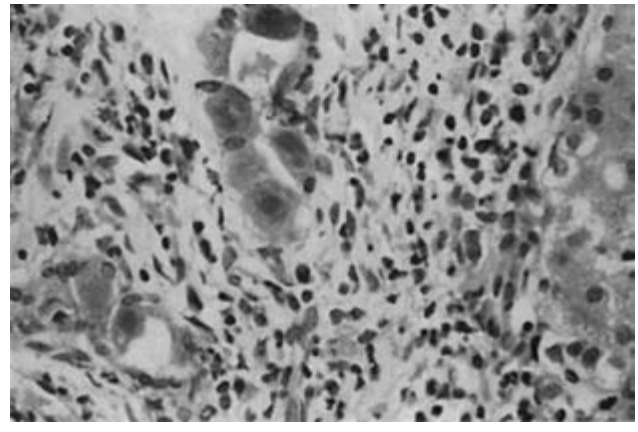

**Figure 47.1** Intranuclear inclusion bodies in CMV infection.

attenuated, live CMV vaccine, and also because infection takes place in the second or third trimester.[19,20] It is not usually necessary to treat neonatal infection as it is a self-limiting illness, but severe cases may respond to ganciclovir 7.5 mg/kg twice a day for 2 weeks followed by 10 mg/kg three times a week for 3 months.[21] CMV persists in a latent form that can be reactivated later.

#### *Human immunodeficiency virus (HIV) infection*

Infants with congenital HIV infection may present with hepatosplenomegaly, but conjugated hyperbilirubinaemia in the neonatal period is rare. Neonatal hepatitis in HIV-positive infants is more likely to be associated with concomitant congenital CMV infection.[22] Congenital HIV infection may present clinically as hepatitis with jaundice and hepatosplenomegaly typically at ~6 months of age.[23]

## Acute liver failure in the neonate

Acute liver failure in neonates is rare, but potentially fatal without liver transplantation. The aetiology includes inborn errors of metabolism, mitochondrial disorders, disorders of fatty acid oxidation, generalized sepsis and viral infection.

### Clinical presentation and diagnosis

Infants may present with intrauterine retardation, hypoglycaemia, jaundice, coagulopathy and encephalopathy within hours or weeks of birth. It is important to exclude other causes of liver failure and to treat with appropriate therapy (Table 47.3).

**Table 47.3** Causes of fulminant viral hepatitis in children

| Aetiology | Disease | Incidence |
|---|---|---|
| Neonates | | |
| | Herpes virus 6 | Rare |
| | Echovirus | Rare |
| | Adenovirus | Rare |
| | HBV | Frequent |
| | Parvovirus | Rare |
| | Coxsackie | Rare |
| Older children | | |
| | HAV | Frequent |
| | HBV | Rare |
| | HDV | Rare |
| | NA–G | Common |
| | EBV | Rare |
| | Herpes viruses | Rare |

HAV, hepatitis A virus; HBV, hepatitis B virus; HDV, hepatitis delta; NA–G, non A–G virus.

### Herpes simplex virus

Herpes simplex virus (HSV) (*Herpesvirus hominis*) is a DNA virus that causes a generalized disease with associated hepatitis. The incubation period is 2–12 days and it is transmitted by close bodily contact, or perinatally by contact with maternal body fluids.

#### *Clinical features*

Neonatal HSV infection presents with a severe multisystem disorder with encephalitis, severe hepatitis, or acute liver failure[24,25] due to either type 1 or type 2 virus, although type 2 virus shed from the infected cervix at birth is more common. Infants have progressive jaundice, hepatosplenomegaly, raised hepatic transaminase levels and coagulopathy, most commonly during the second week of life. Skin vesicles are present in 60% of adult patients, but the typical herpetic skin, mouth or eye lesions may not be present in neonates.[26] Fatal herpetic hepatitis has been described.[25,27]

#### *Diagnosis*

Diagnosis is made by the isolation of virus from vesicle swabs or other tissue/aspirates or demonstration of HSV antigens by direct immunofluorescence on vesicle swabs, nasopharyngeal aspirates, skin scrapings or biopsy tissue. Intranuclear inclusion bodies and multinucleate giant cells in scrapings or biopsy tissue are a feature of herpes viruses. The demonstration of specific neutralizing antibodies in the sera is confounded by the presence of passively transferred maternal antibody, although the demonstration of a specific IgM response would confirm infection in an infant. As with all perinatal infections, active disease in the mother and premature rupture of membranes are risk factors. Active genital lesions at the time of delivery present the greatest risk, although infection can occur in the absence of maternal lesions. Liver biopsy shows areas of necrosis with viral inclusions in intact hepatocytes.[28] Scrapings from vesicular skin lesions reveal HSV.

#### *Treatment*

Acyclovir (10–20 mg/kg per dose every 8 hours) is the drug of choice for disseminated HSV infection, with best results being obtained when treatment is started on the first day of illness. Liver transplantation may be indicated for acute liver failure if multi-organ failure is not present.[29]

### Enteric viruses

#### *Echovirus*

The enteroviruses are a rare cause of systemic viral infection in the newborn period, but are associated with severe hepatitis or acute liver failure. The incidence is highest in late summer and early autumn. Vertical infection at the time of birth is associated with more severe disease in the infant. Most infants present between 1 and 5 weeks old with lethargy, jaundice, very high levels of hepatic aminotransferases and severe coagulopathy. Meningitis may also be present. Echovirus serotypes 3, 6, 7, 9, 11, 14, 19 and 21 have all been reported in severe infections with hepatitis,[30] although echovirus serotype 11 appears to be most virulent for neonates. There is no specific treatment, but liver transplantation is effective for acute liver failure.

#### *Coxsackie virus*

Coxsackie virus is a human enterovirus which normally causes a self-limiting gastrointestinal disease. In neonates Coxsackie A and B viruses present in a similar way to echovirus with fulminant hepatitis, but with myocarditis or heart failure.[31,32]

#### *Adenovirus*

Adenoviruses are respiratory tract pathogens which also cause acute gastroenteritis, haemorrhagic cystitis, meningoencephalitis, hepatitis and myocarditis in the newborn and immunosuppressed patients.[33,34]

Neonatal adenovirus infection produces a severe illness with hepatomegaly, thrombocytopenia and coagulopathy in the first 10 days of life. Mortality with acute liver failure is of the order of 85–90%.[35] There is widespread necrosis of the liver with Feulgen-positive intranuclear target-like inclusions in the hepatocytes. On electron microscopy, paracrystalline arrays of adenovirus virions may be seen. There is no known treatment for adenovirus hepatitis, but supportive management of acute liver failure is essential. Hepatic function in survivors is normal.

### Syncytial giant cell hepatitis

Syncytial giant cell hepatitis is secondary to paramyxovirus infection. The liver disease varies with the age of the patient. In neonates, syncytial giant cell hepatitis presents with a severe hepatitis, with moderately elevated serum aminotransferases and may progress to chronic cholestasis and decompensated cirrhosis over 6–12 months. Some infants may have a chronic active hepatitis with autoimmune haemolytic anaemia. In older children, fulminant hepatic failure is common, while rapidly progressive chronic hepatitis occurs in adults.

The diagnosis depends on demonstrating the characteristic syncytial-type giant cells and viral inclusions consistent with the morphology of paramyxoviruses[36] on liver histology and electron microscopy. Spontaneous recovery is uncommon. Treatment with the antiviral agent ribavirin may be effective.[37] Most infants require liver transplantation.

## Acute hepatitis in older children

### Hepatitis A virus (HAV)

#### *Prevalence*

HAV has a worldwide distribution. It is endemic in early childhood in areas with poor living conditions and low socio-economic status. Seropositivity to HAV was noted in 70% of children 3–4 years of age in Liberia,[38] in 76% of children between 9 and 11 years in Venezuela[39] and in 98% of children between 6 and 10 years in India.[40] The mean age of infection increases with improvement in sanitation. In Thailand, with its economic growth and improved levels of public sanitation, the prevalence of antibody to hepatitis A among children 10–15 years old has fallen from 50–70% in 1977 to 20–25% in 1992.[41,42] In Hong Kong, the prevalence of anti-HAV antibody has declined over a 10-year period from 45% to 17% for subjects between 11 and 20 years of age.[43] In the UK, only 10% of individuals <15 years of age have serological evidence of past HAV infection, and the current annual incidence of hepatitis A in 5–14-year-olds is between 0.5% and 1.9%.[44]

Transmission of the disease is by faecal contamination of drinking water or food and by person-to-person contact. Epidemics and sporadic cases of HAV in developed countries are usually associated with infected food handlers and contaminated food or water.[45] Outbreaks of hepatitis A have been described in day-care centres[46] and institutions for children with learning disabilities.[47] Rarely, parenteral transmission of hepatitis A has been implicated. An outbreak of symptomatic HAV infection in both children and adult haemophiliacs caused by inadequately treated factor VIII concentrate has been reported.[48] One case of vertical transmission has been described leading to an epidemic in a neonatal intensive care unit,[49] although during an epidemic of hepatitis A affecting 431 pregnancies in Shanghai, China, no neonate had detectable anti-HAV IgM.[50]

#### *Clinical features*

Asymptomatic infection has been described in 84% of those infected between 1 and 2 years old..[51] Clinical cases

of HAV are usually seen in older children, who are more likely to be symptomatic in both developing and developed countries.[52,53] In an epidemic in the UK, only one of 43 children aged <5 years became icteric compared with one of five between eight and 10 years of age.[53]

After a prodromal period of 4–10 days, jaundice is the first sign of liver disease. The following clinical features were recorded in 281 cases (aged 3 months to 12 years): jaundice (99%), dark urine (85%), anorexia (83%), lethargy (81%), vomiting (72%), abdominal pain (64%), fever (57%), diarrhoea (18%), pale faeces (17%), rash (7%) and arthritis (5%).[54] Liver function tests returned to normal between 1 and 18 months after onset. Atypically, children with HAV infection may have clinical and ultrasonographic features suggestive of acute cholecystitis.[55] Enlargement of lymph nodes located in the hepatic hilum, pancreatic area and lesser omentum may be present in acute HAV infection.[56] The majority (99.9%) of children with HAV infection recover completely.

### *Diagnosis*

Diagnosis of acute hepatitis A is by detection of hepatitis A specific IgM class antibody in serum. Virus particles can be demonstrated by immune electron microscopy in faeces in the incubation period and early acute phase of infection. Virus RNA can be amplified by genome amplification techniques from faeces and acute phase sera for epidemiological studies.

### *Complications*

As in adults, the most serious complication of the disease is fulminant hepatic failure, with encephalopathy and coagulopathy and progressive jaundice. In one hospital-based study, fatal fulminant hepatitis A was reported in 3 of 2174 (0.14%) patients. Two were children, aged 5 and 15 years.[57] The survival of patients with grade III–IV hepatic encephalopathy with specialized intensive care was 67%.[58]

In 3–20% of patients with icteric hepatitis, a relapse may occur within 2–12 weeks after initial improvement of their liver function tests.[59] These episodes are associated with a rise in alanine aminotransferase (ALT) levels and a recurrence of jaundice. Patients usually recover completely.[60] HAV in the stools has been demonstrated during episodes of relapse, implicating HAV as the causative agent of relapsing hepatitis.[61]

### *Prevention*

Active immunization against HAV infection is now possible with the use of formalin-inactivated hepatitis A vaccine derived from the HM175 or CR 325F′ virus strains.[62] HAV vaccine was protective in 97% of 38 000 Thai schoolchildren aged 2–16 years.[41] Vaccine protection against both disease and infection occurs within 1 month after administration of two doses and persists for at least 1 year.[63] The vaccine is safe and well tolerated. The most common reaction is soreness at the site of injection.

HAV vaccine is also effective in the control of HAV outbreaks in low endemicity areas. Only one of 404 (0.25%) schoolchildren from Slovakia who were given at least one dose of 360 EIU HAV vaccine developed icteric hepatitis as compared with 8 of 157 (5%) unvaccinated children.[64] The vaccine was also more effective than post-exposure IgG prophylaxis in reducing the epidemic.

Protective antibody titres (>20 mIU/mL) in 106 vaccinees persisted for at least 30 months after the third dose of vaccine, with 94% having titres >200 mIU/mL.[62] A recent consensus statement concluded that immunity lasted at least 10 years and that there was no evidence to support the need for booster doses in healthy groups of patients, although more information was needed in groups of patients at special risk.[63]

## Hepatitis B virus (HBV)

### *Prevalence*

Hepatitis B infection is a major public health problem, with an estimated 350 million hepatitis B surface antigen (HBsAg) carriers worldwide. It is primarily a disease of childhood in endemic areas of the world such as Africa and China, where 15–20% of the population are HBsAg carriers.[65] Infection in the perinatal period or early infancy occurs in 40% of infants in Taiwan, but in only 1–5% in sub-Saharan Africa. The difference is in part explained by the higher prevalence of hepatitis B e antigen (HBeAg) in Chinese (40%) than African (15%) mothers. In Africa, the majority of infections are acquired between 6 months and 6 years of age, with other family members implicated as a source of infection.[65,65a]

In areas of intermediate endemicity (Italy, Japan, Spain, Greece, Portugal), where 2–10% of the population are HBsAg carriers, infection occurs in both adults and children. In Italy, the HBsAg carrier rate among pregnant women was 5% and the prevalence of hepatitis B markers in children <11 years was 1.7%.[66] In areas of low endemicity (north-west Europe, North America, UK, Australia), infection in infancy and childhood is uncommon and <1% of the population has chronic HBV infection.[67]

### *Transmission*

Infection is either blood-borne or through contaminated body fluids. The mode of transmission is by parenteral exposure (e.g. blood transfusion) or percutaneous ex-

posure (e.g. use of unsterilized instruments, tattooing, acupuncture, ear piercing). Inapparent spread of infection may also occur through intimate contact with body secretions and skin lesions and sharing of household utensils among family members.

Maternal–infant transmission is an important means by which the virus is maintained in the population. HBsAg can be detected in up to 5% of samples of cord blood taken at delivery from HBsAg-positive mothers, which is an indication of infection *in utero*.[68–70] One important mode of infection is inoculation or ingestion by the newborn of infected maternal blood and vaginal secretions around the time of delivery. The risk of infection is 15–40% if the mother is HBsAg-positive, but increases to 70–90% if the mother is HBeAg-positive.[71] In the presence of maternal anti-HBe, the risk of viral transmission to the infant is only 10–20%.[67] However, if their offspring are infected, they are at risk of developing fulminant liver failure.[72–75] Some 70% of mothers with acute hepatitis B during pregnancy may transmit the virus if infection occurs during the third trimester of pregnancy, and 90% will do so if it occurs within 8 days of delivery. There is no increased risk of abortion or malformation.

### *Clinical features and prognosis*

More than 80% of infants born to HBeAg- and HBsAg-positive mothers become chronic carriers.[76] Rarely, infection during the perinatal period may cause an acute icteric or fulminant hepatitis.

The clinical features of acute hepatitis B infection, by either perinatal or horizontal transmission include jaundice (97%), dark urine (79%), lethargy (69%), anorexia (55%), fever (52%) and vomiting (45%). The clinical course is more insidious than hepatitis A infection.[54] Extrahepatic manifestations include arthritis (14%) and skin eruptions (10%) (e.g. maculopapular or urticarial rash). The arthritis is symmetrical and polyarticular, involving the hands and the knees, and may last for about 3 weeks. The Gianotti-Crosti syndrome has been described with hepatitis B infection and consists of fever, lymphadenopathy, hepatomegaly and a non-pruritic, erythematous papular exanthem of the face and extremities.[77]

The majority (>90%) of children with acute hepatitis B infection recover completely within 6–12 months. Out of 28 children, 96% cleared the HBsAg, and only one patient became a chronic carrier. Anti-HBs seroconversion occurred after 6 months in 77% and in 96% after 1 year.[54] A study from Italy showed that hepatitis B-infected children recovered more slowly than children infected with hepatitis A, with 30% becoming chronically infected for up to 2 years, but some of these showing later resolution of infection.[78]

Fulminant hepatitis, may occur in <1% but is more frequently observed when there is co-infection or superinfection with the delta agent[79] (see section on hepatitis D virus) or in neonates born to mothers who are anti-HBe-positive.[72] Mutations in the precore region of the HBV DNA have been implicated.[80,81]

### *Diagnosis*

Acute hepatitis B is diagnosed serologically by the presence of HBsAg in serum along with IgM antibody to HBcAg. Other markers which can be assayed to indicate progression of the acute infection are the transition from HBeAg to AntiHBe and changes in the titre of HBsAg and HBV DNA. Most acute HBV will resolve with clearance of HBsAg and development of antiHBs and natural immunity.

## Hepatitis E virus (HEV)

### *Prevalence*

The disease occurs in the form of waterborne epidemics on the Indian subcontinent, south-east and central Asia, Africa and North America. In developed countries, sporadic cases are related to HEV infection among people returning from visits to endemic areas. The incubation period is 6 weeks (range 2–9 weeks) after primary exposure. It has a low secondary attack rate among exposed household members.

Population-based studies have shown that HEV infection is infrequent among children <10 years of age. In India, where HEV is endemic, only 5 of 103 (5%) children were noted to be anti-HEV IgG-positive.[40] Similarly, in areas where HEV epidemics have not been reported, the presence of anti-HEV IgG was noted in 2 of 73 (3%) children aged 1–10 years from Hong Kong[82] and in 1 of 300 (0.3%) Taiwanase children aged 6–10 years.[83]

Co-infection with hepatitis A and hepatitis E has been reported.[82,84] Clinically overt disease is observed mostly among young adults between 15 and 40 years of age (2.95%), and the prevalence is only 1.4% in subjects under 14 years.[85]

### *Clinical features*

The clinical features of the disease are similar to acute hepatitis A or B. Of 23 Sudanese children with icteric hepatitis, concomitant symptoms included vomiting (61%), fever (48%) and arthralgia (30%).[84] A striking and unexplained feature is the severity of HEV infection in pregnant women, with a mortality rate as high as 20%. Vertical transmission has been described with significant perinatal morbidity and mortality.[86]

Complete recovery usually follows acute infection in children. Progression to chronic liver disease has not been observed. The frequency of secondary cases in household members is low. Superinfection with HEV inpatients with chronic liver disease may cause severe decompensation.[87]

### *Diagnosis*

Acute HEV is diagnosed by the presence of IgM and IgG antibody to recombinant HEV antigen.[87a] HEV RNA can be demonstrated in acute phase serum and stool by reverse transcription-polymerase chain reaction (RT-PCR). HEV RNA in serum precedes peak ALT. IgG antibody is detectable for up to 5 years after an acute infection, but the duration of persistence is not known.

### *Treatment and prevention*

There is no specific treatment for HEV infection. Recombinant hepatitis E vaccines given either orally or intramuscularly have been shown to protect experimental animals against challenge[88,89] and are now undergoing clinical trial.[90]

## Hepatitis F

In a proportion of fulminant non A–E hepatitis, small particles resembling bunya viruses or toga viruses have been observed in liver by electron microscopy. A feature of these infections is the reinfection of transplanted livers with the production of a haemorrhagic fever-like illness.[91,92] The role of these viruses is still to be established.

## Hepatitis G

Molecular methods have assisted in the recognition of further 'hepatitis' viruses. Hepatitis G virus (HGV) or GBV-C is a transfusion-transmissible agent related to hepatitis C which has been implicated in both acute and chronic infections, although most people with HGV viraemia have no biochemical evidence of any liver disease.[91,92] Vertical transmission has been described with molecular studies showing relationship between maternal and infant virus.[95] Transmission of HGV occurred at a lower rate than HCV in co-infected women, although transmission was more frequent from mothers who were also infected with HIV.[96–99] Such transmission events were not associated with abnormal liver function in babies followed up for periods up to 1 year.[100]

The prevalence of HGV infection in children has not been established. However, in a study of children who had undergone liver transplantation, the HGV prevalence was 30% and infection was persistent, but not associated with chronic hepatitis.[101]

## Other transfusion-transmissible viruses

TT virus is a transfusion-transmissible virus named after the first patient with this infection.[102] It may be spread parenterally and by the faecal-oral route. It is highly prevalent in the general population, and its role in causing otherwise unexplained acute hepatitis is not established. Another virus, which has been shown to be parentally transmitted, is SEN virus.[103] Both of these viruses have been shown to be transmitted perinatally. However, the long-term outcomes in children have yet to be described.[99,104,.105]

## Non A–E hepatitis

It is clear that acute or fulminant hepatitis may be caused by other, unidentified viruses, labelled non A–E hepatitis or non A–G hepatitis. Children and young adults are affected with a severe hepatitis illness with little spontaneous recovery. Non A–E hepatitis is the commonest viral cause of fulminant hepatic failure requiring liver transplantation in children the UK and the USA. It may be further complicated by transient bone marrow suppression or aplastic anaemia: in one series of 32 children and young adults who underwent liver transplantation for non-A, non-B hepatitis, 28% developed aplastic anaemia.[106] Furthermore, in a series of eight children with both acute liver failure and bone marrow failure, two had parvovirus B16 infection, and six had non A–G hepatitis.[107] Management is supportive, with early consideration of liver transplantation in view of the poor chance of spontaneous recovery.

## Measles virus

Measles is a 120–250-nm RNA virus of the paramyxovirus family that causes febrile exanthema in children and young adults and is transmitted by droplet infection from nasopharyngeal secretions. The presence of abnormal hepatic transaminases without jaundice is common in young children,[108,109] while hepatobiliary disease is more common in adolescents and adults.[110] Spontaneous resolution is usual. Measles has been proposed as a trigger for a type 1 autoimmune hepatitis occurring within 3 months of infection.[111]

### *Diagnosis*

Measles virus can be isolated from throat swabs and saliva samples and infection can be confirmed by specific IgM antibody.

## Parvovirus B19

Human parvovirus (HPV) B19 infection in childhood

presents with erythema infectiosum or haemolytic anaemia which may lead to an aplastic crisis. Infection during pregnancy may lead to fetal ascites in the infant. HPV B19 infection is now associated with hepatic dysfunction with raised hepatic aminotransferase enzymes. Fulminant liver failure (with and without aplastic anaemia) in association with HPV B19 is described.[107]

## Herpes viruses

The herpes viruses are a family of icosahedral double-stranded DNA viruses which may cause acute hepatitis. They often become latent, persisting in the host after primary infection despite high levels of neutralizing antibody. Reactivation occurs in immunosuppressed patients. Replication by herpes virus DNA polymerase is inhibited by antiviral agents.

## Herpes simplex viruses 1 and 2

Herpes simplex virus (HSV) hepatitis is rare outside the neonatal period in an immunocompetent host.

## Cytomegalovirus

Cytomegalovirus (CMV) usually occurs in neonates (see above) but may cause a mild illness in childhood similar to infectious mononucleosis. Hepatic involvement with raised transaminases, alkaline phosphatase and bilirubin resolves without treatment and a chronic course is unusual.

## Epstein-Barr virus

Epstein-Barr virus (EBV) is a herpes virus which causes infectious mononucleosis. The pharynx is the initial site of replication, but the virus spreads throughout the lymphatic system, where it persists for life and may be periodically reactivated. In developing countries, 90% of children are infected before 4 years of age. In affluent societies it is a disease of adolescents and adults.[112] Transmission is by oropharyngeal secretions with an incubation period of 30–40 days.

### *Clinical features*

In childhood, EBV infection is asymptomatic or associated with mild non-specific symptoms. Primary infection in adolescence or early adulthood is associated with acute infectious mononucleosis (IM) or 'glandular fever' which is characterized by pharyngitis and malaise. Splenomegaly and lymphadenopathy are present in 50%, with hepatomegaly in 20% and jaundice in 5%. Although elevated aminotransferase enzymes (up to five times normal) are detected in up to 80%, hepatitis is usually mild with a complete recovery.

Approximately 30% of cases of childhood haemophagocytic lymphohistiocytosis have been described in association with primary EBV infection.[113,113a] Fatal X-linked lymphoproliferative disease (Duncan syndrome) occurs in boys unable to mount a cytolytic T-cell response.[114]

### *Diagnosis*

The diagnosis is made by finding atypical lymphocytes in the peripheral blood, viral isolation from throat washings or by serological assays. Antibody to viral capsid antigen (VCA): IgM is positive in early acute infection, IgG is usually present at clinical presentation, then declines, but persists for life. Antibody to Epstein-Barr nuclear antigen (EBNA) increases during convalescence, persists for life and may increase during reactivation. Antibody to early antigen (EA) transiently increases during infection and reactivation.

The Paul-Bunnell test demonstrates acute non-specific antibody production in response to EBV infection. Unlike in adults, where the Paul-Bunnell test is usually diagnostic of IM, in up to 50% of children and immunosuppressed patients the heterophile antibodies are not detectable.

Detection of EBV-encoded products including latent membrane protein (LMP), nuclear antigen (EBNA) and EBV encoded RNA (EBER) by immunohistochemistry, and detection of EBV genome by *in situ* hybridization permits specific detection of EBV in infected tissues.[115] In transplant recipients, PCR detection and quantitation of EBV RNA in blood monitors viral load, so that immunosuppressive therapy can be adjusted appropriately.

Liver histology shows inflammation with mononucleocyte infiltration in the portal tracts, Kupffer cell hyperplasia, cholestasis and foci of liver cell necrosis. Progression to hepatic cell necrosis and chronic hepatitis has been reported.[116]

### *Treatment*

Treatment is supportive in most cases, but the combination of intravenous acyclovir and prednisolone may improve pharyngeal symptoms and fever in 12 of 15 (90%) patients with fulminant mononucleosis.[117]

EBV-related lymphoproliferative disease post-transplantation is a serious disease which is treated by decreasing immunosuppression, high dose acyclovir, surgical removal of localized disease, autologous T-cell therapy[118] or chemotherapy in selected cases.[119]

## Human herpes virus 6

Children are infected with human herpes virus 6 (HHV6)

in the first year of life[120] and may develop roseola infantum (exanthem subitum), characterized by a fever for 3–5 days, which subsides as a rose-pink macular rash becomes apparent.

Liver dysfunction in association with HHV6 infection includes an infectious mononucleosis-like syndrome, hepatitis and fulminant hepatic failure.[121] Serological diagnosis is based on the appearance of specific HHV6 IgM antibody or a fourfold rise in IgG titre.

Antiviral therapy is usually not required, except in immunosuppressed patients. Acyclovir, ganciclovir, cidofovir and famciclovir are all effective against herpes viruses.

## Varicella zoster

Varicella zoster occasionally effects the liver. The infection is spread by direct contact with a patient, who may transmit the disease from 1 day before onset of rash until all the vesicles have become dry. The incubation period is 10–21 days.

In older children, liver disease is unusual except in immunosuppressed children with HIV infection or post-transplant recipients who require intravenous acyclovir and famciclovir.[122,123]

### *Prevention*

Varicella zoster immune globulin (125 units/10 kg) is recommended for newborns whose mother had varicella zoster infection 5 days before to 2 days after delivery and for premature infants with exposure to chickenpox. For the immunosupressed, varicella zoster immune globulin should be given within 96 hours of exposure to a patient with varicella infection.

Attenuated live varicella vaccines are available and, if possible, varicella vaccination should be administered before transplantation or before patients undergo chemotherapy for haematological malignancies.

## HIV

HIV is a 105–120-nm RNA-containing retroviral agent that replicates by reverse transcription. It causes acquired immunodeficiency syndrome (AIDS) and impairs the immune system by attacking the helper/inducer (T4) lymphocytes and binding to the CD4 receptor. Transmission may occur by the transplacental or perinatal route or by exposure to infected blood or blood products.

The initial manifestation may be a cholestatic hepatitis,[23] as reported in seven infants who presented between 5 and 10 (median 7) months of age. All seven infants died, six secondary to HIV-related complications and one from liver failure. In a longitudinal study of 31 children with perinatally acquired HIV infection followed up from 2 to 82 months (mean 30), 18 (58%) had biochemical or histological evidence of hepatic involvement. Clinical outcome in this study showed that liver disease in HIV-infected infants is indicative of a poor prognosis. Nine (50%) infants with liver disease died from persistent multiple viral infections as opposed to only one of 13 without hepatic involvement.[124]

Histological findings include giant cell transformation (23%), CMV inclusion (17%), Kaposi sarcoma (13%), lymphoplasmacytic infiltrate (7%) and granulomatous hepatitis secondary to fungal infection (3%). Non-specific liver abnormalities included steatosis (47%), portal inflammation (24%) and periportal necrosis (10%).[125] Chronic active hepatitis with predominantly T8 lymphocytes, as determined by tissue immunochemistry, was demonstrated in five of twelve (42%) children with HIV infection.[113] The development of primary malignant fibrosarcoma of the liver has been reported in an 8-year-old African girl with HIV infection.[126]

## Flavivirus

### *Dengue haemorrhagic fever*

Dengue haemorrhagic fever (dengue shock syndrome) is a mosquito-borne infection (*Aedes aegypti*) common in the western Pacific and south-east Asia. The disease is characterized by a sudden onset of fever, myalgia and headache followed 2–3 days later by bleeding diathesis, encephalopathy and cardiovascular collapse. Definitive diagnosis is made by rising titres to dengue antigen.

Hepatitis, with hepatomegaly and transaminase elevation, is present in 90% of patients as part of multi-organ involvement. Aspartate aminotransferase (AST) levels increase on the third day of illness, reach a peak level (nine times normal) on days 7–8, and normalize 3 weeks after onset of illness. Pathological lesions in the liver are varying degrees of fatty metamorphosis, focal mid-zonal necrosis, Kupffer cell hyperplasia and the presence of non-nucleate cells with vacuolated acidophilic cytoplasm, resembling Councilman bodies in the sinusoids.[127] The dengue viral antigen may be demonstrated in the Kupffer cells. Fulminant hepatitis is rare but fatal.[128]

Survival is directly related to correction of fluid and electrolyte loss. For prevention, eradication of the mosquito vector is essential.

### *Yellow fever virus*

Yellow fever virus is a member of the flavivirus (group B arbovirus), a spherical 35–45-nm particle containing a single-stranded RNA genome.[129] It causes a disease endemic in West Africa and some parts of South America

and is transmitted to humans by the mosquito vector, *Aedes aegypti* or *Aedes africanicus*. There is an incubation period of 3–6 days, with viraemia for 5–10 days.

Diagnosis is made by viral isolation or by demonstration of viral antigen in the acute-phase blood samples. Available serological tests for antibody determination include complement fixation, haemagglutination inhibition and enzyme-linked immunoabsorbent assay (ELISA).[130]

*Clinical features*

The disease varies in severity from subclinical to fatal illness. In the severe form, jaundice, renal and cardiovascular symptoms and bleeding diathesis are present on days 4–5 of illness.

The liver is tender, but not enlarged, and splenomegaly is unusual. The mortality rate in hospitalized patients approaches 40–50%. Liver pathology reveals widespread mid-zonal coagulative necrosis with eosinophilic degeneration of hepatocytes (Councilman bodies), microvesicular steatosis and minimal inflammation. For patients who survive, hepatocellular regeneration is rapid and post-necrotic fibrosis does not occur.

*Treatment*

Treatment of yellow fever is supportive. The disease may be prevented with the administration of a live attenuated vaccine to infants 6 months or older residing in an endemic area. Travellers to endemic areas should be vaccinated at least 10 days before arrival.

### Viral haemorrhagic fevers

This group of viruses includes, yellow fever, Lassa fever, Marburg and Ebola fever and they are endemic in Africa, South America and Asia. They are characterized by massive hepatocellular necrosis and disseminated intravascular coagulation (DIC), and a very high mortality.

#### *Arenavirus (Lassa fever)*

The Lassa fever virus is a single-stranded RNA virus that infects the African house rat, *Mastomys natalensis*. The rodent excretes the virus in the urine and saliva, and humans become infected by consumption of contaminated food or water. Nosocomial infection may likewise occur by close contact with infected secretions and excretions from patients. Diagnosis is confirmed by viral isolation from the throat, urine or blood, or by detection of specific Lassa antibodies present in the second week of illness by immunofluorescence or by rising antibody titres.

Epidemics of Lassa fever have been reported in Nigeria, Sierra Leone and Liberia. Lassa fever infection during pregnancy has been reported to cause an 87% fetal and neonatal loss. The risk of maternal death is higher if the infection occurs in the third rather than in the first or second trimester of pregnancy.[131]

*Clinical features*

The clinical features are variable and range from an asymptomatic infection to a fatal disease. In children, the disease is heralded by a slowly rising temperature, headache, conjunctivitis, pharyngitis, abdominal pain and diarrhoea. Patients either recover spontaneously or deteriorate, with anasarca and a bleeding diathesis.[131a]

The liver is the main target organ, although jaundice has not been reported. Lassa virus hepatitis occurs in three phases: active hepatocellular injury (<20% necrosis), necrosis, or early recovery with regeneration. All three phases may be present at the time of death.[132]

*Treatment*

Ribavirin, a broad-spectrum antiviral agent, may be effective for Lassa virus infection.[133]

## Acute liver failure (ALF)

Viral hepatitis is responsible for most cases of fulminant hepatic failure in children of all ages.[134,135] In a recent study from the National Institutes of Health (NIH) ALF study, 63% of cases in children under 2 years of age and 35% of cases in children over 2 years old had viral or presumed viral hepatitis (personal communication, R. Squires, 2003).

### Hepatitis A

Acute HAV infection is a common cause of fulminant hepatic failure. The prevalence among patients of all ages with fulminant hepatic failure in published series has varied from 1.5% to 31% from both developing countries[136]and developed countries.[137] In the USA, HAV causes <5% of fulminant hepatic failure and only one of the 86 cases in the NIH ALF study was due to HAV (personal communication, R. Squires, 2003).

### Hepatitis B

In contrast, the overall rate of fulminant hepatic failure in acute HBV infection is estimated to be about 1%. It is uncommon to document HBV infection in children with acute liver failure from Western Europe and the USA, as demonstrated in the NIH ALF study, except in infants born to HBV-positive, HbeAg-negative mothers,[72] in endemic areas,[138] or after bone marrow transplant.[139] The prognosis of HBV-related fulminant hepatic fail-

ure is generally worse than with other aetiologies, with spontaneous recovery occurring in fewer than 20% of cases.[140,140a]

### Hepatitis C

HCV is an unusual cause of fulminant hepatic failure in children.[140] HDV and HEV have rarely been associated with fulminant hepatic failure in children, HGV and TTV do not cause fulminant hepatic failure.

Sporadic non-A–G hepatitis is diagnosed when there is evidence of acute hepatitis in the absence of markers for hepatitis virus infection, the absence of clinical and/or serological evidence of systemic infection with other infectious agents, no exposure to drugs or toxins, and negative markers of autoimmune disease.[135] The prognosis in non-A–G fulminant hepatic failure is poor, with the rate of spontaneous recovery from 5% to 30% indicating the need for early referral for transplantation.

### Other viruses

EBV may cause fulminant hepatic failure, almost always in immunocompromised hosts, with the EBV most frequently implicated. Paramyxovirus, parvovirus B19 and toga virus have been identified in some cases.

## Acute viral hepatitis in transplant recipients

### CMV

CMV hepatitis in liver transplant recipients is common and must always be considered in the differential diagnosis of spiking fever elevated transaminase levels, especially if there is no evidence of rejection on liver biopsy.[141]

#### *Prevention and treatment*

Transplant recipients should be given CMV-negative blood or blood products. Prophylaxis includes intravenous immune globulin (IgG, 0.5 mg/kg) at weekly intervals for 6 weeks and oral acyclovir for 3 months after transplantation;[142] or high-dose acyclovir for 3 months or ganciclovir (5 mg/kg twice a day for 1 week) followed by acyclovir (800 mg four times a day for 3 months).[143]

CMV is successfully treated with a combination of specific immune globulin and either acyclovir (800 mg four times a day) or ganciclovir (5 mg/kg twice a day) for 14 days.[143]

### EBV

EBV-associated lymphoproliferative disease (LPD) (Fig. 47.2) after liver transplantation has been reported in 4–11% of recipients.[144] A higher incidence has been observed in paediatric liver transplant recipients younger than 5 years of age who were seronegative pretransplant, and treated with FK506. Post-transplant lymphoproliferative disease is particularly common following small bowel transplantation, because of the intensive immunosuppression required.[145]

### Adenovirus

Adenovirus hepatitis is a severe illness in paediatric liver transplant recipients, mainly as a result of serotype 5, which has a high mortality.[146]

## Chronic hepatitis

### Hepatitis B

Chronic hepatitis B is defined as failure to clear HBsAg after 6 months and is more likely if infection occurs early in life, if it is asymptomatic, or if there is a general defect in the immune system.[147] More than 80% of infants infected during the first year of life become chronic carriers as compared with a rate of 6–10% if infection occurs after the sixth year of life.[148] HBeAg loss occurs at an annual rate of 10–16%.

In a prospective study of 420 HBsAg carriers in Taiwan in whom infection was detected from <1 month to 17 years of age and observed for 1–12 years, spontaneous loss of HBsAg occurred in only 10 patients (0.6% per year).[147] Annual HBsAg clearance rate was significantly higher in those who were anti-HBe-positive than those with HBeAg (1.7% versus 0.4%). Carrier children whose mothers were HBsAg-negative had a higher incidence of HBsAg clearance (5.6% versus 0.8%).

In perinatally infected children, HBeAg clearance was 30% by the age of 10 years, but only 4% had HBsAg clearance.[149] Liver histology in this group showed that 60% of the children had mild hepatitis and fibrosis, while 18% showed evidence of moderate to severe fibrosis despite almost normal transaminases.

Of infants who acquire HBV infection perinatally, boys have a higher risk of developing histologically aggressive disease with progression to cirrhosis,[150,150a] seven being less than 4 years of age. A male preponderance (76%) has also been found among children with HBV-related hepatocellular carcinoma (HCC).[151]

HBV infection may have an important role in the development of HCC in children. In Taiwan, 51 consecutive children with HCC had detectable HBsAg, either in the blood or in the liver tissue.[146] In Germany, seven of eleven (64%) cases of HCC in childhood had positive HBsAg serology.[152] Integrated HBV DNA sequences have been found in neoplastic liver tissues of children with previous HBV infection.[153]

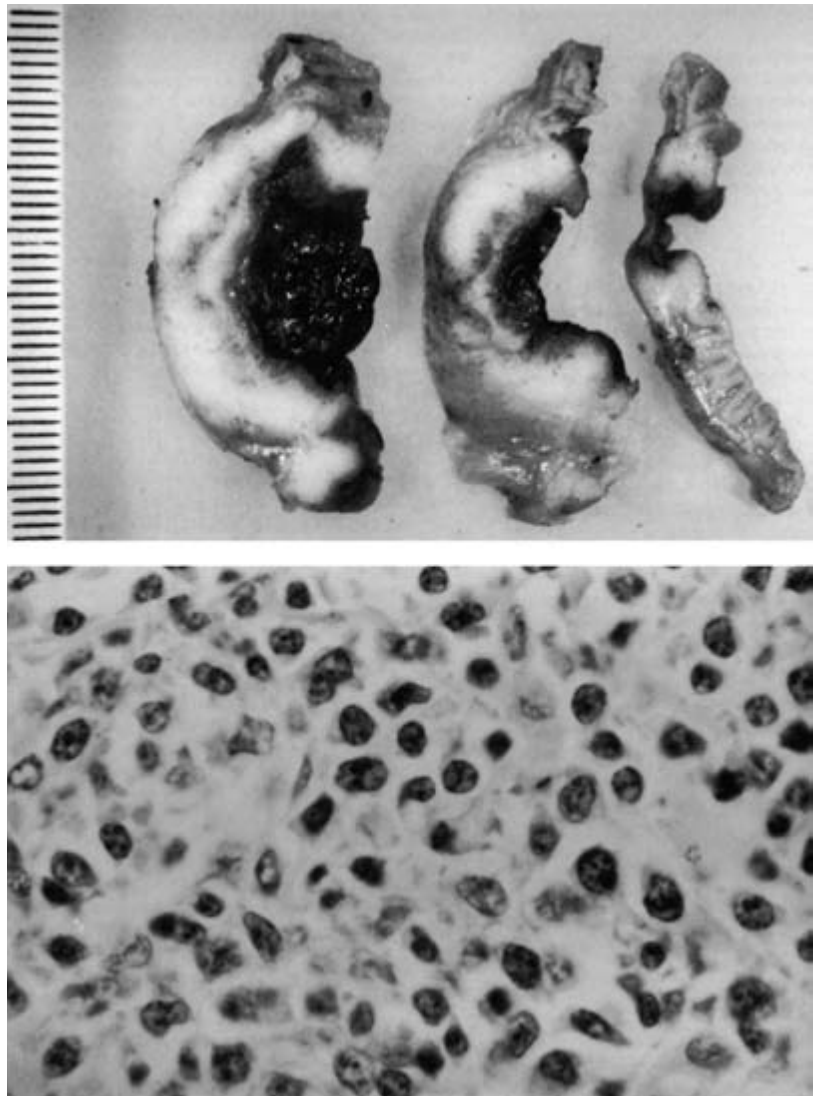

**Figure 47.2** EBV-induced lymphoproliferative disease of the gut in a child after liver transplantation. (a) Macroscopic and (b) microscopic appearance.

### *Perinatal transmission*

The risk of perinatal transmission of hepatitis B is directly associated with the infectivity of the mother, which was first demonstrated by the presence of circulating HBeAg[154] and later by direct measurement of HBV DNA.[155] Intervention such as amniocentesis[156] and delivery by caesarean section do not affect the transmission rate,[157] although lower 'microtransfusions of HBsAg' during delivery occur when elective caesarean section is chosen.[158] Studies on placental tissue show that there is evidence of cell-to-cell transfer of hepatitis B antigen by immunohistochemistry staining[159] and HBV DNA by *in situ* hybridization,[160] showing a gradient of infection from the maternal to the fetal side. These studies also showed a direct association between transplacental HBV infection and maternal HBeAg positivity (OR = 17.07, 95% CI 3.39–86.01): threatened pre-term labour (OR = 5.44, 95% CI 1.15 –25.67), higher levels of maternal HBsAg and HBV DNA, and active infection of the placenta particularly in layers close to the fetal side.[159,160] Breastfeeding does not affect the outcome in babies of HBV carrier mothers,[161] especially in the post-vaccination era.[162]

Persistent infection in neonates of HBV HBeAg-positive mothers may be associated with the transfer of maternal HBeAg, a soluble antigen, across the placenta. The HBeAg antigen shares epitopes with the virus core antigen and induces a specific unresponsiveness of helper T cells to HBcAg in the neonates.[147] It has been demonstrated that cord blood mononuclear cells from neonates born to HBeAg-positive mothers do not prolif-

erate in response to HBcAg, suggesting that transplacental exposure to HBeAg induces non-responsiveness in the developing fetal immune system.[163] HBeAg contains several sequence similarities with HBcAg, the principal target of cytotoxic T cells involved in hepatocellular damage leading to HBV clearance.[164] Such immune tolerance has been demonstrated in a transgenic mouse model and it is postulated that the function of HBeAg is to induce tolerance *in utero* and that it may be strategically important in the natural history of hepatitis B.[165,166]

### *Prevention of perinatal infection*

The options for prevention of perinatal transmission of hepatitis B are described below.

First, passive immunization using hepatitis B immunoglobulin (HBIG) was shown to protect babies of HBeAg-positive mothers, but repeated doses of globulin were required and although some babies developed active immunity, it was observed that post-natal infection led to a persistent infection as the passive protection waned.[154,167,167a]

Secondly, active immunization with hepatitis B vaccine is effective in the prevention of perinatal transmission of hepatitis B in babies of HBeAg-positive mothers. It is also as an effective means of reducing the carriage of hepatitis B in populations in areas of high and intermediate endemicity.[168,169]

In Taiwan, the prevalence of HBsAg in children <5 years old has decreased from 9.3% (31/332) in 1984 to 2% (9/457) in 1989 as a result of a mass hepatitis B immunization programme.[170] Other studies have shown that hepatitis B vaccine alone given for three or four doses during the first year of life is effective in preventing perinatal transmission.[171] This scheme of prevention has important economic implications for countries that are unable to afford hepatitis B immunoglobulin. In Gambia, where the majority of infections occur after 5 months of life, the prevalence of HBV infection in 1–14-year-old children after mass immunization with vaccine alone has decreased from 60% (474 of 791) in 1984 to 9% (57 of 629) in 1993.[172] Integrating HBV vaccination into the routine childhood immunization programme (i.e. DPT) may be the most cost-effective means of preventing infection. The introduction of mass immunization has already had an impact on the incidence of HCC in children in Taiwan.[173]

The third option is combination of active and passive immunization. Many studies have shown that the administration of hepatitis B immunoglobulin and hepatitis B vaccine within 48 hours of birth and followed by further doses of vaccine in a variety of possible schedules (e.g. 0, 1, 6; 0, 1, 2, and 6 or 12 months) has been shown to prevent perinatal transmission of HBV in up to 95% of infants of HBsAg carrier mothers.[174] Delayed first dose of the vaccine beyond 7 days increases the risk of infection.

In areas of low endemicity, the current recommended policy is the screening of all pregnant women for HBsAg. Newborns of HBsAg-positive mothers, whether they are HBeAg-positive or not, should be given specific immunoglobulin and HBV vaccine. In the UK, only babies born to mothers who are not anti-HBe-positive are given HBIG as well as vaccine based on risk assessment and in order to limit the exposure of newborns to blood products.

Universal vaccination, however, is the only effective measure to eradicate infection within populations. The choice is either to integrate hepatitis B vaccination with childhood immunizations or to vaccinate adolescents before they begin risk behaviour. Different strategies will be appropriate for different countries, according to their local epidemiology.

For infants who have received the full series of immunizations, protective anti-HBs levels (>10 mIU/mL) may persist up to 10 years of age.[175–178] An adequate anamnestic response, most frequently around 4 years, has been shown in vaccinated children, whose anti-HBs titres fall below protective levels, thus questioning the recommendation for HBV vaccine boosters at 5 years. The vaccine is ineffective in infants who acquire the infection *in utero* and are HBsAg-positive at birth.

HBV 'escape mutant' strains with alteration in the 'a' determinant of the surface protein have been described in vaccinated infants.[178a] Studies in Taiwan since the introduction of universal vaccination show an increasing accumulation of these variants in the population in children who fail to be protected by immunization.[179] Mathematical modelling studies are optimistic that the rate of accumulation of these variants and the decreasing likelihood of exposure of susceptible individuals to these variants suggest that it would take 20 years till the variants became dominant.[180]

The fourth option comprises antiviral treatment during pregnancy. Antiviral treatment during pregnancy effectively prevents mother to baby transmission of HIV[181] and has prompted the investigation of the use of lamivudine in pregnancy in women with persistent hepatitis B.[182] A single case report in which complete viral suppression on lamivudine therapy failed to protect the baby from infection despite active and passive immunization is not encouraging.[183] In contrast, lamivudine treatment during the last month of pregnancy in eight mothers with very high viraemia (>$10^9$genome equivalents/mL) reported that only one baby was not protected (12.5%), compared with a failure rate of 28% (7 of 25) in historical controls.[182] Further evaluation of lamivudine in pregnancy requires larger controlled tri-

als. Antiviral treatment in pregnancy would reduce or eliminate the use of HBIG in newborns, thus limiting exposure of children to blood products, and concentrate immune prophylaxis on vaccine alone.

### *Management of chronic HBV infection*

Chronic HBV carriers should have persistent medical supervision, in order to identify natural seroconversion, progress of liver disease, for consideration of antiviral therapy and for detection of HCC. It is important to screen and immunize family members and to provide support and education for the whole family with regard to minimizing transmission while avoiding social isolation or stigmatization.

### *Treatment*

The aim of treatment is to eradicate the virus, reduce transmission and prevent or ameliorate the underlying liver disease. The decision to treat depends on disease activity, histology, likelihood of response and treatment-associated side-effects. To date, treatment is only partially successful because of side-effects, poor efficacy and viral resistance. In children as in adults, success of treatment is based on the rates of clearance of HBeAg and of seroconversion to anti-HBe, rarely to anti-HBs. Agents for which efficacy has been claimed include interferon (IFN)-α with or without prednisolone priming and lamivudine.

#### *IFN*

IFN-α has been assessed in controlled studies, but these are difficult to compare because of small numbers and different forms of IFN-α given in different doses and for different durations. In children, the response rates to IFN-α therapy are very variable, but not dissimilar to those reported in adult studies. Differences in response rates depend on route of infection, ethnic origin, disease activity and treatment regime. Sustained clearance varies between 0 and 50% of those treated, and is usually around twice that of untreated controls.[184]

Predictors of IFN responsiveness include: active hepatitis on histology; low HBV DNA levels (<1000 pg/mL); high serum aminotransferase enzymes (more than twice upper limit of normal), short duration of disease, Mediterranean origin, horizontal transmission.[185] IFN therapy does not benefit children with perinatally acquired infection who have normal or minimally elevated aminotransferase enzymes.

IFN is limited by its side-effects, although children tolerate treatment better than adults. Fever and flu-like symptoms are invariable during initiation of treatment, and bone marrow suppression is common. Autoimmune thyroid disease and alopecia are frequent, and mental disturbance including severe depression may occur in older children. IFN treatment is contraindicated in patients with cirrhosis or prior to seroconversion, as a flare of immune activity with increased immune damage may lead to decompensation of liver function.

The transient rise in transaminases that occurs during treatment is associated with increased likelihood of HBeAg clearance. Pretreatment with corticosteroids ('prednisolone priming') and their withdrawal *prior* to commencing IFN may exacerbate the host immune response, facilitating seroconversion. In a randomized controlled trial of IFN-α with or without prednisolone pretreatment in 90 Chinese children (aged 2–17 years), slightly better results were achieved with prednisolone for 6 weeks, followed by IFN-α for 16 weeks.[186] Prednisolone priming and IFN may reduce the time to seroconversion long-term in both adults and children.[187,188] The higher rate of anti-HBe seroconversion in European children may be related to horizontal infection with higher pretreatment transaminases.

Based on European experience, consensus recommendations for IFN therapy include: children over the age of 2 years, who are HBeAg- and HBV DNA-positive, with low–intermediate HBV DNA levels and abnormal aminotransferase enzymes.[189] IFN (5 mU/m$^2$) is given three times per week for 6 months. Retreatment in nonresponders is not indicated. IFN is contraindicated in children with decompensated liver disease, bone marrow depression, severe renal or cardiac disorder and autoimmune disease.

#### *Lamivudine*

Lamivudine is a pyrimidine nucleoside analogue which is incorporated into viral DNA and competitively inhibits viral reverse transcriptase. It reduces plasma HBV DNA by 97% within 2 weeks of treatment,[190] and to undetectable levels within 4 weeks.[191] Loss of HBeAg after 1 year of treatment occurs in 17–33% of those receiving lamivudine compared with 11–13% in controls and is higher in those with elevated transaminases before treatment in both adults and children.[192,193] Prolongation of treatment for up to 3 years improves seroconversion, but increases resistance. Relapse following completion of therapy is common, but the main limitation to treatment is the development of resistance with a specific HBV mutation (tyrosine-methionine-aspartate-aspartate or YMDD mutation) in the polymerase gene.[194] The mutant virus may revert to wild-type after lamivudine therapy is withdrawn.

A dose ranging study of lamivudine in children has confirmed the dose to be 3 mg/kg/day (maximum 100 mg).[195] A subsequent international, randomized, double-blind, placebo-controlled trial of 286 children

with chronic HBV demonstrated a complete response (HBeAg clearance and undetectable HBV DNA after 52 weeks of treatment) in 23% compared with 13% with placebo.[74] The response rate was higher in those with ALT >2 (34% compared with 16%). The YMDD variant emerged in 18%. A number of small studies have compared the combination of IFN and lamivudine, but have not shown improved efficacy or tolerance.[196,197]

*Adefovir*

Adefovir is a purine analogue, which inhibits viral replication and increases natural killer cell activity and endogenous IFN activity.[198] HBV strains resistant to lamivudine and famciclovir are susceptible to adefovir.[199] A recent multicentre study of 185 adults has demonstrated histological, biochemical and virological improvement, but seroconversion rates were low.[200] A pharmacokinetic and dose-finding study in children is underway, and the agent appears to be well tolerated. A clinical trial is planned.

*Recommendations for treatment of hepatitis B infection*

The effect of treatment must be compared to the natural seroconversion rate and the potential side-effects. In a recent study, with a mean follow-up period of 4.9 ± 2.9 years, clearance of HBeAg occurred in 58% of 90 children treated with IFN, lamivudine or IFN then lamivudine compared with 37% of 68 untreated controls. Loss of HBsAg occurred in 10 treated and one untreated patient. The cumulative probability of HBeAg clearance and HBsAg clearance 10 years after the initial visit were both significantly higher in the treated patients.[201] At present, clear guidelines are available for IFN treatment, but the availability of pegylated IFN (PEG-IFN) and other antiviral agents may improve outcome.

*Hepatitis B in the immunosuppressed patient*

Patients co-infected with HBV and HIV, organ transplant recipients and chronic carriers requiring chemotherapy may respond to lamivudine,[184] either as pre-emptive treatment[202] or in the treatment of acute or fulminant hepatitis.[203]

### *Liver transplantation*

End-stage liver failure due to chronic HBV is an uncommon indication for transplantation in children and will recur unless prevented with immunoglobulin or lamivudine.[204] In fulminant HBV infection, HBV reinfection is uncommon.[205]

## Hepatitis C virus (HCV)

### *Prevalence*

HCV accounted for >90% of transfusion-transmitted hepatitis. Screening tests for anti-HCV for blood and organ donors was introduced in the early 1990s. HCV is efficiently transmitted by infected blood or organs.[206,207] Many haemophiliac children became infected with hepatitis C as the result of the preparation of clotting factor from large pools of blood products.[208] A further cohort of infected children have been identified through 'look-back' exercises carried out by blood services to identify patients infected by anti-HCV-positive donors before donor screening was introduced.[209,211] In children with haemophilia, anti-HCV seroprevalence ranged from 50 to 82%.[208] Studies on HCV-infected children identify two major groups: those infected prior to blood donor screening and those infected perinatally from HCV-infected mothers.[199,212] Potential acquisition of HCV infection was high in children exposed to multiple donors, either by receiving multiple blood transfusions or by repeated infusion of pooled products.

The reported prevalence of anti-HCV antibody in healthy children varies from 0.9% to 14.5%.[213,214] The prevalence was higher in lower than upper (16% vs 8%) socio-economic groups and in rural than urban (21% vs 12%) children.

In high-risk group children, the reported prevalence of anti-HCV ranges from 55% to 83% in thalassaemics[215] and from 80% to 95% in haemophiliacs.[216] In 5 of 27 (18.5%) anti-HCV-positive dialysis patients (age 25.9 ± 1.6 years), the length of time on haemodialysis, and hence presumably the number of units of blood transfused, was the most predictive factor for HCV infection (mean of 105 months for those who were anti-HCV-positive vs 41 months for the 22 who were anti-HCV-negative.[217] Of 50 leukaemic children with known chronic liver disease followed for 1–12 years after chemotherapy, 11 (22%) remained persistently positive for anti-HCV, 10 of whom were viraemic as determined by PCR.[218] Of 203 paediatric cancer survivors, 41 (20%) were anti-HCV-positive as detected by a combination of first-, second- and third-generation assays.[219] A retrospective analysis on the prevalence of HCV infection in 149 paediatric liver transplant recipients from France investigated 9 months to 5 years post-surgery demonstrated 14 (9%) children to be HCV RNA-positive,[220] with six having evidence of HCV infection before and eight after surgery.

Among children with chronic cryptogenic liver disease, HCV antibodies were found in 16 of 33 (48%) children in Italy,[221] and 14 of 144 (9.7%) Taiwanese children,[222] but only in one of 163 (0.6%) children in the UK.[199]

### *Perinatal transmission*

Mother to baby transmission of HCV occurs in <10% of pregnancies. The seroprevalence of HCV infection in pregnant women in the UK is estimated to be 0.2%, with an estimated 1150 pregnancies occurring each year in women infected with HCV and 70 infants acquiring infection.[223] In a study of infants born in the UK and Ireland, the vertical transmission rate was 6.7% overall, and 3.8 times higher in HIV co-infected than HIV-negative women.[224] In a systematic review of studies of transmission risks for infants born to HCV mothers, Thomas and colleagues[225] established that transmission from mothers with an HCV viraemia of $<10^6$ copies/mL was very rare. Only two out of thirty (6.6%) transmitting mothers had a viraemia of $<10^6$ copies/mL and only 8 transmissions out of 976 infants followed up were identified from non-viraemic mothers. Studies reviewed were those with adequate follow-up of the children, as defined by PCR at 6 months or serology at 18 months. The results of this review demonstrated that maternal viraemia is a more significant risk than co-infection with HIV. Mothers without HIV co-infection generally had lower HCV viraemia.[224,226–228] The systematic review also examined method of delivery and infant feeding. The conclusions were that there is no evidence of a positive effect in caesarean section, and that in HIV-negative women there is no difference in the transmission rate in breastfed and non-breastfed infants, although HCV RNA has been demonstrated in colostrum.[220] These conclusions have been confirmed by later studies published from the European Paediatric Network.[229] Recommendation for caesarian section and avoidance of breastfeeding should be considered for those women who are also HIV-positive. Transmission may be higher in mothers with transfusion-acquired infection or in intravenous drug abusers.[228]

### *Diagnosis*

HCV infection is suggested by the serological detection of anti-HCV antibody by enzyme-linked immunoassay (EIA) and confirmed by HCV RNA in children. The detection of anti-HCV is variable and may initially be absent. It may persist for up to 10 years after clearance of viraemia. It may also be undetectable in patients with HCV infection who are immunocompromised.

### *Screening the newborn infant*

Determination of HCV status in the newborn infant is difficult, as maternal anti-HCV may persist in the newborn for up to 18 months. Loss of maternal anti-HCV varies from 50% by 8 months to 95% by 13 months.[224] The estimated proportion of uninfected children who continue to have detectable maternal antibody at 18 months is <0.1%.[230]

HCV RNA detection is the only way to confirm infection in infancy. The specificity of HCV RNA detection by PCR in one study was 97% irrespective of age,[63] but the sensitivity was only 22% for infants under 1 month, but 97% after 1 month. A recent study suggests that in some babies with chronic infection, HCV RNA may remain undetectable until 8 months of age.[231]

### *Clinical features*

Children with chronic HCV infection are usually asymptomatic. Of 606 children with chronic HCV infection, only 8% had symptoms or signs, which included anorexia, weight loss, abdominal pain, hepatomegaly and splenomegaly.[212] Most children have minimal disturbance of liver enzymes, even in the presence of hepatic inflammation. In those with persistently elevated liver enzymes, the existence of other diseases, particularly hepatitis B and autoimmune liver disease, must be considered. In a multicentre study of 77 (mean age 4 years, 35 boys) Spanish and Italian children with chronic HCV infection and no underlying systemic disease, only 17 (22%) were symptomatic (asthenia, anorexia, abdominal pain) at presentation. The rest were diagnosed incidentally on routine screening.[232] At presentation, only 9 (32%) of 28 patients showed histological features of chronic active hepatitis, whereas 11 had chronic persistent hepatitis and 8 had chronic lobular or non-specific reactive hepatitis. The clinical features and outcome were similar in both the post-transfusion and community-acquired cases. During a mean observation period of 6 (1–14) years, the majority of patients remained asymptomatic (81%) with inactive histological disease (29/40, 72%), but only 10% achieved sustained aminotransferase normalization.

A study on the natural history of hepatitis C in 76 children born in the UK, who acquired their infection by blood or blood products (68%), organ transplants (3%), or through perinatal transmission (28%), showed that those who were HCV RNA-positive had a very low rate of clearance of HCV RNA without treatment. Those children who had liver biopsies all showed mild to moderate inflammation and fibrosis.[233] The long-term outcome of chronic hepatitis C is unknown, although uncommon progression to cirrhosis and end-stage liver disease has been described in childhood.[234,234a]

### *Prevention*

There is currently no effective vaccine and prevention is focused on reducing the risks of parenteral acquisition by screening blood donors for anti-HCV, and the

use of vapour-heated and wet-heated clotting factor concentrates which decrease the risk of HCV transmission. Most developed countries have also introduced either HCV RNA or HCV core antigen testing in addition to HCV antibody testing of blood donations in order to identify blood donors in early stages of infection and increase the safety of the blood supply.

Programmes of enhanced surveillance and detection of HCV infection in adults may benefit women of childbearing age who could be treated before becoming pregnant, and reduce the risk of vertical transmission.

### *Treatment*

Children with chronic HCV infection require annual review to monitor viraemia, detect seroconversion, assess liver dysfunction and its progression, consider optimal timing of antiviral therapy and detect HCC.

The aims of antiviral treatment are to: eradicate HCV infection (loss of HCV RNA in peripheral blood); prevent progression of liver inflammation and fibrosis; normalize liver function; and improve quality of life.

Current treatment options include: IFN monotherapy, combination therapy with IFN (or PEG-IFN) and ribavirin

#### *IFN monotherapy in children*

IFN monotherapy produced a favourable response in 50% of treated adult patients, as indicated by normalization of serum transaminase levels and histological improvement, but only 20–30% had a sustained response after treatment withdrawal. An analysis of 19 trials of IFN-α for children with HCV infection compared the effect of IFN in 366 children compared with 105 untreated controls:[235] 54% (range 0–91%) initially responded to treatment, with a sustained response in 36% (0–73%); 27% of children with genotype 1 had a sustained response compared with 70% in those with other genotypes. The spontaneous clearance rate in untreated children was 5%. Treatment regimes varied, with duration of therapy ranging from 6 to 18 months. Most studies used 3 MU/$m^2$ by subcutaneous injection three times weekly.

#### *Combination therapy: IFN/ribavirin*

Ribavirin is a guanosine nucleoside analogue, which although ineffective as monotherapy,[236] is more effective with IFN-α. In adults, combination therapy has superceded monotherapy as sustained response rates are improved. Response is higher in female adults with baseline viral load <3.5 million copies/mL, minimal histological disease, age <40 and genotypes 2, 3 or 4.

Small studies of combination therapy in children indicate that the combination of IFN and ribavirin is as effective as in adults and achieves more sustained HCV RNA clearance than IFN-α alone.[237,238] As in adults, children with genotype 2 or 3 had the highest response (70%) compared with genotype 1 (40%).[237] Similar efficacy has been demonstrated in children with previous malignancy and co-infected with HIV.[239] The most common side-effects are related to IFN (flu-like symptoms, neutropenia and depression) and weight loss, which resolves when treatment is discontinued. Ribavirin causes a haemolytic anaemia in the first 12 weeks, which resolves with time or discontinuation of the drug. Six months of treatment with IFN (3 MU/$m^2$ three times per week) and ribavirin (15 mg/kg/day) is recommended, with a further 24 weeks in patients with genotype 1 if clearance of HCV RNA has occurred in the initial 24 weeks.

#### *Future treatment strategies*

PEG-IFN may be more effective than IFN monotherapy[240] and is more likely to reduce the rate of progression of fibrosis and improve necroinflammatory damage.[241] A pharmacokinetic study has established the dose in children and clinical trials of combination therapy are planned.[242]

## Hepatitis delta

### *Prevalence*

Considerable regional variation in HDV infection has been noted.[243,244] The role of environmental and genetic factors or HBV strain is unknown. In the Amazon Basin of Brazil, infection rates increase with age from 5% in children <10 years, to 26% in those between 10 and 14 years and to >40% in subjects >15 years of age. Among the Yucpa Indians of Venezuela, HDV prevalence varies significantly with age, being highest in those between 15 and 19 years of age (44%) and then progressively lower in those between 5 and 14 years (38%), >24 years (18%) and <5 years (14%) of age.[245] Serological evidence of HDV infection was demonstrated in 34 of 270 (12.5%) Italian children who were HBsAg carriers,[79] but in only 4 of 247 (1.6%) Taiwanese children who had acute or chronic HBV infection.[246] In the Guangzhou area, 6 of 44 (13.6%) Chinese children had superinfection with the delta agent, a prevalence rate identical to that in adults.[247]

### *Clinical features*

In 34 Italian children with serological evidence of HBV-associated delta agent infection,[79] histological features at presentation included chronic active hepatitis (71%), chronic persistent hepatitis (18%) and cirrhosis (12%); 38% showed histological deterioration of liver disease

after 2–7 years of follow-up. This is in contrast to 236 delta-negative HBsAg carriers, with improvement in 55% and deterioration in only 7%. A study of 30 anti-HDV-positive and 30 anti-HDV-negative long-term leukaemia survivors demonstrated that anti-HDV-positive children had significantly higher transaminase levels 3 years after cessation of chemotherapy and more frequent histological evidence of chronic hepatitis or cirrhosis, suggesting that HDV infection is a major cause of morbidity and an adverse prognostic factor in terms of leukaemia-free survival.[248]

In the Amazon Basin, delta virus infection was demonstrated in 74% of patients with fulminant hepatitis (Labrea hepatitis) and in 100% of patients with chronic hepatitis B.[243] Thirty-two of the 44 (73%) cases of fulminant hepatitis were in children <15 years of age, 31 of whom were boys. In the same study, 44 delta virus-negative HBsAg carriers were followed up for 1–5 years; among these, four boys <10 years of age became superinfected with HDV and three developed fulminant hepatitis, which was fatal in two. Post-mortem studies of patients with fulminant hepatitis showed eosinophilic necrosis and microvesicular steatosis of the liver. A similar type of fulminant hepatitis with the same epidemiological and histological features has been described in Colombia (Santa Marta hepatitis) in 81 patients, with the majority (63%) being males and children <15 years old (58%). In 69%, the delta antigen was demonstrated in the liver in combination with microvesicular steatosis, granular eosinophilic necrosis, portal lymphocytic inflammation and characteristic morula cells.[249]

### *Prevention and treatment*

There is no specific treatment for HDV infection. As the greatest risk of HDV infection occurs in HBV carriers, infection may be prevented by giving only anti-HDV-negative blood or blood products to HBsAg-positive patients. HBV vaccination should prevent and limit the spread of HDV. Successful IFN-α treatment of a child with chronic HBV and HDV infection has been reported.[250] The incidence of HDV infections has reduced with increasing use of hepatitis B vaccines.

# Chapter 48
# Management of hepatocellular cancer

Helen L Reeves, Jordi Bruix

## Background

HCC is the commonest primary liver tumour, the incidence of which is rising worldwide.[1] The major risk factors for HCC vary to some extent with its geographical distribution, but include cirrhosis of the liver regardless of its aetiology, viral infection and chemicals or toxins. Chronic hepatitis B virus (HBV) and hepatitis C virus (HCV) infection contribute to HCC development in as many as 80% of cases. Chemicals include aflatoxin B1 (AFB1) uptake, cigarette smoking and heavy alcohol consumption. Each is an independent risk factor, but they do have synergistic effects.[2,3] The prevalence of hepatitis C has major clinical implications as it is the major contributor in Western developed countries where HCC is increasing.[4] The rising incidence of non-alcoholic fatty liver disease (NAFLD)[5] associated with diabetes or obesity is also a major cause for concern, as not only do these conditions predispose to the development of HCC,[5–7] but emerging data support accelerated HCV disease in fat diabetics.[8] The synergistic effect of alcohol and increased risk of HCC development in the presence of hepatitis B and C or diabetes is well recognized.[6] The reality is that these diseases are all increasing, and whatever the aetiology or synergistic mechanisms leading to chronic liver disease, it has been shown that currently HCC is the leading cause of death in cirrhotics.[2,9–11] Thus, both prevention and treatment of this neoplasm are major health concerns.

## Risk factors and prevention of disease

It is now widely accepted that cancers develop on a background of accumulated genetic change conferring survival advantages to abnormal cells. As most patients develop HCC after a long-standing hepatitis, it is reasonable to relate the persistent inflammatory changes to cancer formation. The chronic proliferative state of the injury and repair process, associated with cell necrosis, death and regeneration, all increase the risk for DNA mutation and subsequent accumulation.[12] However, continuous severe inflammation is also a feature of autoimmune hepatitis, where the incidence of HCC in the absence of cirrhosis is extremely rare.[13] Even in the presence of autoimmune-mediated cirrhotic disease, HCC is less common than in the viral or alcoholic liver diseases.[14] Inflammation or cirrhosis alone, therefore, do not appear to be the sole predetermining features of malignant disease. With this in mind, effective prevention of HCC should, wherever possible, prevent the occurrence of the causative liver disease, i.e. 'primary prevention'. Often this is not possible and 'secondary preventive' measures – preventing the progression of active inflammatory disease to cirrhosis – are the focus of health-care workers.

In HBV infection, the virus itself may have direct genetic or epigenetic effects, explaining why tumours often arise in pre-cirrhotic HBV-related disease. In most tumours, HBV gets integrated into host genome and this is accompanied by rearrangement and increased mutagenesis.[15–17] The active inflammation and proliferation may act synergistically by both increasing the opportunity for such events to occur and promoting their selection. HBV is the main cause of HCC in the world and it could be prevented by vaccination. Vaccination of children in Taiwan has led to a drastic decrease in the incidence of HCC,[18] indicating a clear cost-effective benefit of widespread immunization programmes in developing countries with high rates of infection.

The viral replication of HCV, an RNA virus, does not involve a DNA synthesis step, and thus does not integrate into host genome. Unsurprisingly, therefore, the strongest association with HCC development is in the context of cirrhotic disease. As there is no effective vaccine against HCV, primary preventive measures are limited to health education highlighting the methods of viral transmission. Secondary prevention, namely preventing the progression of inflammatory disease to cirrhosis, is of critical importance for those infected with the virus. This includes antiviral therapy in pre-cirrhotic disease and advice about limitation of other factors, such as alcohol, which adversely affect disease progression. Chemoprevention of HCC, treating individuals with established cirrhosis with interferon (IFN), has also

been proposed, but current data regarding this strategy are conflicting in nature.[19–21]

Most of the non-viral causes of HCC including chronic alcohol intake, obesity-related liver diseases, metal storage diseases and aflatoxin exposure are characterized by the generation of reactive oxygen species (ROS) leading to oxidative stress. In fact, oxidative stress as a mechanism of injury is also evident in viral disease. Either the ROS themselves or the products of lipid peroxidation may be involved in hepatocarcinogenesis by reacting directly with DNA and causing mutations in cancer-related genes, or by reacting with proteins involved in the regulation of DNA repair, the cell cycle and apoptosis. Primary prevention in these diseases is currently limited to health education, which may well be stepped up in coming years, given the increasing health burden attributable to alcohol and obesity in Western countries. Whether or not increased oral intake of anti-oxidants reduces the risk of cancer development is unknown. The vitamin A derivative, polyprenoic acid, may have chemo-preventive properties.[22] Its anti-tumour effects, however, are attributed to it being a nuclear hormone receptor ligand, rather than as a result of any anti-oxidant effect. Other ligands for the nuclear hormone receptor family, including peroxisome proliferator-activator receptor PPARγ ligands, acting either on their own receptor or possibly as heterodimers on retinoic acid receptors, have also shown promise inhibiting tumour cell growth *in vitro*.[23]

A proviso which should be remembered is that, apart from specific measures directed at high-risk individuals, the success of preventive strategies is likely to also depend on an increased awareness of the frequency of chronic liver disease in the general population. Whether population screening for the presence of chronic liver disease will ever be a cost-effective measure remains an area of active debate.[24]

## Surveillance and recall of high-risk individuals

The mean annual incidence of HCC in cirrhotic patients in Western countries is 3–4%. The risk increases in parallel with liver function deterioration and specific characteristics imply a higher risk. Thereby, male sex and increased alpha-fetoprotein (AFP) concentration constitute the most powerful risk predictors,[2] while others such as irregular regeneration, high proliferative stage and presence of dysplastic foci are less widely accepted. Surveillance for HCC in these patients has been advocated for years, even though a benefit in survival has not been clearly demonstrated. The purpose of surveillance is to recognize HCC at an early stage, when the tumour could be cured.

The failure of previous studies to show a survival benefit is probably a result of a number of factors, including poor ultrasound (US) performance, the absence of clear-cut diagnostic criteria and the absence of curative treatments. It is now generally believed that, even accounting for the contribution of lead-time bias (i.e. patients apparently surviving longer, simply because their tumours were diagnosed earlier) and length-time bias (the interval between screening misses the more aggressive tumours that will be detected upon symptoms appearance), improved methods of surveillance, diagnosis and treatment will lead to improved cost-effectiveness of surveillance programmes. Consequently, the European Association for the Study of the Liver panel of experts suggests 6-monthly abdominal US scanning and AFP measurements for high-risk individuals.[2] Nevertheless, AFP is known to have reduced sensitivity, and probably it merely serves to identify patients at higher risk and its repeated measurement does not reach proper cost-efficiency,[25] as surely happens with most biochemical assessments in cirrhotic patients. The recall procedures for individuals in whom an abnormality is detected are shown in Fig. 48.1, while the criteria required to confirm HCC diagnosis are shown in Table 48.1. In brief, nodules <1 cm that are detected in a cirrhotic liver are malignant in <50% of cases, and therefore close follow-up every 3 months to detect any increase in size is recommended. Whether or not fine-needle aspiration or biopsy of these small lesions would help clinical management is currently unknown. Fine-needle biopsy is recommended for nodules 1–2 cm in diameter (Fig. 48.2), but even in these larger lesions does not necessarily rule out malignancy if negative, as cytohistology is falsely negative in 30–40% of these cases. For nodules >2 cm within a cirrhotic liver, the diagnosis of HCC can be made based on the concomitant findings of two imaging techniques – CT (Fig. 48.3) or MRI scan (Fig. 48.4) – with contrast-enhanced US confirming characteristic arterial hypervascularization. Alternatively, it can be made by a single imaging study confirming arterial hypervascularization in asso-

**Table 48.1** Diagnostic criteria for hepatocellular carcinoma (HCC)

| Cytohistological criteria |
|---|
| Non-invasive criteria (cirrhotic patients) |
| 1. Radiological criteria: two coincidental imaging techniques* |
| a. Focal lesion >2 cm with arterial hypervascularization |
| Combined criteria: one imaging technique associated with AFP |
| 1. Focal lesion >2 cm with arterial hypervascularization |
| a. AFP levels >400 ng/mL |

*The four techniques considered are: ultrasound (US), spiral CT, MRI and angiography.

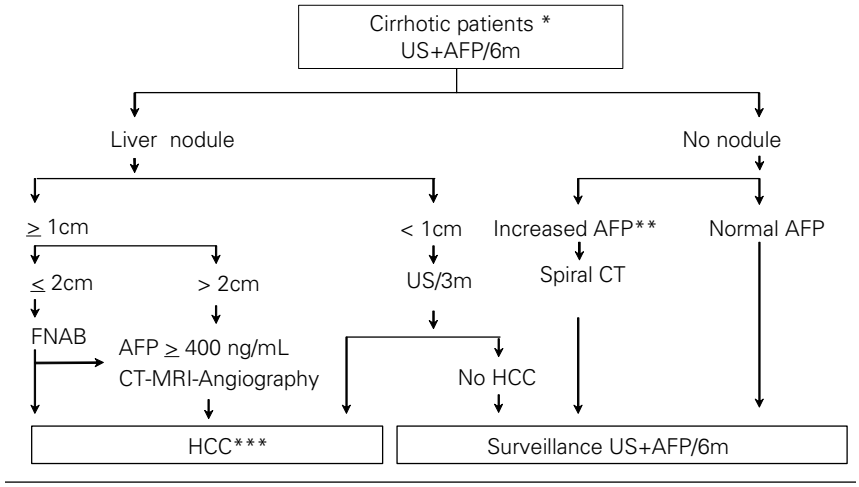

**Figure 48.1** Screening strategy as proposed by the panel of experts of the EASL Conference on Clinical Management of Hepatocellular Carcinoma. US, ultrasound; AFP, alpha-fetoprotein; FNAB, fine-needle aspiration biopsy; CT, computed tomography; MRI, magnetic resonance imaging; HCC, hepatocellular carcinoma. *Available for curative treatments if diagnosed with HCC. **AFP levels to be defined. ***Pathological confirmation or non-invasive criteria.

**Figure 48.2** Hepatic ultrasound (US) depicting a nodule measuring 25 mm in diameter. Diagnosis can be ensured by biopsy or, if detected within a cirrhotic liver, the coincidental findings of two imaging techniques.

**Figure 48.3** Computed tomography (CT): the right hepatic lobe contains a solitary tumour with evident arterial enhancement after contrast administration. The washout of contrast during the venous phase is characteristic of hepatocellular carcinoma (HCC).

ciation with an AFP >400 ng/mL.[2] US, spiral computed tomography (CT) and MRI are the imaging modalities conventionally used to assess disease extension. With the improvements in these techniques, angiography for diagnostic and staging purposes is rarely necessary.

Further data are needed to confirm the benefit of other proposed markers such as protein induced by vitamin K absence (PIVKA),[26,27] glypican-3[28,29] and AFP fractions[30] in clinical practice.

## Staging systems in HCC

Generally speaking, the prognosis of solid tumours is largely related to tumour stage, and it is typically this that guides management decisions. In HCC, however, the degree to which the underlying liver function is impaired is an additional important determinant of outcome. This makes staging and prognostication of patients with HCC difficult. Unsurprisingly, therefore, a worldwide consensus is lacking and HCC staging remains a very controversial area. A well validated and internationally accepted staging system should stratify patients into subgroups with significantly different outcomes and should enable health-care providers to give accurate information to their patients about long-term life expectancy, as well indicate the most adequate treatment and predict outcome after treatment. Historically, HCC has been classified by the TNM[31] or Okuda staging systems.[32]

The TNM system has been modified repeatedly on account of its poor accuracy. Its general use is limited because it relies predominantly on pathological findings, which are often unavailable, and liver function is not considered. In contrast, the Okuda classification excludes pathology and is based on tumour size (on imaging/surgery) and liver function. As with the TNM scheme, it can be unhelpful in individuals with intermediate forms of HCC.

Several scoring systems have been recently proposed to stratify patients according to expected survival. Schemes have been proposed in Uganda,[33] the United States,[34] Barcelona,[35] France,[36] Italy,[37] Austria,[38] Hong-Kong[39] and Japan.[40] Although all of them divide patients into strata with different prognoses, their major usefulness is the identification of end-stage patients with grim prognosis, but none provides any link to treatment in-

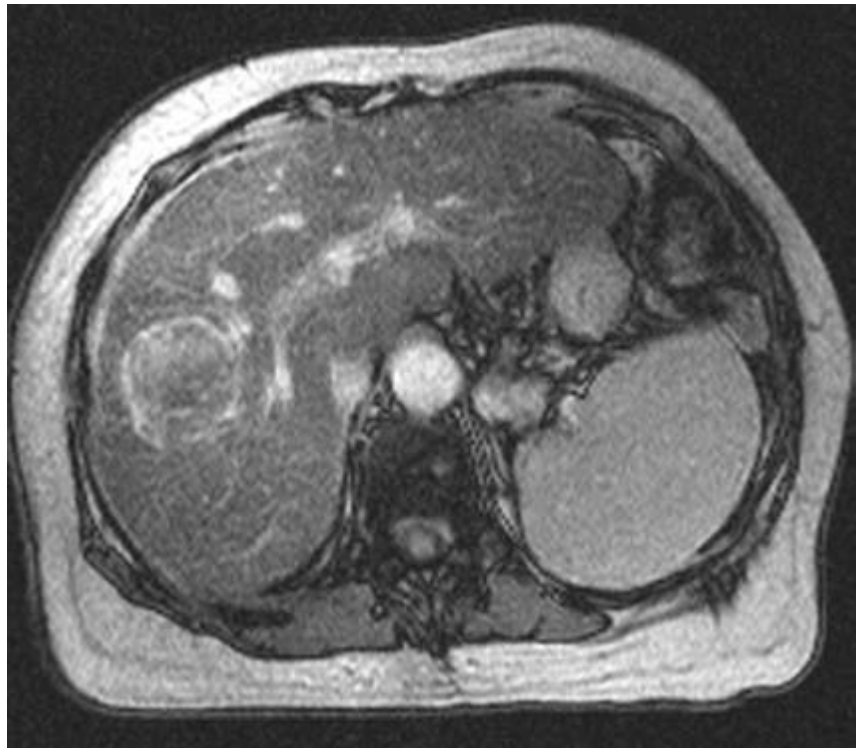

**Figure 48.4** Magnetic resonance imaging (MRI) showing a hepatocellular carcinoma (HCC) located in the right lobe.

dication. Furthermore, survival data of the strata have neither been reproduced from different geographical origins, nor do they retain their prognostic power in comparison with other staging systems. The lack of reproducibility suggests heterogeneity between the different patient groups that may preclude the introduction of a universal scoring/staging system.

The Barcelona-Clínic-Liver-Cancer (BCLC) staging system[41,42] was constructed on the basis of results obtained in the setting of several cohort studies and randomized clinical trials (RCTs) by the Barcelona group. The proposal, shown in Fig. 48.5, is not a scoring system, but rather a regularly updated staging classification resulting from the combination of the data of several independent prognostic studies in different disease stages and treatments. As a whole, it has become a widely used clinical tool for treatment decision-making. It includes variables related to tumour stage, liver functional status, physical status and cancer-related symptoms. It identifies those with early disease who may benefit from curative therapies, those who may benefit from palliative treatments, as well as those with a particularly poor outlook who should receive symptomatic care only. Patients diagnosed at an early stage may achieve a 5-year survival between 50% and 70%. Those that are diagnosed at an intermediate or advanced stage belong to the so-called non-surgical HCC category and their survival depends on the existence of cancer-related symptoms and the presence of vascular invasion or extrahepatic spread. Thereby, those who are asymptomatic without invasion or dissemination may achieve a 50% survival at 3 years, while the median survival for those with an adverse profile is <1 year (Fig. 48.6).

The hope for the future perhaps lies in the genomic and proteomic characterization of HCC. This should make it possible to identify a group of genes and/or proteins that define a molecular classification of HCC with predictive power for survival and response to treatment modalities.

## Treatment

Treatment options for HCC patients include curative interventions, such as resection, liver transplantation and percutaneous ablation, as well as palliative chemoembolization. Before any decision regarding treatment is made, however, the initial patient assessment should address and answer a number of key issues. These are discussed below, but are also summarized in the treatment algorithm shown in Fig. 48.5

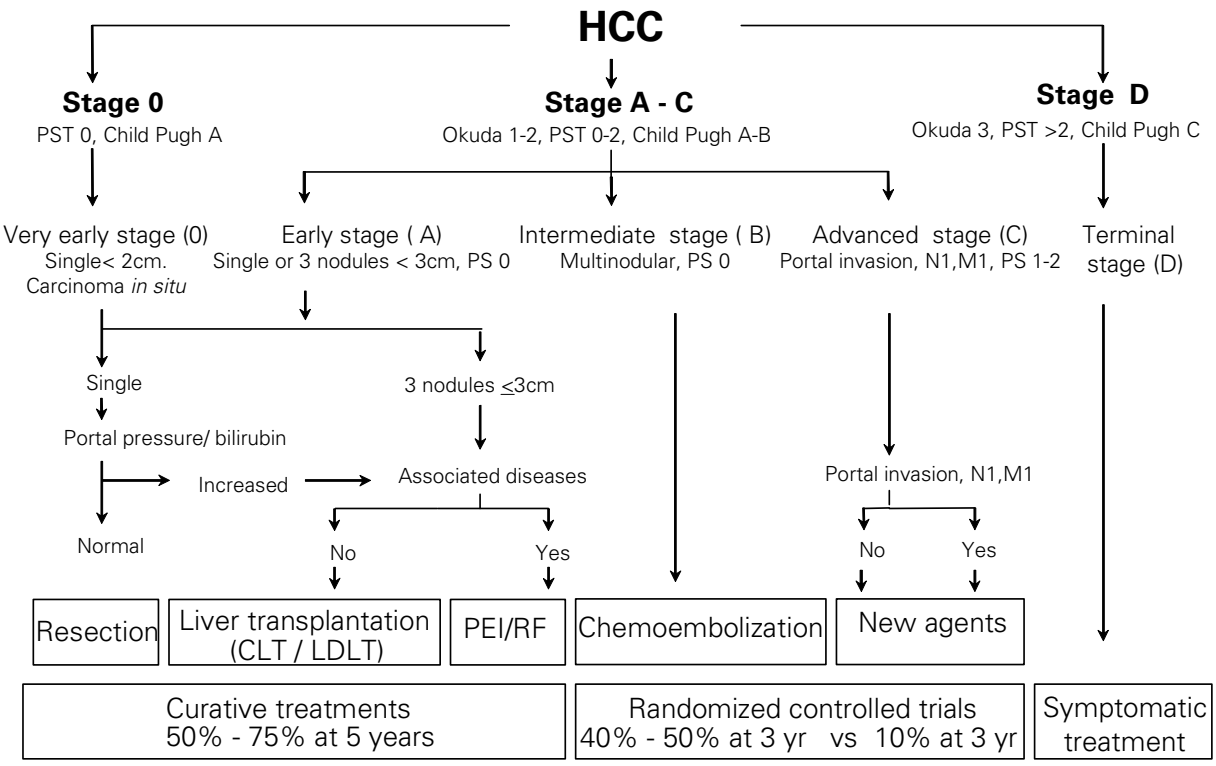

**Figure 48.5** Staging system and treatment strategy according to the BCLC criteria. Patients are stratified according to their clinical, tumour and biochemical characteristics into major strata: early, intermediate, advanced and terminal. Treatment selection is decided according to stage allocation. HCC, hepatocellular carcinoma; CLT, cadaveric liver transplantation; LDLT, living donor liver transplantation; PEI, percutaneous ethanol injection RF; radiofrequency

## The status of the non-tumorous liver

Knowledge of the status of the non-tumorous liver is essential. Patients with non-cirrhotic disease are good candidates for liver resection or other potentially liver damaging therapies such as chemoembolization. The vast majority of HCC patients, however, have either established cirrhosis (85–90%) or non-cirrhotic chronic liver disease. The management of these patients presents a challenge. Clearly, individuals with decompensated cirrhosis cannot undergo any invasive therapy that may precipitate or accelerate liver failure. These include both surgical and some locoregional approaches such as chemoembolization. The first-line option for these decompensated individuals, if they meet additional criteria, is liver transplantation.[2,42] In fact, only individuals with Child Pugh A chronic liver disease should ever be considered for resection and only after a more sophisticated assessment to identify the subgroup that will perform well after surgery. This includes individuals with a normal serum bilirubin and/or those without even mild portal hypertension (PHT; portal venous pressure gradient <10 mmHg).[43,44]

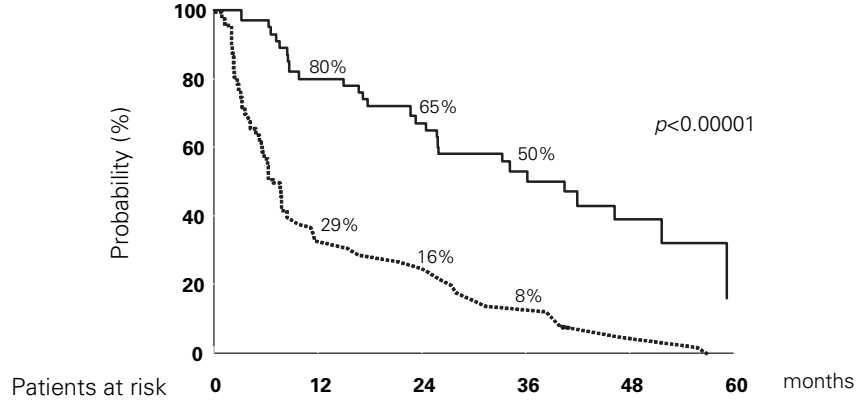

**Figure 48.6** Survival of patients with non-surgical hepatocellular carcinoma (HCC) who were untreated because of their allocation to the untreated control arm within prospective randomized trials. Asymptomatic patients without vascular invasion or extrahepatic spread may achieve a 50% survival at 3 years, while only 10% of those with symptoms and/or vascular invasion/extrahepatic spread reach this time-point.

## The size and extension of the tumour

Evaluation of tumour extension, with a search for the presence of daughter nodules, extrahepatic disease and/or portal vein thrombosis, is necessary in all cases. This can be performed using a combination of US and CT scan or MRI. Angiography has largely been superseded by these less invasive techniques. The search for extrahepatic disease may include a chest CT scan or a bone scan. The presence of tumoral portal invasion or metastatic disease leads to a bleak prognosis and precludes curative intervention.

## The general condition of the patient

The general condition of the patient should be assessed before taking any therapeutic decision. This includes consideration of co-morbid conditions that may increase perioperative or intervention-related morbidity and mortality, but also the assessment of cancer-related symptoms as reflected by their performance status (PS) score. This is used to quantify functional status in cancer patients[45] and if heavily affected (PS = 3–4) serves to identify patients with advanced or terminal disease that will not benefit from any form of active intervention.[46]

## Resection

This is the treatment of choice for HCC in non-cirrhotic patients, i.e. 5% of cases in Western countries and up to 40% of cases in Asia owing to the increased frequency of HBV-related disease. In cirrhotic patients, however, the 3-year survival post-resection 20 years ago was <50%.[47,48] Several major advances have steadily improved these figures in recent years, including earlier diagnosis in asymptomatic phases of disease, accurate staging of the disease identifying favourable tumour characteristics, and refined functional evaluation of the underlying liver function enabling the prediction of outcome after surgical intervention.

Most groups restrict the indication for resection to patients with a single tumour, as shown by state of the art imaging techniques. The size of the tumour is not a clear-cut limiting factor – the risks of vascular invasion and dissemination increase with size, but occasionally tumours may grow slowly to a huge size, without evidence of invasion or satellite disease. In these cases, the risk of recurrence post-resection is not significantly increased compared to smaller tumours. Some groups perform chemoembolization of larger tumours, hoping to convert larger non-surgical lesions into resectable ones.[49] Others use portal vein embolization of the hepatic lobe hosting the tumour to induce compensatory liver growth in the non-affected lobe in order to increase its functional capacity if a major resection is planned.[50] The benefits of these interventions in large series are not well established. Large RCTs defining the risks and benefits of these practices are required.

For many years, the selection of candidates with potentially resectable tumours has been based upon the Child Pugh score. However, even Child Pugh A patients may perform poorly. The Japanese groups rely on the indocyanine retention test of hepatic function, using the rate of hepatic clearance of the dye to guide their decisions regarding the appropriateness and extent of liver resection.[51,52] Portal pressure and bilirubin have been established as the best parameters to select optimal surgical candidates in Europe.[42,44] Clinically relevant PHT can be defined as the presence of either a hepatic vein pressure gradient of ≥10 mmHg,[43] oesophageal varices, or splenomegaly with a platelet count of <100 000/mm$^3$. Subjects without relevant PHT and normal bilirubin achieve 5-year survival rates of 70%, whereas this decreases to 50% in patients with PHT, and to 25% in those with PHT and a raised bilirubin.[44]

Even restricting resection to the best candidates, tumour recurrence rates exceed 50% at 3 years. When present, it influences long-term survival. The most powerful predictors of postoperative recurrence are the presence of microvascular invasion, poor differentiation and satellite lesions.[44,53–55] This reflects the fact that the majority of recurrences result from dissemination from the primary tumour, rather than being 'new' or *de novo* HCC.[56] Currently, there is no effective method proven to diminish recurrence. Preoperative chemoembolization or adjuvant chemotherapy have no efficacy and may complicate the intervention.[57] Preliminary studies indicating benefit from internal radiation[58] and adoptive immunotherapy[59] (using activated lymphocytes) require validation, as do the apparent successes of retinoids[22] and IFN in preventing *de novo* tumours,[60] as has been also suggested after percutaneous ablation.[61]

## Liver transplantation

Individuals with HCC played a major role in the pioneering days of liver transplantation. At a time when the success of this radical intervention was unknown, the risks were considered acceptable for HCC patients, owing to the lack of alternative treatments and a dismal life expectancy. Although recurrence was high in the early years (32–54%) and survival poor (<40% at 5 years), this practice changed the treatment strategy for HCC and was instrumental in defining the criteria we now use for selection of favourable candidates.[62] By selecting the 'optimal patients', i.e. those with a single HCC ≤5 cm or up to three nodules ≤3 cm, the 5-year survival is 70% with a recurrence rate below 15%.[44,63,64]

Although many believe that transplantation should be the first-line option for treatment of early HCC, as it

cures both the tumour and the underlying disease, the shortage of donors and long waiting list times impose a grim reality even for those eligible at the time of first assessment. The United Network of Organ Sharing (UNOS) data indicate that almost as many patients are excluded while waiting, as a result of progressive disease, as are effectively transplanted.[65] In the United States, UNOS adopted the Model for End-Stage Liver Disease (MELD) system to rank or prioritize patients awaiting orthotopic liver transplantation. A composite score based on the bilirubin, prothrombin time, creatinine and aetiology is used for non-cancer patients and a variable score was initially granted to HCC patients.[66] Patients in stage I (single <2 cm) received 24 points and patients in stage II (single 2–5 cm or three ≤3 cm) 29 points. However, this resulted in an unfair priority for HCC patients as compared with non-cancer patients. Thus, points were reduced to 20 and 24, respectively, and depending on the results obtained the system may be again changed.[67] In fact, one of the main issues when priorities are established is to ensure an equitable distribution of organs. As the MELD score favours the transplantation of HCC patients, of which there are many in some centres, there are concerns that it may increase the drop-out rate and subsequent death of non-cancer patients. At the same time, it is mandatory to avoid excessive priority for too ill patients with dismal outcome after transplant. These aspects are not yet solved and no firm recommendation can be given.

According to estimates from available data, a waiting time of 6 months would reduce the drop-out of HCC patients from transplant waiting lists to <10%. For waiting times above this, several strategies to impede tumour progression while waiting for a donor have been proposed. Systemic chemotherapy has no efficacy despite encouraging preliminary results.[68] Robust RCTs comparing active intervention versus no therapy for these individuals are lacking. Most groups perform transarterial chemoembolization upon listing because it reduces tumour burden and delays tumour progression.[49,69] As this treatment may induce liver failure and death in patients with decompensated disease, it cannot be applied to all candidates. Patients with small tumours can be ablated by percutaneous ethanol injection or radiofrequency ablation.[70] One potential drawback of this practice is seeding due to tumour puncture. The risk is mostly restricted to peripheral tumours that cannot be accessed through a rim of non-tumoral liver,[71] and is more likely using larger needles. As ethanol injection uses thinner needles, this may be the most appropriate course of action, but direct puncture of nodules without a rim of non-tumour liver should always be avoided. A laparoscopic approach and radiofrequency ablation for peripheral tumours may circumvent this issue.

An alternative solution to the long waiting list times is to expand the numbers of available livers. While strategies here include the use of marginal livers as well as domino or split-liver transplantation, it is the introduction of living donor liver transplantation (LDLT)[72] that possibly has the greatest potential. Over 2000 adult LDLTs using the right hepatic lobe have been performed throughout the world. The drawbacks are the 0.5% donor mortality and 20% recipient morbidity. At present, recipient survival post LDLT appears similar to cadaveric transplantation, but the long-term outcome is unknown.[73] There is a suggestion, for example, that reinfection of the graft in HCV patients is more severe in recipients of live than of cadaveric transplantations.[74] While accepting that long-term data are still awaited and live donation programmes are likely to face the problems of patient and/or donor refusal, blood group incompatibility, medical contraindications and funding restrictions, there may be potential within LDLT practice to extend the limits currently applied to HCC transplantation. As the transplant can be done without delay, with highly accurate staging, a set of expanded criteria have been proposed by several groups.[75,76] In the Barcelona Liver Unit we proposed the following limits for live donation: single tumour ≤7 cm, three nodules ≤5 cm, five nodules ≤3 cm, or a down-staging to conventional criteria after local or regional therapy lasting more than 6 months.[46] It is expected that survival will still exceed 50% at 5 years, but the applicability of this programme is clearly reduced. In general, live donation may not only benefit some individuals with more extensive disease, but may also reduce waiting list times for cadaveric recipients.

Initial concerns that immunosuppression post-transplant may accelerate the growth of recurrent or metastatic HCC[77] are now thought to be unfounded,[78] adherence to selection criteria being the single key factor predicting postoperative recurrence. There are currently no data indicating that systemic chemotherapy pre- or post-transplant for these individuals has any impact on disease recurrence. Some centres administer systemic chemotherapy to all individuals with satellites or vascular invasion at pathological examination post-transplant, but there are no data to support this policy.

### *Percutaneous treatments*

Destruction or ablation of tumour cells can be achieved percutaneously by the injection of chemical substances (ethanol, acetic acid and boiling saline) or by inserting a probe that modifies local tumour temperature (radiofrequency, microwave, laser and cryotherapy). These are the best options for patients with early HCC who are ineligible for resection or transplantation.[79–84] Whether

or not they may be the best option for all patients is unknown due to the lack of RCTs comparing them with resection. Some Japanese centres, however, do offer ablation as first-line therapy.[85]

Percutaneous ethanol injection (PEI), usually performed under US guidance, is the best known and studied of the percutaneous therapies. It is highly effective for small HCCs and has a low rate of adverse effects. It achieves complete tumour necrosis in 90–100% of HCCs <2 cm in diameter. This is reduced to 70% in 2–3-cm tumours and 50% in 3–5-cm tumours.[80,86] The injection is repeated on successive days and the efficacy of ablation is assessed at 1 month by dynamic CT.[2] The absence of contrast uptake in the tumour reflects tumour necrosis, while the recognition of contrast uptake constitutes treatment failure. The 5-year survival of Child Pugh A candidates with a complete response is 50%.[81] Complete necrosis in tumours >3 cm, however, is rarely achieved, possibly because of the presence of septae preventing the ethanol accessing the whole tumour volume. Overall, the rate of recurrence is similar to that seen for surgical resection and occurs within the vicinity of the treated nodule.

Radiofrequency ablation (RFA) is the most extensively used alternative to PEI. It can be applied through single or multiple cooled-tip electrodes, either percutaneously, laparoscopically or intra-operatively. It is claimed to achieve the same objective response as PEI in significantly fewer sessions.[87,88] Theoretically, it may be superior in tumours >3 cm by disrupting intra-tumoral septae. The main drawbacks of RFA are its higher cost and associated mortality of 0.5% and morbidity of 10%. Superficial tumours should not be treated percutaneously by direct puncture because of the risk of tumour seeding.[71] In addition, tumours in close proximity to the hilum or gallbladder should not be treated by RFA as there is a high risk of damaging the biliary tree. Treatment of tumours in close proximity to the heart or major vessels should also be avoided.

## Palliative therapy

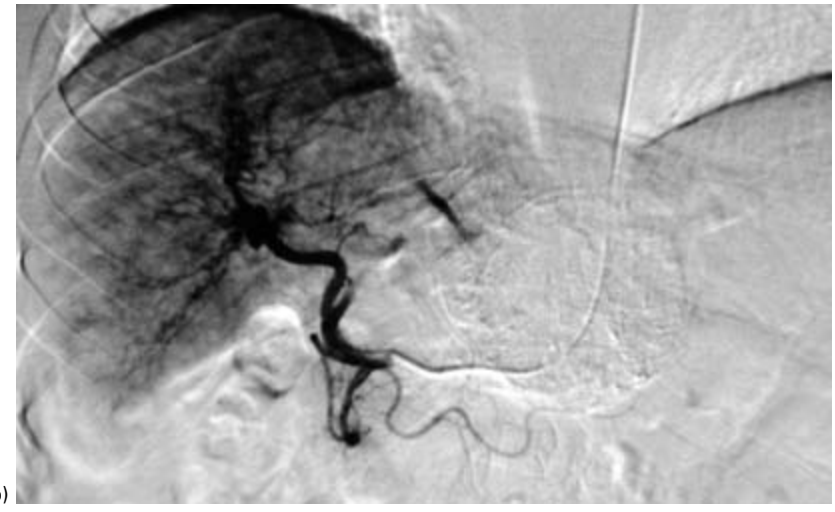
As the majority of HCC patients over the last 25 years have been diagnosed at advanced stages of disease, where no standard therapy has been universally established, a whole host of alternative therapies have been advocated. In the main, relatively small studies have analyzed the effectiveness of treatments such as embolization, chemoembolization, arterial or systemic chemotherapy, internal radiation with $^{131}$I, proton beam radiation, hormonal compounds and immunotherapy.[89] Systematic review and meta-analyses of all available studies indicate that only chemoembolization has a beneficial impact on survival.[89] In contrast, oestrogen blockade with tamoxifen unequivocally lacks anti-tumoral effect and has no impact on survival.[89] All other treatment approaches, including internal irradiation with $^{131}$I,[90,91] octreotide[92,93] and IFN[94,95] have been assessed in the setting of too few small studies that do not have the statistical power as yet to provide solid conclusions. Initially positive results with IFN[94] and octreotide[92] have since been contradicted.[93,95] As the majority of intra-arterial chemotherapy trials have not included a no-treatment arm, no definitive conclusions can be drawn from these. Similarly, systemic chemotherapy (most often doxorubicin) has marginal activity (<10% response rate) with no proven impact on survival.[96,97]

## Arterial embolization

The majority of hepatic blood flow in a normal liver arises from the portal vein (70%), while the remainder arises from the hepatic artery. In contrast, HCC are predominantly supplied by the hepatic artery. Arterial neo-angiogenic activity in malignant tumours typically results in lesions that are hypervascular. This characteristic forms the pathologic basis of both the typical diagnostic radiological features of HCC and the therapeutic rationale supporting arterial obstruction. Embolization of the arterial blood supply to the tumour is a practice typically considered for individuals with non-surgical HCC who are also excluded from percutaneous ablation (often because of multifocal disease or tumour size), but in whom there is no extrahepatic disease. The main contraindication is the lack of portal blood flow (secondary to portal vein obstruction with thrombosis or tumour, portosystemic anastomosis or hepatofugal flow), as in these individuals the arterial supply may be the predominant liver blood supply and any intervention obstructing this may precipitate liver failure. Patients with advanced disease (Child Pugh C) should also be excluded from this treatment.

Obstruction of the hepatic artery induces extensive tumour necrosis. Gelfoam prepared as 1-mm cubes is the most commonly used agent, but polyvinyl alcohol, alcohol, starch microspheres, blood clots and metallic coils have all been used. Hepatic artery obstruction is performed during an angiographic procedure and is known as transarterial, or transcatheter arterial embolization (TAE). The procedure requires the advancement of the catheter into the hepatic artery and then lobar and segmental branches (Fig. 48.7a). The aim is to interrupt blood flow to the tumour in as selective a way as possible (Fig. 48.7b), avoiding injury to the surrounding non-tumour liver as much as possible. This may not be possible if treating multifocal HCC involving both right and left hepatic lobes. The injection is done slowly to avoid the backward flow of gelfoam particles that could embolize arterial vessels outside the liver. Care to avoid obstruction of the cystic artery and ensuing necrosis of the gallbladder is standard practice.

(a)



(b)

**Figure 48.7** (a) Hepatic angiography depicting a large hypervascular mass located in the left lobe corresponding to a hepatocellular carcinoma (HCC). Impaired liver function and associated conditions precluded surgical resection and liver transplantation. Large tumour size excluded the patient from percutaneous ablation and the recommended treatment was transarterial chemoembolization. (b) The catheter was advanced selectively into the left hepatic artery feeding the tumour, and at that time-point chemotherapy mixed in lipiodol and gelatin fragments was injected until blood flow interruption was achieved. The figure shows that all blood flow to the tumour is completely abolished.

When TAE is combined with the prior injection into the hepatic artery of chemotherapeutic agent, most commonly doxorubicin, mitomycin or cisplatin, the procedure is known as transarterial chemoembolization (TACE). It is usual to suspend the chemotherapeutic agent in lipiodol, an oily contrast agent that is selectively retained within the tumour, enhancing the exposure of the tumour cells to the chemotherapy. The dose of chemotherapy administered should be distributed between the affected lobes. Common practice is to inject 25% of the total volume into the tumour-free lobe, aiming to act on any potentially undetected tumour cells.

The side-effects of intra-arterial injection of chemotherapy are the same as for systemic administration, namely nausea, vomiting, bone marrow suppression, alopecia and renal impairment. In addition, hepatic artery obstruction with induced necrosis of the tumour may be associated with what is known as 'post-embolization syndrome'. This is seen in >50% of individuals and consists of fever, abdominal pain and a moderate degree of ileus. It is usually self-limiting and most patients can be discharged within 48 hours. Fasting is required for 24 hours prior to the procedure and intravenous hydration is mandatory. Prophylactic antibiotics are not routinely used. Post-procedure fever is usually a reflection of tumour necrosis, but if it persists severe infectious complications such as a hepatic abscess or cholecystitis should be considered.

A partial response, accompanied by delayed tumour progression and vascular invasion, is induced by both TAE and TACE in 15–55% of patients[69,98] and can be assessed by the decrease in concentration of tumoral markers and/or the identification of intra-tumoral necrosis and reduced tumour burden on dynamic CT scan or MRI. However, the residual tumour typically recovers its blood supply and repeated treatment is necessary. In the cumulative meta-analysis of all RCTs[69,98–103] a significant survival benefit (41% at 2 years versus 27% in the control group) has been shown for chemoembolization, but never confirmed for embolization alone.[89]

## The future

Despite significant advances in the management of this disease over the last 20 years, the majority of patients are still diagnosed at advanced stages of disease and have little hope of cure. Future improvements will more than likely include advances at the level of prevention in the form of immunization and antiviral therapies, at the level of detection and staging with ever better imaging modalities, as well as at the treatment level, with the increasing opportunities to expand the donor pool and improve surgical and possibly ablative techniques. Hopefully, however, the application of advances in genomics and proteomics will also play a major role. Several human tumours, including breast,[104–106] prostate,[107,108] and lung cancer,[109] non-Hodgkin's B lymphoma[110] and melanoma,[111] have recently been classified, with respect to their stage, prognosis and/or response to treatment, according to gene or protein profiling using microarray[112,113] or proteomic technologies.[114] These molecular classifications are still being validated, but there is hope that they may be far more accurate in predicting prognosis or response to therapies than traditional staging systems.

The basis of molecular classification lies in the accumulation of genetic defects and associated changes in gene and protein expression that take place as tumour pathways are initiated and subsequently progress. Chronic liver disease not only creates an environment where DNA damage is likely to occur, but the persistent repair and regenerative response to injury enables the clonal selection and perpetuation of any cells with damaged genes afforded a proliferative or survival advantage. Whatever the aetiology of the chronic liver disease, genetic change contributes to the creation of clones of abnormal cells we term low-grade dysplastic nodules (LGDN). In association with additional genetic changes these LGDN progress to high-grade dysplastic nodules (HGDN), early HCC, and subsequently intermediate and later stages of disease. An extensive literature suggests that the different stages of HCC development can be defined by changes in DNA, mRNA or proteins.[115,116] Some of these changes may have direct clinical relevance. For example, both HSP70[117] and Glipycan-3[29] have been proposed as markers of early HCC and may possibly distinguish HGDN and early HCC. Similarly, a recent gene array in HCV-related HCC cases has proposed a '50 gene set', including TP53, the RAS oncogene and TNF families as genes which could be used in combination to confirm diagnosis of an HCC.[118,119] Some genes, including p16, SOCS-1 and PEG10, are reportedly associated with tumour progression, while nm23-H1, ostepontin and Rho C form part of a proposed 'genetic signature' predicting disseminated HBV-related HCC.[120]

It will probably be a number of years before studies such as these are validated and their practical value is assessed. Ideally, we would like to identify DNA changes, study their origin and impact, and devise effective means of preventing their occurrence, detecting and monitoring their presence, as well as developing means of inhibiting their deleterious effects. In practical terms for HCC, this might mean chemo-preventive strategies inhibiting the development of chromosomal instability in chronic liver disease, sensitive serum biomarkers capable of detecting early disease, serum biomarkers for staging, monitoring disease and predicting response to therapeutic strategies, and the development of novel targeted therapies. With these approaches, in combination with improvements in the strategies that have already had a dramatic impact on HCC management, we may see the prognosis of this once universally dismal tumour change yet further in the coming years.

## Conclusion

Hepatocellular cancer (HCC) is a common malignancy with a particularly poor prognosis. It is associated with chronic liver diseases, particularly those secondary to viral infection or toxic agents such as alcohol. Over the last 10–20 years, significant advances have been made in both the ways we detect these tumours and the ways in which we treat them. Unfortunately, although tumours diagnosed early may be cured by resection, liver transplantation or ablation, the majority of patients with this disease are still diagnosed at an intermediate or advanced stage. Advances in care for these individuals have not been as successful, but a significant palliative survival benefit has recently been confirmed for some of those receiving transarterial chemoembolization of their tumour. The principal focus of this chapter is to review not just the therapies available, but also the current clinical practices for identifying tumours and staging the disease. Early detection, established recall procedures and accurate staging have a major influence on the success of treatment application.

# Chapter 49
# Application of molecular biology to the diagnosis of viral hepatitis

Jean-Michel Pawlotsky

In the past decade, improvements in molecular biology-based techniques have yielded highly valuable tools for use in the management of liver diseases related to hepatitis B virus (HBV) and hepatitis C virus (HCV) infections. Molecular tools have been used for years to diagnose these infections. Nowadays, molecular assays have also become mandatory in the management of antiviral therapy. They are particularly useful to establish treatment indications, tailor therapy to the individual patient and assess virological responses and resistance to antiviral drugs. This chapter reviews current molecular biology-based techniques and assays, and their practical use in the management of viral hepatitis.

## Molecular biology-based techniques

### Detection and quantification of viral genomes

Viral genomes are generally present in relatively small amounts in body fluids of infected patients, hindering their detection by simple molecular hybridization-based techniques. Thus, their detection and quantification requires a preliminary 'amplification' step. This can be achieved by using two categories of molecular biology-based techniques, namely target amplification and signal amplification.

#### *Target amplification techniques*

The principle of target amplification techniques is to synthesize a large number of copies of the viral genome (amplicons) in a cyclic enzymatic reaction. In the 'classical' target amplification methods, the amplicons are detected at the end of the reaction by various methods and the amount of viral genomes in the clinical sample can be quantified through competitive amplification. In the 'real-time' target amplification techniques, detection and quantification are performed during the reaction in the closed tube, by a non-competitive method.

*Polymerase chain reaction*

The polymerase chain reaction (PCR) method[1] uses several temperatures and one enzyme, a thermostable DNA polymerase. The amplicons are double-stranded DNAs. PCR can be applied to DNA viruses (such as HBV) directly, after extraction of nucleic acids or lysis of the viral envelope and capsid. In contrast, a reverse transcription step is required for RNA viruses (such as HCV), in order to synthesize a complementary DNA (cDNA) for use as a template in the PCR reaction. Each complete PCR cycle doubles the number of DNA copies. After n cycles, $2^n$ copies of each DNA molecule present at the beginning of the reaction are theoretically synthesized. In fact, the reaction is saturable and reaches a plateau, generally after 35–45 cycles. Detection of PCR amplicons is classically based on specific hybridization to immobilized oligonucleotide probes. Amplicon-probe hybrids are revealed in an enzymatic reaction, followed by detection of a coloured or luminescent signal. Quantification is based on competitive amplification of the viral template with a known amount of synthetic standard added to each reaction tube. The relative amounts of viral template and standard amplicons are measured at the end of the procedure and the results are read from a standard curve established in parallel.

*Real-time PCR*

The principle of real-time PCR is to detect amplicon synthesis and to deduce the amount of viral genomes in the starting clinical sample during rather than at the end of the PCR reaction.[2] This method is more sensitive than classical PCR and is not prone to carryover contamination. The dynamic range of quantification of real-time PCR techniques is consistently wider than that of classical target amplification techniques, making them particularly useful for quantifying the full range of viral loads observed in untreated and treated patients with HCV or

HBV infection.[3–13] Several real-time PCR methods can be used in various devices, such as the TaqMan™ technology, the fluorescence resonance energy transfer (FRET) method, the SYBR Green I dye method or methods using molecular beacons.[14] Real-time PCR can be partly or fully automated and adapted to high throughput settings. Whatever the technique used, software is used to calculate the threshold cycle in each reaction from which there is a linear relationship with the initial amount of DNA. In each run, parallel processing of a panel of quantified standards is used to establish a standard curve for quantification.

*Transcription-mediated amplification*

In transcription-mediated amplification (TMA),[15] the reaction is isothermal and uses two enzymes, a reverse transcriptase and a T7 RNA polymerase. The amplicons are single-stranded RNAs. After lysis of the viral envelope and capsid, the viral genome (DNA or RNA) is captured by oligonucleotide probes and bound to magnetic microparticles. Amplification involves autocatalytic isothermal production of RNA transcripts with the two enzymes. Each newly synthesized RNA re-enters the TMA process and serves as a template for the next round of replication, resulting in exponential amplification of the target RNA. TMA reactions, like PCR reactions, reach a plateau after a certain number of cycles. Detection of TMA amplicons is based on specific hybridization to immobilized oligonucleotide probes. Amplicon-probe hybrids are revealed in an enzymatic reaction, followed by detection of a coloured or luminescent signal. Quantification can be performed by competitive amplification of the viral template with a known amount of synthetic standard added to each reaction tube.

### *Signal amplification techniques*

In signal amplification techniques the viral genomes are first hybridized to a holder, by means of specific 'capture' oligonucleotide probes. Then the signal emitted by the hybrids is amplified for detection and measurement.

*Hybrid capture*

In the hybrid capture system,[16] HBV DNA is hybridized to specific RNA probes to create RNA-DNA hybrids. The hybrids are captured on a solid phase coated with universal capture antibodies specific for RNA-DNA hybrids, and are detected with multiple antibodies (resulting in signal amplification) conjugated to a revelation system based on chemiluminescence. Luminescence is proportional to the initial amount of the template, and quantification is based on a standard curve generated simultaneously with known standards.

*Branched DNA technology*

In the 'branched DNA' (bDNA) assay, the third generation of which is currently available,[17–23] viral genomes are specifically captured on microwells by hybridization with oligonucleotide probes. A preamplifier molecule is added to the bDNA complex and synthetic bDNA amplifier molecules are hybridized to immobilized target hybrids in the microwells. Signal amplification is achieved through the multiple repeat sequences within each bDNA amplifier molecule that serve as sites for hybridization with alkaline phosphatase-conjugated oligonucleotide probes. Detection is based on alkaline phosphatase-catalyzed chemiluminescence emission from a substrate. As for hybrid capture, luminescence is proportional to the initial amount of the template nucleic acid, and quantification is based on a standard curve generated simultaneously with known standards.

## Analysis of the viral genome sequence

Viral genome sequence analysis is aimed at identifying signature sequences and/or amino acid substitutions at specific positions. In practice, signature sequences are used to classify viral strains into phylogenetic groups of clinical interest, called genotypes (including HBV and HCV types, and HCV subtypes).[24,25] It is also possible to identify amino acid substitutions known to be associated with viral resistance to antiviral drugs (for instance, lamivudine or adefovir resistance of HBV), or with particular forms of liver disease (for instance, precore and core promoter mutations in HBV).[26–30] The entire genome of HBV or HCV cannot be routinely analyzed, and available techniques therefore study particular genomic regions. Genome sequence analysis is based on direct sequencing, which provides the full sequence of the analyzed fragment, or on alternative techniques that identify specific sequences at given positions.

### *Direct sequencing of PCR amplicons*

Direct sequencing of PCR amplicons is performed after the sequencing reaction in an automated DNA sequencer. It can be used to determine the exact nucleotide and deduced amino acid sequence of the analyzed fragment. This can be applied to the detection of known clinically relevant motifs or mutations, and can also be used for 'blind' analysis aimed at detecting new motifs or mutations. The sequences must be analyzed and interpreted carefully, because the co-existence of variant viral populations in the same blood sample (quasi-spe-

cies distribution of viral genomes) may lead to sequence ambiguities.[31] Identification of amino acid substitutions at specific positions relies on direct examination of the generated sequences, whereas genotype determination is based on phylogenetic analysis of the generated sequences relative to reference sequences. Direct sequencing is the gold standard for genomic sequence analysis.

### *Reverse hybridization of PCR amplicons*

As direct sequencing is labour-intensive and only available in specialized laboratories, alternative techniques have been developed for routine clinical use. These techniques necessitate prior knowledge of the target motifs or mutations. By far the most widely used assays are based on reverse hybridization of PCR amplicons.[32–38] In these assays, PCR amplification of the region of interest is followed by stringent hybridization with oligonucleotide probes fixed to a solid phase. The probes are designed to be complementary to the various possible sequences. Revelation is based on a colorimetric reaction. Hybridization to a particular probe means that the analyzed fragment has the complementary sequence. This technique has the potential to detect mixed populations representing 10% or more of a quasi-species mixture.

## Application of molecular biology to HBV infection

### Available assays

#### *HBV DNA detection and quantification*

Table 49.1 shows the commercial assays that can currently be used to detect and quantify HBV DNA. HBV DNA quantitative units used in the various assays (pg/mL or copies/mL) do not represent the same actual amount of HBV DNA in a given clinical sample. The World Health Organization (WHO) has established an international standard for universal standardization of HBV DNA quantification units, and an HBV DNA international unit (IU) has been defined.[39] This IU must be preferred to any other quantitative unit and should now be implemented in all commercial HBV DNA quantitative assays. This will be particularly useful for establishing clinically relevant thresholds and universal recommendations for clinical decisions based on HBV DNA load. Table 49.1 shows the conversion factors from relative units used in the current assays to HBV DNA IUs.

Figure 49.1 shows the dynamic ranges of quantification of the current commercial assays stated by the manufacturers, in log IU/mL. The dynamic range of

**Table 49.1** Available HBV DNA detection and quantification assays and conversion from non-standardized, assay-specific units into IUs

| Manufacturer | Assay | Method | Dynamic range of quantification* | Conversion to IUs |
|---|---|---|---|---|
| Digene Corp., Gaithersburg, MD, USA | HBV Digene Hybrid-Capture™ II | Hybrid capture signal amplification in microplates | 142 000–1 700 000 000 copies/mL | To be determined |
| | Ultrasensitive HBV Digene Hybrid-Capture™ II | Hybrid capture signal amplification in microplates after centrifugation | 4700–57 000 000 copies/mL | To be determined |
| Roche Molecular Systems, Pleasanton, CA, USA | Amplicor HBV Monitor™ v2.0 | Manual quantitative RT-PCR | 1000–4 000 000 copies/mL | To be determined |
| | Cobas Amplicor HBV Monitor™ v2.0 | Semi-automated quantitative RT-PCR | 200–200 000 copies/mL | 1 IU = 5.6 copies/mL |
| | Cobas TaqMan 48 HBV | Real-time quantitative RT-PCR | 30–110 000 000 IU/mL (lower limit of detection if the assay is used as a qualitative, non-quantitative assay: 6 IU/mL) | 1 IU = 5.8 copies/mL |
| Bayer Corporation, Tarrytown, NY, USA | Versant TM HBV DNA 3.0 Assay | Semi-automated branched DNA signal amplification | 357–17 857 100 IU/mL | 1 IU = 5.6 copies/mL |

*The HBV DNA units are those currently given by the assays; they should be interpreted according to the conversion factors to and from IUs.

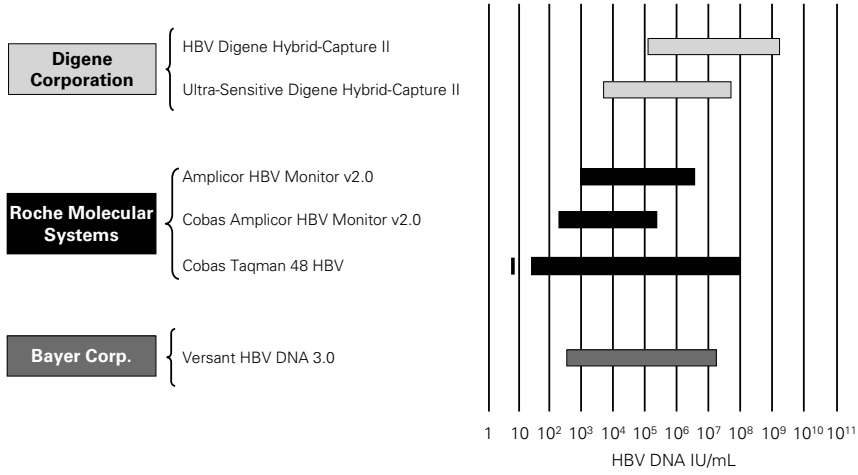

**Figure 49.1** Dynamic ranges of quantification of the current HBV DNA assays relative to the range of potential HBV DNA levels observed during infection, in log IU/mL. The dynamic range of quantification is indicated by a horizontal bar. When the lower limit of detection differs when the assay is used as a qualitative assay, non-quantitative from the lower limit of quantification, it is indicated as a vertical bar.

quantification can be extended to higher values by diluting and retesting high viral load samples falling above the upper limit of quantification of any of these assays, but the dilution step is time-consuming, increases the cost and may affect accuracy. By far the broadest dynamic range of quantification is achieved by real-time PCR techniques,[3–5,7–9,11,12,40] and this will be further improved in the future. This is particularly useful in the case of HBV infection, due to the great variability of baseline viral loads, sometimes reaching very high levels, and potentially very low HBV DNA loads observed upon antiviral therapy.

All of these assays have been shown to be specific and accurate within their respective dynamic ranges of quantification.[16,18–20,41–46] The possible influence of the HBV genotype on quantification has not been extensively studied. It is generally recommended not to take into account HBV DNA load variations of less than threefold (i.e. ± 0.5 $\log_{10}$), whereas variations of more than threefold (i.e. 0.5 $\log_{10}$) can reliably be considered to reflect significant changes. However, in the case of HBV infection where HBV DNA load may spontaneously fluctuate, it is recommended that baseline viral loads be established on the basis of several determinations before therapy.

### *HBV genome sequence analysis*

HBV genome sequence analysis has three potential applications, including HBV genotype determination, identification of precore and core promoter mutations, and identification of antiviral drug resistance mutations.[47,48] The clinical utility of these determinations is currently under study. All of them can be achieved by means of 'home-made' sequencing. Genotype determination is based on sequence comparison with banks of reference sequences, eventually through phylogenetic analysis, that allows classification of the typed HBV strain based on sequence similarities. Previously known precore and core promoter mutations can be identified by sequencing the corresponding region after PCR amplification.[47] Finally, mutations known to confer HBV resistance to lamivudine are identified by analyzing the sequence of the HBV polymerase at known amino acid positions.[27–30] Additional mutations, recently suggested to confer HBV resistance to adefovir dipivoxil, can also be identified through direct sequencing of the HBV polymerase.[26]

Commercial assays are being developed to be used in these indications. Line probe assays are now available to determine the HBV genotype, identify precore and core promoter mutations and identify mutations of the HBV polymerase known to confer resistance to lamivudine.[35,49–54] Compared with direct sequencing, these assays have the advantage of potentially detecting mixtures of quasi-species variants in patients' blood. On average, minor variants representing 10% or more of the viral populations can be identified together with the major population. This may be particularly interesting to diagnose HBV resistance to specific inhibitors before the resistant population has completely replaced the 'wild-type' sensitive one. If confirmed to be clinically relevant, resistance mutations to adefovir and future antiviral drugs will be added in the future generations of these assays.

## Practical use

### *Screening of blood donations for HBV*

Routine screening of blood donations for HBsAg and total anti-HBc antibodies has drastically reduced the risk of post-transfusion hepatitis B, which was estimated to be approximately 1/137 000 donations in the 1997–1999 period in the United States and 1/475 000 donations in France during the same period. No extra donors would

be rejected on the basis of pooled HBV DNA testing than by using the most sensitive HBsAg tests on an individual basis. However, HBV DNA can be detected on average 21 days prior to the appearance of HBsAg, even when HBsAg is assayed with the most sensitive tests. In addition, HBV DNA testing may identify 'occult' HBV infection in HBsAg-negative donors.[55] Thus, individual HBV DNA screening of blood donations by sensitive molecular biology techniques could improve viral safety. The same applies to organ, tissue and cell donors.

### *Diagnosis of HBV infection*

No molecular biology-based assays are necessary for the diagnosis of acute hepatitis B, which is based on serological testing. Chronic hepatitis B is defined by HBsAg persistence in serum for >6 months. In this setting, HBV DNA detection-quantification is necessary to determine whether or not HBV is replicating and the level of HBV replication.[56] When HBV DNA is detected, the quantitative result should be interpreted according to HBeAg status, alanine aminotransferase (ALT) activity and histological status, including the activity and degree of fibrosis.

In the presence of HBeAg, the diagnosis of replicating chronic hepatitis B is made whatever the viral load.[56] In contrast, the interpretation of HBV DNA quantification is difficult in HBeAg-negative/anti-HBe antibody-positive patients (precore mutant HBV), who generally have lower replication levels than HBeAg-positive patients. The current highly sensitive assays, which can detect HBV DNA in the vast majority of HBsAg carriers (Fig. 49.1), make it necessary to define a clinically relevant replication threshold. The best discriminatory threshold (or interval, as overlaps may exist) may vary from patient to patient, or between different patient subgroups, and remains to be established in appropriate clinical studies using highly sensitive and accurate HBV DNA assays. These thresholds may indeed be particularly important in making appropriate therapeutic decisions.

### *Assessment of disease severity and prognosis*

Histological examination of liver biopsy material is still the best way of assessing the severity of chronic hepatitis B and establishing the prognosis. HBV DNA detection also provides valuable prognostic information. Indeed, active HBV replication is associated with a significant risk of progression to chronic hepatitis B complications (including cirrhosis and hepatocellular carcinoma – HCC).[56] This risk is low in the absence of detectable HBV DNA, except in patients with cirrhosis, who may subsequently develop HCC despite the absence of HBV replication. However, most of the HBsAg carriers are now HBV DNA-positive with highly sensitive assays. It has been suggested that HBV DNA loads lower than approximately $10^2$–$10^3$ IU/mL were associated with inactive liver disease. Nevertheless, the possible prognostic significance of HBV DNA load, and informative thresholds, need to be determined in appropriate clinical studies with the highly sensitive assays.

### *Treatment of HBV infection*

HBV DNA detection and quantification is a key tool for treatment monitoring in chronic hepatitis B.

#### *Decision to treat*

The decision to treat patients with chronic hepatitis B must be taken individually, on the basis of precisely weighed parameters. Elevated serum ALT activity, a liver biopsy showing chronic hepatitis with or without cirrhosis, and the presence of significant levels of HBV DNA are strong arguments for initiating antiviral therapy.[56] As stated above, no precise clinically relevant HBV DNA thresholds are known, and prospective trials are needed to determine HBV DNA loads (in IU/mL) above which patients with chronic hepatitis B should be treated (and below which they should not be treated).

#### *Selection of optimal therapy*

Patients with chronic hepatitis B can now be offered two treatment options: (1) short-term treatment with pegylated interferon-α (PEG-IFN-α) administered weekly[57,58] or HBV inhibitors administered daily[59–67] with the aim of achieving a sustained response (such as HBeAg or HBsAg seroconversion); (2) long-term 'suppressive' treatment with specific HBV inhibitors,[59–67] that would ideally combine a nucleoside analogue and a nucleotide analogue in order to delay the occurrence of HBV resistance in patients who will be treated for several years. The individual indication for these two treatment options is still debated.[56,78] Algorithms combining several clinical, biological, virological and histological parameters need to be established in order to define which is the best first-line option for each individual patient. In this context, it is likely that HBV DNA quantification will help in selecting optimal therapy. For instance, the HBeAg-positive patients with a low HBV DNA level, who generally have high ALT values, are more likely than those with a high HBV DNA level to have a sustained response to short-term therapy.[56,68] However, the precise HBV DNA cut-off point that discriminates between 'low' and 'high' pretreatment replication levels needs to be determined. Further studies are needed to define the best individual tailoring options and the utility of HBV DNA quantification in this process.

*Treatment monitoring*

HBV DNA quantification is critical in treatment monitoring. A significant antiviral effect of therapy can be defined as a reduction of HBV DNA levels of 1 log or more relative to baseline (i.e. a baseline viral load divided by 10 or more). The magnitude of this antiviral effect can be measured by the log HBV DNA reduction compared to baseline. However, the interpretation of antiviral effects of therapy may be complicated by the fact that baseline HBV DNA loads are often fluctuating, especially in HBeAg-negative patients. Thus, baseline viral load should be established by several determinations prior to treatment initiation. The criteria for 'successful' inhibition of HBV replication (antiviral efficacy) are not defined. While treatment efficacy is easy to establish in the case of an HBe seroconversion, the log reduction or target HBV DNA thresholds to be reached in non-HBe seroconverters or HBeAg-negative patients have not been precisely determined, especially in the light of the subsequent outcome of liver disease. This is urgently needed for patients receiving long-term 'suppressive' therapy based on nucleotide/nucleoside inhibitors. Overall, HBV DNA load quantification is a crucial tool to monitor HBV treatment, but the end-points of treatment efficacy need to be precisely determined.

*Assessment of HBV resistance to nucleoside/nucleotide analogue HBV inhibitors*

HBV resistance to lamivudine is frequent. It is related to the selection of HBV mutants bearing amino acid substitutions located within or close to the catalytic site of HBV DNA polymerase.[69–79] Cross-resistance with newly developed nucleoside analogues, such as FTC, entecavir or LdT, has been described both *in vitro* and *in vivo*. HBV resistance to adefovir has recently been shown to occur, although it is delayed and less frequent than lamivudine resistance.[26] Its molecular mechanisms are still under study, but HBV polymerase mutations conferring adefovir resistance have been identified. Cross-resistance with tenofovir remains to be demonstrated.

The assessment of HBV resistance to specific inhibitor molecules is based on HBV DNA load monitoring. There is currently no consensus on the rhythm at which such determinations should be performed. Initial treatment efficacy should be assessed on average 3 months after treatment initiation. Subsequently, HBV DNA determinations can be performed every 3 months (like during HIV treatment with highly active anti-retroviral therapy) or every 6 months. If HBV resistance is suspected, it is necessary to eliminate non-viral causes of antiviral treatment failure, such as poor or non-adherence to therapy, or metabolic causes of lack or reversion of the drug's antiviral effect. Primary HBV resistance to an antiviral inhibitor molecule is defined by the lack of a significant antiviral effect of the drug, i.e. the inability of the drug to decrease baseline HBV DNA load by more than 1 log. Secondary resistance occurs in patients who experienced a significant HBV DNA reduction (1 log or more) upon therapy and relapsed while on treatment. It is defined by a re-increase of viral replication of 1 log or more compared with the HBV DNA nadir. This relapse must be confirmed by a second determination 1 month later. Highly sensitive assays with a broad dynamic range of quantification must be preferred to monitor HBV treatment responses.

Resistance mutations can be detected by direct sequencing or reverse hybridization.[27,29,35,49,53] These techniques currently have no routine indications, given the small number of available molecules. However, identification of antiviral resistance mutations might be useful in future when several drugs and combination therapy options become available.

## Application of molecular biology to HCV infection

### Available assays

#### *HCV RNA detection and quantification*

Table 49.2 lists the commercial assays that can currently be used to detect or quantify HCV RNA. Qualitative, non-quantitative assays are based on target amplification, i.e. PCR or TMA. They can detect the presence of HCV RNA, but they cannot measure HCV viral load. Qualitative assays have been clinically useful because they are more sensitive for HCV RNA detection than most of the currently available quantitative assays. They will probably lose their clinical utility with the advent of highly sensitive quantitative assays.

Quantitative HCV RNA assays are based on bDNA technology, competitive PCR or real-time PCR. Until recently, the quantitative units used in the various assays did not represent the same amount of HCV RNA in a clinical sample. WHO has established an international standard for universal standardization of HCV RNA quantification units and an HCV RNA international unit (IU) has been defined.[80,81] It is currently used in all commercial HCV RNA quantitative assays.[82–86] The use of standardized IUs for HCV RNA quantification has been recommended by the 2002 National Institutes of Health Consensus Conference on Hepatitis C in order to allow recommendations and guidelines to be derived from clinical trials and applied in clinical practice with any quantitative HCV RNA assay.[87]

The manufacturers' stated dynamic ranges of quantification of the currently available tests are shown in Fig. 49.2. The dynamic range of quantification can be extend-

**Table 49.2** Available diagnostic HCV RNA detection and quantification assays

| Manufacturer | Assay | Method | Lower limit of detection | Dynamic range of quantification* |
|---|---|---|---|---|
| Roche Molecular Systems, Pleasanton, CA, USA | Amplicor™ HCV v2.0 | Manual qualitative RT-PCR | 50 IU/mL | None |
| | Cobas Amplicor™ HCV v2.0 | Semi-automated qualitative RT-PCR | 50 IU/mL | None |
| | Amplicor™ HCV Monitor™ v2.0 | Manual quantitative RT-PCR | 600 IU/mL | 600 to <500 000 IU/mL |
| | Cobas Amplicor HCV Monitor™ v2.0 | Semi-automated quantitative RT-PCR | 600 IU/mL | 600 to <500 000 IU/mL |
| | Cobas TaqMan 48™ HCV | Real-time quantitative RT-PCR | 10 IU | 30–200 000 000 IU/mL |
| Bayer Corporation, Diagnostics Division, Tarrytown, NY, USA | Versant™ HCV RNA Qualitative assay | Manual qualitative TMA | 6 IU/mL | None |
| | Versant™ HCV RNA 3.0 assay | Semi-automated quantitative branched DNA signal amplification | 615 IU/mL | 615–7 700 000 IU/mL |
| Abbott Diagnostic, Chicago, IL, USA | LCx™ HCV RNA Quantitative assay | Semi-automated quantitative RT-PCR | 23 IU/mL | 23–2 300 000 IU/mL |
| | HCV Quant ASR | Real-time quantitative RT-PCR | 25 IU/mL | 25–50 000 000 IU/mL |
| National Genetics Institute, Los Angeles, CA, USA | SuperQuant | Semi-automated quantitative RT-PCR | 30 IU/mL | 30–1 470 000 IU/mL |

RT-PCR, reverse transcriptase-polymerase chain reaction; TMA, transcription-mediated amplification.
*Quantitative assays only.

ed by diluting and retesting high viral load samples, but the dilution step is time-consuming, increases the cost and may affect accuracy.[14,88] Real-time PCR assays yield the broadest dynamic range of quantification, which covers well the range of HCV viral loads generally observed in untreated and treated patients. All currently available assays have satisfactory specificity. Their stated specificity is higher than 95% in all instances, and reaches 98–99% in most cases. They accurately quantify HCV RNA within their respective dynamic ranges of quantification, with no difference among the various HCV genotypes.[21,82–93] It is generally recommended not to take into account HCV RNA load variations of less than threefold (i.e. ± 0.5 log), which may be related to the intrinsic vari-

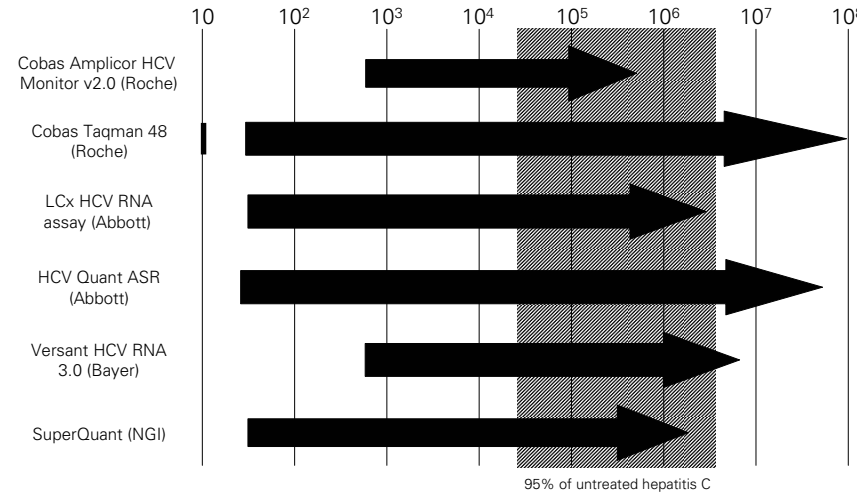

**Figure 49.2** Dynamic ranges of quantification of the current HCV RNA assays relative to the range of potential HCV RNA levels observed during infection, in log IU/mL. The grey area indicates the range of HCV RNA levels found in approximately 95% of untreated patients with chronic hepatitis C. The dynamic range of quantification of each assay is indicated by an arrow. When the lower limit of detection differs when the assay is used as a qualitative assay, non-quantitative from the lower limit of quantification, it is indicated as a vertical bar.

ability of the assays. In contrast, variations of more than threefold (i.e. 0.5 log) can reliably be considered to reflect significant differences in HCV RNA load. However, when samples from the same patient taken at different time-points are tested in the same laboratory with the same technique, the precision of HCV RNA quantification is of the order of ± 0.2 log. This is important when assessing the log drop of HCV RNA during treatment of patients with HCV genotype 1 infection.

### *HCV genotype determination*

Table 49.3 shows the commercial assays based on molecular methods that can be used to determine the HCV genotype. Genotyping based on sequence analysis in the NS5B region is considered the gold standard for genotype determination.[25] However, most of the assays target the 5′ non-coding region of HCV genome, which can be amplified by PCR in nearly all patients. In the 5′ non-coding region, mis-typing is exceptional, whereas mis-subtyping is frequent (approaching 10% of cases). This has no clinical consequences, as clinical decisions are not currently based on the HCV subtype.

## Practical use

### *Screening of blood donations for HCV RNA*

Routine screening of blood donations for anti-HCV antibodies has drastically reduced the risk of post-transfusion hepatitis C.[94] HCV RNA detection in pooled or individual donations by molecular biology techniques (e.g. qualitative PCR or TMA assays) has been implemented in blood banks in the European Union and the United States in order to reduce the 'serological window' between HCV infection and the detection of specific antibodies, and to improve the viral safety of blood products.[95,96] This measure has made it possible to further reduce the residual risk of HCV transmission, which is currently less than 1/1 000 000 donations in France (S. Laperche, personal communication). We recently reported cases of HCV RNA detection in the absence of anti-HCV antibodies in organ and tissue donors,[97] suggesting that HCV RNA screening in the setting of organ, tissue and cell transplantation might be useful to further reduce the risk of HCV transmission. This could be of particular interest in organ donors, who were shown to have a higher prevalence of HCV infection than the general population. However, molecular biology techniques will have to be modified to allow single determinations performed in emergency for use in this setting.[97]

### *Diagnosis of HCV infection*

A sensitive HCV RNA assay, able to detect 50 IU/mL or less, should be used for the diagnosis of HCV infection. This lower limit of detection is achieved by the current qualitative assays and by some quantitative assays (Table 49.2).[87]

#### *Acute hepatitis C*

In acute HCV infection, anti-HCV antibodies are detected in only 50–70% of patients at the onset of symptoms. In the remaining patients, anti-HCV antibodies usually emerge after 3–6 weeks.[98–100] Thus, HCV RNA must be sought in patients with acute hepatitis who have no serological markers of viral hepatitis (including anti-HCV antibody negativity).[87] HCV RNA detection strongly suggests acute hepatitis C, which is confirmed by subsequent antibody seroconversion. In contrast, negative HCV RNA detection makes this diagnosis very unlikely. When both anti-HCV antibodies and HCV RNA are present during acute hepatitis, it may be difficult to discriminate among acute hepatitis C, an acute exacerbation of chronic hepatitis C, and acute hepatitis of another cause in a patient with chronic hepatitis C. Finally, when anti-HCV antibodies are present in the absence of

**Table 49.3** Available HCV genotyping assays

| Manufacturer | Assay | Method | Ability to identify types | Ability to identify subtypes |
|---|---|---|---|---|
| Innogenetics, Ghent, Belgium | Inno-LiPA HCV II or Versant® Genotyping Assay | Reverse hybridization of PCR amplicons | 1, 2, 3, 4, 5, 6 | 1a, 1b, 1a/1b, 1, 2a/2c, 2b, 2, 3a, 3b, 3c, 3, 4a, 4b, 4c/4d, 4e, 4f, 4h, 4, 5a, 6a, 10a |
| Bayer Corporation, Diagnostics Division, Tarrytown, NY, USA | Trugene™ HCV 5′NC Genotyping kit | Direct sequencing of the 5′ non-coding region of HCV genome followed by sequence comparison with an HCV genotype sequence database | 1, 2, 3, 4, 5, 6 | 1a, 1b, 1c, 2a, 2b, 2c, 2d, 3a, 3b, 3c, 3d, 3e, 3f, 3g, 4a, 4b, 4c, 4d, 4e, 4f, 4g, 5a, 6a, 6b |
| Abbott Diagnostic, Chicago, IL, USA | HCV Geno ASR | Multiple real-time PCR amplifications of the 5′ non-coding and NS5B regions with genotype-specific primers | 1, 2, 3, 4, 5, 6 | 1a, 1b, 2a, 2b, 3a, 4a, 5a, 6a |

HCV RNA, acute hepatitis C is unlikely. However, HCV RNA should be retested a few weeks later, as transient negative HCV RNA detection can occur at the late stage of acute HCV infection before the infection becomes chronic.[88]

*Chronic hepatitis C*

In patients with symptoms of chronic hepatitis, HCV RNA testing must be performed when anti-HCV antibodies are present, to assess viral replication and to confirm the diagnosis of HCV infection.[87,88,101,102] HCV RNA testing should also be performed when no antibodies are found and hepatitis C is suspected in haemodialyzed or immunosuppressed patients who may (occasionally) have seronegative chronic hepatitis C, especially if the immunodepression is profound.[87]

*Mother-to-infant transmission*

Babies born to HCV-infected mothers usually carry HCV antibodies for between a few months and 1 year, due to passive transfer from the mother.[103–106] The diagnosis of HCV infection in the baby is thus based on HCV RNA detection.[87] The dates at which the test should ideally be performed are not precisely known. In case of HCV RNA negativity, the lack of transmission is confirmed by the gradual disappearance of HCV antibodies. If the baby is infected, HCV RNA detection may be positive at birth or only later during the first year of life, while anti-HCV antibodies persist. Due to a higher rate of spontaneous resolution in children than in adults,[107] HCV RNA persistence must be confirmed after the first year of life in the babies identified to be HCV RNA-positive at birth or soon afterwards.

*Accidental exposure*

HCV RNA can generally be detected in serum within a few days to a few weeks after accidental exposure to HCV-infected blood. Elevated ALT activity and seroconversion are observed a few weeks later in the absence of therapy.[87] Antiviral therapy, which prevents progression to chronicity in a large proportion of cases, is not an emergency and may be started once the diagnosis of acute hepatitis C is made.[108]

### *Assessment of disease severity and prognosis*

No virological parameters can be used to assess the severity of HCV-related liver disease (which is currently evaluated by means of liver biopsy or serological markers of activity and fibrosis), or to establish the prognosis. In particular, neither the HCV genotype nor HCV viral load at the time of liver biopsy appear to correlate with necroinflammatory activity or the extent of fibrosis, or to predict subsequent outcome. Therefore, repeated HCV RNA determinations are not needed during follow-up of untreated patients.

### *Treatment of HCV infection*

The reference therapy for chronic hepatitis C is now a combination of weekly PEG-IFN-α and daily ribavirin administration.[87] Molecular biology-based techniques are particularly useful for managing the successive phases of treatment. Figure 49.3 presents an algorithm for treatment decisions based on molecular biology techniques.

*Decision to treat*

Chronic hepatitis C is curable. Therefore, in the absence of contraindications to antiviral therapy, treatment is theoretically indicated for all patients with HCV RNA positivity, whatever their ALT levels, severity of liver disease or extrahepatic manifestations.[87] The strategy, however, varies according to the HCV genotype, because of consistently different outcomes of therapy.[109–111] Thus, HCV genotype determination is mandatory when treatment is envisaged.[87] Patients infected with HCV genotypes 2 or 3 should be treated in the absence of contraindications, because >80% of them will achieve a sustained virological response (defined by an HCV RNA clearance maintained for 24 weeks after treatment withdrawal), the end-point of therapy that corresponds to a cure of infection in the vast majority of cases.[109–111] In patients infected with other genotypes, who have lower rates of sustained virological response (40–50% in genotype 1),[109–111] or in patients with genotypes 2 or 3 and relative contraindications to therapy, the decision to treat must be weighed up according to the natural prognosis of HCV-related liver disease.[87] ALT levels, liver biopsy or serological markers of fibrosis, extrahepatic manifestations and the patient's motivation for therapy are useful in deciding which of these patients should be treated.[87]

*Selection of optimal therapy*

Both the duration of treatment and the dose of ribavirin must be tailored to the HCV genotype.[87,110] Patients with HCV genotypes 2 and 3 must be treated with PEG-IFN-α and 800 mg/day of ribavirin for 24 weeks.[87] Patients infected with HCV genotype 1, as well as those infected with genotypes 4, 5 or 6 pending further studies, must receive a higher dose of ribavirin (1000–1200 mg/day according to body weight) and must be treated for 48 weeks (according to the virological response to therapy in genotype 1).[87]

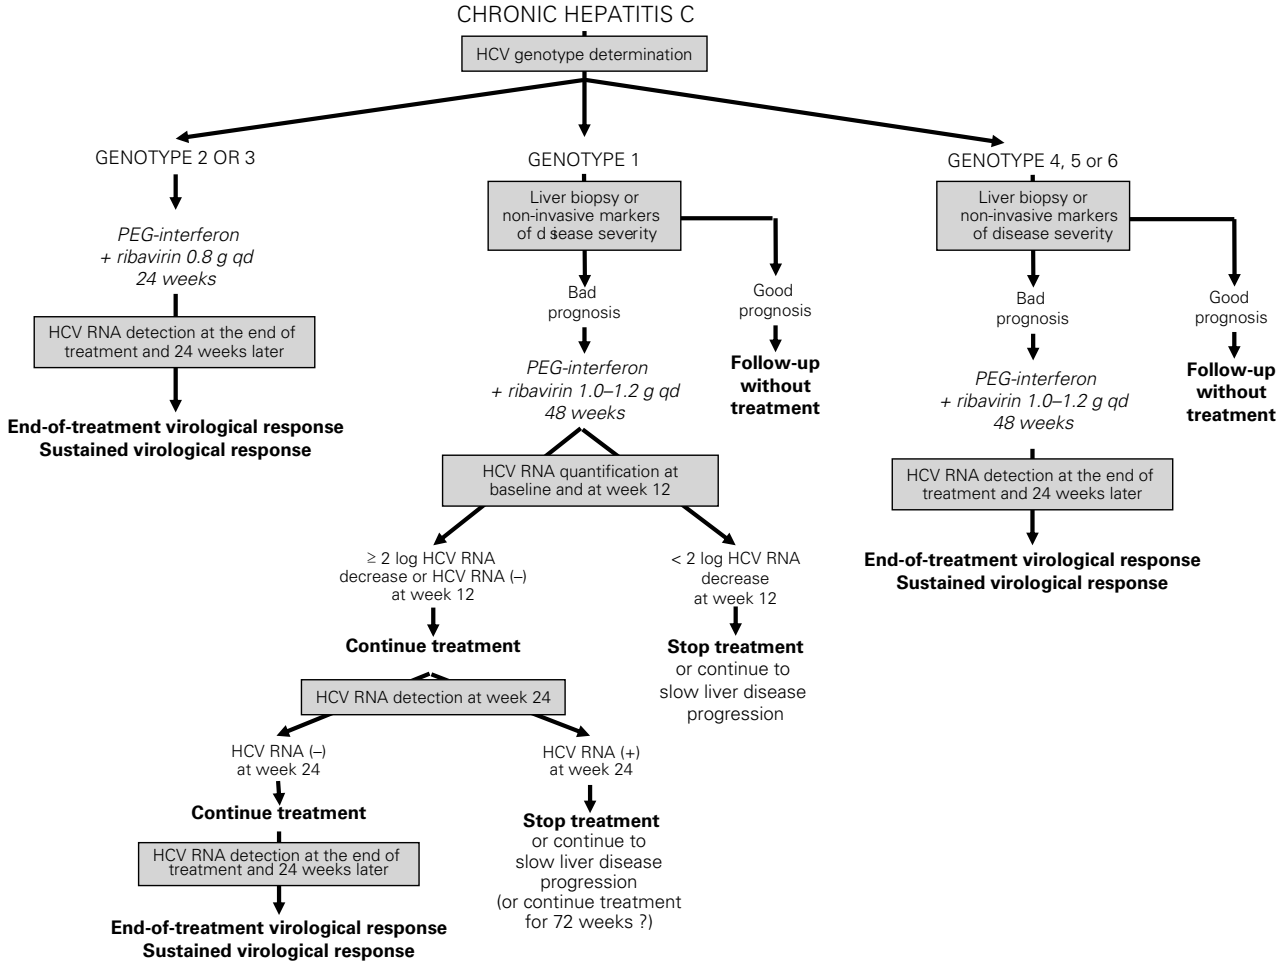

**Figure 49.3** Algorithm for treatment decisions in chronic hepatitis C based on molecular biology techniques.

*Treatment monitoring*

HCV RNA detection at the end of treatment is highly predictive of post-treatment relapse. It is better achieved with a highly sensitive technique (lower limit of detection ≤50 IU/mL).[87] HCV RNA non-detection at the end of treatment demonstrates a virological response. These patients should be retested for HCV RNA 24 weeks later with a sensitive method to assess the sustained virological response, which corresponds with a cure of infection in the vast majority of cases.[87]

HCV RNA assay before and after 12 weeks of treatment is used to monitor genotype 1 chronic hepatitis C treated with PEG-IFN-α and ribavirin.[87,109,112] Treatment can be continued when a 2 log (100-fold) drop in HCV RNA level occurs, or when HCV RNA is undetectable at week 12. Otherwise the likelihood of achieving a sustained virological response is virtually nil, and treatment can be stopped, or continued in an attempt to slow liver disease progression (without clearing the virus).[87,109,112] In patients who continue on therapy, HCV RNA can be again assessed at week 24 with a sensitive assay. If HCV RNA is undetectable (<50 IU/mL), treatment should be continued until week 48. If HCV RNA is detectable (≥50 IU/mL), the likelihood of a sustained virological response is virtually nil.[87,112] These patients could, however, benefit from longer (72 weeks) therapy,[113] pending further studies. The end of treatment, and most importantly the sustained virological response, must be assessed at the end of treatment and 24 weeks later, respectively, with a sensitive HCV RNA assay.[87] The potential utility of assessing the virological response during therapy in patients infected with a genotype other than 1 remains to be determined.

## Application of molecular biology to other hepatitis viruses

No molecular biology tool is useful for the diagnosis of hepatitis A or E, which is based on serological assays.

Hepatitis delta virus RNA detection is the most sensitive and specific marker of infection, but is not widely used in clinical practice.

## Conclusion

In the past decade, the introduction and constant improvement of molecular biology-based techniques have provided invaluable tools for the management of chronic viral hepatitis. They can now be used to test blood donations, diagnose active infection, help to establish the prognosis, guide treatment decisions and assess the virological response to therapy. Further work is required to fully standardize assays and quantification units, improve automation, and better define clinically relevant thresholds that can be used to establish universal recommendations for patient care. The development of increasingly sensitive and accurate assays for viral genome detection and quantification will improve the assessment of the response to antiviral therapy and permit earlier detection of viral resistance. Together with the development of new antiviral drugs and novel therapeutic approaches, these improvements will allow us to optimize the treatment of chronic viral hepatitis and improve the global results.

# Chapter 50
# Hepatitis in HIV-infected persons

Janice Main, Brendan McCarron

There are many important epidemiological and clinical interactions between human immunodeficiency virus (HIV) and the hepatotropic viruses. The pattern of hepatotropic virus infection varies according to the risk group. In homosexual men, for example, hepatitis A virus (HAV) and hepatitis B virus (HBV) infections are common, whereas the HIV-infected intravenous drug user or recipient of blood products is more likely to be exposed to hepatitis C virus (HCV). Recent reports, however, describe acute HCV infection among HIV-positive homosexual men, and there are concerns that underlying HCV may increase the risk of anti-retroviral drug toxicity. Co-infection with GBV-C virus may, however, be in some way beneficial for patients with HIV infection.

It is increasingly recognized that HIV infection can modify the clinical course of several other viral infections, whether these occur before the onset of HIV infection, simultaneously or subsequently. The clinical importance of this is increasing with the improved survival of the HIV-infected individual.

## Hepatitis A

Several outbreaks of HAV infection have occurred in homosexual men[1] and intravenous drug users.[2] However, similar seroprevalence rates of previous hepatitis A infection were reported in homosexual (32%) and heterosexual (30%) men attending a large London clinic for sexually transmitted diseases.[3] HAV vaccination has been recommended for people in high-risk groups, although the antibody response is reduced in the presence of HIV infection.[4]

## Hepatitis B

### Epidemiology

HIV and HBV have the same routes of transmission and co-infection is therefore common. In one study, >90% of patients with HIV infection had HBV markers of current or past infection.[5] One study of a predominantly male homosexual clinic reported a co-infection rate of 6%.[6] High seroprevalence rates are also seen in sub-Saharan patients and in patients with a history of intravenous drug use.

### Immunopathology

Direct interaction of viral infections at the cellular level would require that both viruses infect and replicate within the same cell lines. In an analysis of infected lymphoid cells from patients with chronic HBV infection, one study reported the presence of HBV DNA in peripheral blood mononuclear cells (PBMCs) in all patients with HIV and HBV infection, but in only 50% of those who were HIV-negative.[7]

Experimental models suggest that HIV can infect and replicate within CD4-expressing sinusoidal endothelial cells[8] and Kupffer cells.[9] Resultant functional changes have also been described leading to reduced synthesis of von Willebrand factor and reduced secretion of endothelin-1.[10] Human hepatoma cell lines, which are non-CD4-expressing, can also be infected with HIV.[11] Although hepatomegaly, steatosis and abnormal transaminase values are more commonly seen in patients taking anti-retroviral drugs, such findings are seen from time in untreated patients and it is unclear whether this can be attributed to a direct effect of HIV on the liver.

Direct interactions at the molecular level are thought to occur. The long terminal repeat (LTR) of the HIV genome, for example, has several sequences in which cellular transcription factors can bind and upregulate expression of viral genes (Fig. 50.1). NF-κB, a transcription factor, is generally bound to an inhibitor I-κB within the cytoplasm of the cell and on activation is separated from I-κB, passes to the nucleus, and binds to the LTR. Cytokines such as tumour necrosis factor (TNF)-α, can induce NF-κB,[12] and it is thought that the X gene product of HBV can act in a similar way.[13] Studies with hepatocellular carcinoma and lymphoblastic T-cell lines have demonstrated that the expression of the X gene is capable of upregulating the expression of reporter genes under the control of the HIV LTR[14] (Fig. 50.2).

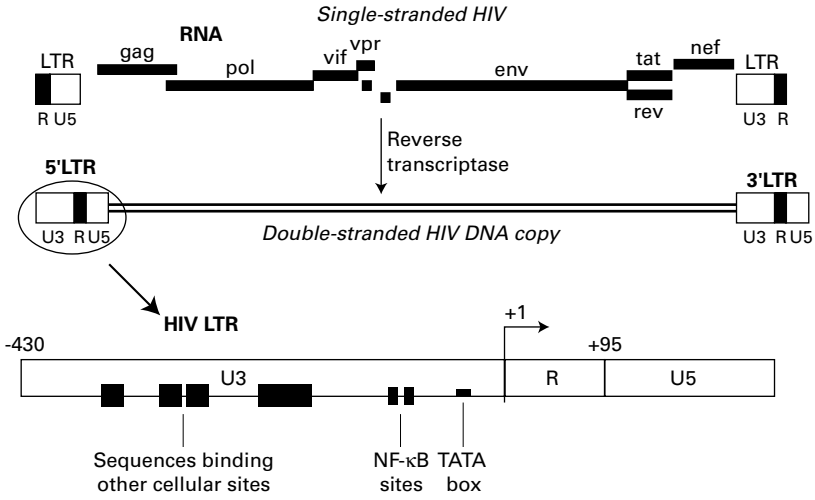

**Figure 50.1** HIV genome and promoter sites on HIV long terminal repeat (LTR).

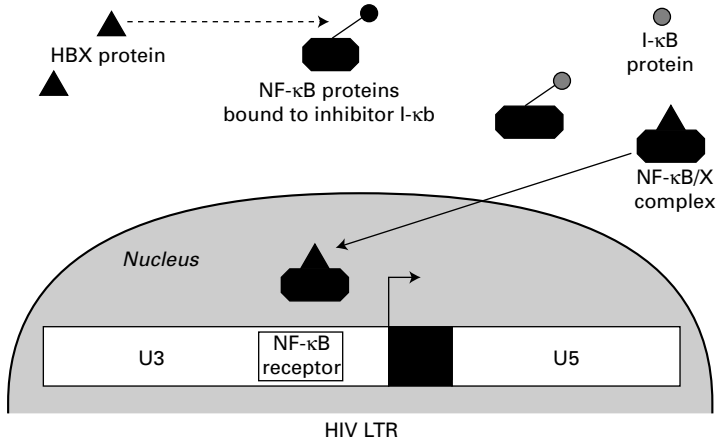

**Figure 50.2** Possible relationship between NF-kB and HBx proteins.

HIV infection leads to a progressive decline in immune function, affecting principally the cell-mediated response, but also with effects on the humoral response. Much of the liver damage seen with hepatitis B is thought to be related to recognition and clearance of infected hepatocytes by cytotoxic T cells.[15] The HIV-mediated reduction of T-cell function and number is inevitably associated with increased HBV replication and less immune recognition of infected hepatocytes. A similar pattern had already been observed in HIV-negative HBV-infected patients receiving immunosuppressive therapy.[16,17] Studies have shown that when HIV-associated immunosuppression develops, there is an increase in HBV DNA levels but a reduction in transaminase levels and a decrease in the hepatic necroinflammatory score.[18–21] Conversely, the immune restoration associated with effective anti-retroviral therapy can lead to immune recognition and destruction of infected hepatocytes, leading to an increase in the transaminase levels.[22]

## Clinical outcome

### *Acute infection (Table 50.1)*[18–21,23–29]

Retrospective analysis of the 1980 Centers for Disease Control multicentre HBV vaccine study has yielded valuable data on the interaction of HIV and HBV.[23] In unvaccinated individuals, the risk of chronic carriage of HBV was 21% in those with HIV infection compared with 7% of those who were HIV seronegative. The average duration of HIV infection before HBV infection was only 8.5 months. Peak transaminase values were similar in both groups, but the duration of elevated transaminase values (>200 IU/L) was significantly prolonged in the HIV-positive group. In an Australian study[18] the risk of chronic HBV infection was 23% (7/31) in HIV-positive individuals, compared with 4% (2/46) in those who were HIV-negative. HIV-infected patients with higher CD4 counts were more likely to clear infection.

**Table 50.1** Effect of HIV on HBV infection

| Effects | References |
|---|---|
| Acute infection | |
| Increased carriage following acute infection | Hadler *et al.*,[23] Bodsworth *et al.*[18] |
| Milder acute disease | Bodsworth *et al.*[24] |
| More severe acute disease with prolonged transaminitis | Hadler *et al.*[23] |
| Chronic infection | |
| Higher HBV DNA load | Krogsgaard *et al.*,[20] Perrillo *et al.*,[21] Bodsworth *et al.*,[24] Goldin *et al.* [19] |
| Reduced hepatocyte necrosis | Krogsgaard *et al.*,[20] Perrillo *et al.*,[21] Bodsworth *et al.*,[24] Goldin *et al.*[19] |
| Reduced response to treatment | McDonald *et al.*,[25] Brook *et al.*[26] |
| Increased risk of HBV reactivation/reinfection | Levy *et al.*[27] |
| Vaccine | |
| Reduced response to vaccination | Collier *et al.*,[28] Loke *et al.*[29] |

### *Chronic infection (Table 50.1)*

In a study by Goldin *et al.*,[19] the necroinflammatory scores of liver biopsies from HBV-infected patients with and without HIV infection were compared. A greater expression of hepatitis B e antigen (HBeAg) and HBV polymerase, but reduced necroinflammation and fibrosis, were seen in the HIV-positive group. Clinical studies of the interactions of HIV and HBV are often hampered by lack of data on the relative timing of the two infections. In a Norwegian study,[30] 80 individuals with HIV infection were monitored, and the outcome of those with anti-HBc antibodies was compared with those who were anti-HBc-negative. The relative risk for progression to AIDS was 3.6 for those with markers of HBV infection.

In the early Multicenter AIDS cohort study[31] HBV infection showed no significant effect on progression to AIDS over 2.5 years, but more recent studies in the setting of decreasing HIV-related mortality rates show an increased risk of liver-related mortality in this group.[32]

There have been several reports of clinically important reactivation of HBV in HIV-infected individuals. This has also been described in patients on cessation of immunosuppressive therapy for other conditions.[33] The mechanism of HBV reactivation in HIV infection is not understood and does not necessarily correlate with changes in the CD4 count or other quantifiable changes in immune function. This diagnosis should be considered in a patient with HIV and HBV infection who develops a flare in the transaminase levels. HBeAg may be negative, however, and the diagnosis may depend on the exclusion of other causes of liver disease, by the detection of HBV DNA levels[27] or by appropriate immunohistochemical stains of liver biopsy material (Table 50.2). Very high levels of HBV may be associated with the development of fibrosing cholestatic hepatitis. This was mainly reported in liver transplant patients prior to the availability of lamivudine and has also been recorded in patients with HIV and HBV infection.[34] It is thought that at very high levels of HBV replication the virus may have a direct cytopathic effect.

## Response to treatment

### *Interferon-α*

It was readily apparent from the early interferon (IFN) trials for chronic HBV infection that underlying immunosuppression was associated with a reduced chance of sustained response. Several studies have now confirmed that the chance of a successful response to IFN is markedly reduced in the setting of HIV infection.[25,26] It is not known whether the poor response to IFN is because of reduced T-cell function or the abnormal cytokine milieu in HIV infection, with high levels of acid-labile IFN,[35] downregulation of IFN-α receptors,[36] or the presence of IFN antibodies.[37] In one study comparing the effects of IFN monotherapy with the combination of corticosteroid

**Table 50.2** Diagnostic and staging tests for chronic hepatitis in anti-HIV-positive patients

| HBV | HDV | HCV |
|---|---|---|
| HBeAg/HBsAg | Anti-HDV | Anti-HCV (ELISA) |

ELISA, enzyme-linked immunoabsorbent assay.

therapy and IFN,[38] two of three HIV-positive patients in the combination group cleared HBV infection. Both had CD4 counts >500/mm$^3$.

The availability of pegylated IFNs (PEG-IFNs) has led to renewed interest in IFN as therapy for chronic HBV infection. This option is only suitable for patients with high CD4 counts as: (1) IFN is less likely to work in patients with CD4 lymphopenia and (2) IFN therapy can be complicated by a decline in the CD4 count.

### *Nucleoside analogues*

HBV and HIV both have reverse transcriptase (RT) activity and many HIV RT inhibitors also have activity against HIV. Zidovudine has only modest activity against HBV but lamivudine has good antiviral activity against both viruses.[39] A lamivudine-containing regimen is therefore a good option for HIV-infected patients where there are clinical concerns regarding HBV disease. Clinicians must be aware, however, that if they decide to change the anti-retroviral regimen, there may be a flare of hepatitis B if lamivudine is discontinued and the new regimen has no anti-HBV activity. The recommended approach is to either continue the lamivudine in addition to the new anti-HIV regimen or to switch to a regimen containing another drug with both anti-HIV and anti-HBV activity such as tenofovir.

With effective treatment for active HBV the transaminase values decline. An increase near the initiation of anti-retroviral therapy raises the possibility of anti-retroviral drug toxicity or immune lysis of infected hepatocytes as part of immune restoration. Subsequent increases in the transaminase values raise the possibility of the emergence of HBV resistance,[40] and this can be confirmed by the detection of HBV DNA levels and the presence of mutation in the YMDD motif.[41] The main approaches are to switch to or to add tenofovir to the regimen.[42,43] Adefovir at high dose has activity against both HIV and HBV but toxicities included renal tubular damage.[44] At low dose (10 mg/day), it appears to be safe[45] and still has anti-HBV activity with activity against lamivudine-resistant HBV.[46] There are concerns, however, that the use of adefovir in this setting may limit the future use of tenofovir as an anti-HIV agent. Many clinicians use both tenofovir and lamivudine in patients where there are concerns about HBV. However, despite the theoretical advantages to such a combination, this has not been proven in clinical practice and leaves limited options when HBV resistance develops. Entecavir, emtricitabine, clevudine and other newer nucleoside analogues may also prove useful.

## Prevention

Protective levels of antibody develop in 90–95% of immunocompetent adults after vaccination with hepatitis B vaccination. The response is less in those with chronic disease such as renal failure,[47] and studies have shown that the response is also reduced in those with HIV infection.[28,29] It has also been noted that the levels of both naturally acquired[48] and post-vaccination anti-HBs antibody levels decrease more rapidly in the patient with HIV.

In one study described by Carne *et al*.[49] HBV vaccination was administered to 35 homosexual men, and only one of the eighteen HIV-negative men failed to develop an antibody response, whereas eight of the seventeen HIV-positive group failed to respond. One study[23] described a high rate of chronic infection in HIV-infected individuals who had received vaccine at about the time of HBV infection.

# Hepatitis C

## Epidemiology

Hepatitis C virus (HCV) infection is particularly common in intravenous drug users or in those exposed to blood products administered before the introduction of HCV screening of blood donors. These risk groups are also exposed to HIV infection, and the presence of both infections is common. Although the risk of sexual transmission of HCV appears low in the setting of a monogamous heterosexual relationship, there are reports of increased prevalence of chronic HCV among homosexual men and more recent reports of acute HCV among HIV-positive homosexual men.[50] There are concerns that the higher levels of HCV RNA seen in the setting of HIV infection may be a factor in this, and may also explain the higher rates of vertical transmission seen with HIV-positive mothers.[51]

The increased survival of HIV-infected individuals with effective anti-retroviral therapy has resulted in patients living long enough to develop the life-threatening complications of HCV infection.[52] Hospitals in Europe and North America have reported that, although there are less patients requiring inpatient care for HIV-related opportunistic infections (OIs), there is increasing use of inpatient facilities for patients with decompensated liver disease and other complications of HCV infection.

## Immunopathology and clinical outcome (Table 50.3)[51,53–60]

### *Effects of HIV infection on HCV disease*

Some studies have suggested a higher rate of HCV chronicity in HIV-infected individuals. In one retrospective study of haemophiliac patients,[61] persisting HCV viraemia was seen in 23 of 25 (92%) HIV-positive patients compared with 20 of 32 (62%) HIV-negative patients.

**Table 50.3** Effects of HIV on HCV infection

| Effects | References |
|---|---|
| Higher HCV viral load | Eyster *et al.*,[53] Telfer *et al.*[54] |
| Increased vertical transmission | Giovannini *et al.*[51] |
| Increase in loss of HCV antibodies | Chamot *et al.*[55] |
| No adverse effect on survival | Wright *et al.*[56] |
| More severe liver disease | Martin *et al.*,[57] Sanchez-Quijano *et al.*,[58] Soto *et al.*,[59] Benhamou *et al.*[60] |

There was no correlation with the CD4 count, but more frequent HCV genotype 1 infection (61% vs 30%) was seen in the HIV-positive group. In many of the studies, the durations of both HIV and HCV infections are unknown.

Our understanding of the immunopathology of chronic HCV infection is limited. There is evidence, however, that HCV has a cytopathic effect on hepatocytes, and more severe disease is seen in immunosuppressed patients receiving corticosteroids and other immunosuppressive agents.[62] An adverse effect on the natural progression of HCV would therefore be expected in patients with HIV infection, and an early report described rapidly progressive liver disease in patients with HCV and HIV infection.[57] The progression of HCV-related liver disease in 32 HIV-positive patients was compared with 44 patients who were HIV-negative.[58] Within 15 years after HCV infection, cirrhosis developed in 8 of 32 (25%) HIV-positive patients and in only 2 of 31 (6.5%) in the HIV-negative group. In one large study of 547 patients, mainly drug users, with chronic hepatitis C more rapidly progressive disease was reported in those with HIV infection.[59] In the histological component of the study, 13 of 87 (14.9%) patients with HIV infection developed cirrhosis compared with only 7 of 272 (2.6%) who were HIV-negative. In patients with haemophilia, there have been several reports of more rapidly progressive liver disease when the patient had HIV and HCV infection.[63,64] HCV RNA levels were higher in those with HIV infection, and this observation has been reported by others.[53,54]

In a detailed histological study, the liver disease progression rate in HIV/HCV-infected individuals was compared with the rate in matched HIV-negative patients.[60] The patients were matched according to other hosts factors known to affect progression (sex, age at time of infection, chronicity of infection, alcohol consumption) and a more rapid rate of progression was seen in those with HIV infection.

Not all studies have confirmed these findings. In HIV-positive homosexual men with HCV infection, one study[56] showed no effect of HIV on HCV progression and vice versa. A total of 512 patients was studied. The group comprised mainly non-drug-using male homosexual patients, 224 of whom had AIDS-defining diagnoses. Seventy-four patients had positive anti-HCV antibody tests and available follow-up (mean 28 months) data were analyzed from 66 patients and compared with matched HCV-negative controls. The presence of HCV viraemia did not shorten survival in those with or without AIDS.

### *Effects of HCV on HIV progression and response to anti-retroviral therapy*

Prior to the availability of more effective anti-retroviral therapy, a large Italian study[65] of 416 patients with HIV infection compared the clinical outcome in HCV-positive (214 patients) and HCV-negative patients. HCV infection had no effect on progression to AIDS or rate of decline of CD4 counts.

The Swiss cohort study[66] evaluated the response to anti-retroviral therapy in HIV-positive patients with and without HCV infection. Although both patient groups had a similar response in terms of reduction of HIV viral load, there appeared to be a reduced CD4 response in those with HCV infection, suggesting that HCV itself had some immunomodulatory effect. A Spanish study reported that HCV-infected patients had a delayed CD4 increase with anti-retroviral therapy.[67] This effect, however, has not been confirmed by a US study[68] which also reported an increase in HCV RNA levels following institution of anti-retroviral therapy.

A syndrome of red fingers in patients with HIV and HCV infection has been reported[69] and, as with HIV-negative patients, there have been reports of cryoglobulinaemia and glomerulonephritis in patients with HIV and HCV infection.

There may be diagnostic difficulties when testing HIV-positive patients for HCV infection. Just as with HBV infection, a reduction in anti-HCV antibodies has been described in HIV-infected patients,[55] and a high number of indeterminate recombinant immunoblot assays has also been noted.[70,71] Although the more recent tests have less false-negative rates, testing for HCV RNA should be considered in these patients and also in those with suspected acute infection where it may take several months to develop an antibody response (Table 50.2).

## Treatment

### *Acute hepatitis C*

Acute hepatitis C is generally asymptomatic and therefore under-recognized. Acute hepatitis C infection has been increasingly diagnosed in HIV-positive patients[50] many of whom, whilst apparently stable on anti-retroviral therapy, have developed a sudden increase in the transaminase level. A positive HCV RNA test and subsequent positive anti-HCV antibody test suggests acute HCV infection. In view of the high levels of response with early treatment of acute HCV infection in HIV-negative individuals (see Chapter 33), similar approaches have been tried in the HIV-positive group. It is also suggested that baseline checks for hepatitis C and annual reviews are performed in patients with HIV infection.[72]

### *Chronic hepatitis C*

#### *IFN monotherapy*

In view of the poor response rates with IFN as therapy for HBV in HIV-positive patients, most of the early HCV trials excluded HIV-positive patients. A large Spanish study[73] found that the response rate was higher in those with a CD4 count >500/mm$^3$, and that following a sustained virological response (SVR) a subsequent relapse was unlikely.[74]

#### *Combination therapy*

Although there have been many studies with standard IFN-α and ribavirin as therapy for HIV/HCV-infected patients, most have evaluated therapy in a small number of patients with different HCV genotypes and different stages of HIV and HCV disease.[75–78] The results demonstrated a lower SVR than is seen in HIV-negative patients and that, just as with the IFN monotherapy studies, the success rate was higher in those with higher baseline CD4 counts.

There have now been several trials investigating the efficacy of PEG-IFNs in combination with ribavirin in HIV/HCV co-infected patients. A Spanish trial reported SVR rates of 28%,[79] the French RIBAVIC[80] trial 27% and the US ACTG 5071 trial with PEG-IFN and ribavirin 27%.[81] The biggest study has been APRICOT (AIDS Pegasys Ribavirin Co-infection Trial) with an overall SVR of 40%.[82] In this study, 868 patients were randomized to receive a year of therapy with standard IFN and ribavirin, PEG-IFN and placebo or PEG-IFN and ribavirin. The results are summarized in Table 50.4. The mean CD4 counts were 520–542/mm$^3$ in the three groups.

Assessing the viral load response at 12 weeks may help discontinue ineffective therapy at an early stage,[79] but further studies are required to determine whether 6 months of therapy are adequate for patients with genotypes 2 and 3 infection. Viral kinetics suggest that co-infection may be associated with slower clearance of HCV.[83]

It has also been suggested that, particularly in those with advanced liver disease who have failed to respond to standard treatment, there may be a role for longer treatment regimens.

However, there have been concerns regarding the potential toxicities of IFN and ribavirin in patients with HIV and the interactions of these agents with anti-retroviral drugs.

IFN can cause CD4 lymphopenia. One Italian group described a sudden decrease in the CD4 count after the administration of IFN.[84] Another group confirmed this and described patients who then went on to develop AIDS-defining diagnoses after the sudden decrease in the CD4 count.[85] Patients on anti-retroviral therapy appear more likely to have a significant decline in haemoglobin as a result of ribavirin.[86]

In terms of interactions IFN and zidovudine are both myelotoxic, so careful monitoring of the blood count is required whilst on therapy. There have been laboratory concerns regarding interactions of ribavirin and other nucleoside analogues.[87–89] Although clinical studies assessing the efficacy of anti-retroviral therapy in patients on IFN and ribavirin have questioned the relevance of these *in vitro* findings,[90] there have been concerns raised regarding lactic acidosis and pancreatitis in patients on regimens that included didanosine.[91–93]

**Table 50.4** APRICOT study[82]

| Parameter | Interferon + ribavirin | Pegylated interferon + placebo | Pegylated interferon + ribavirin |
|---|---|---|---|
| Number treated | 285 | 286 | 289 |
| Overall SVR (%) | 12 | 20 | 40 |
| SVR genotype 1 (%) | 7 | 14 | 29 |
| SVR genotype 2 (%) | 20 | 36 | 62 |
| Discontinued (%) | 39 | 31 | 25 |

SVR, sustained virological response.

*Other approaches*

Successful anti-retroviral therapy is an important strategy for the patient with HIV/HCV infection. It is hoped that with immune restoration the rate of progression of HCV liver damage may be slowed.[94–96]

Heavy alcohol consumption is not uncommon in this group of patients, and it is important to educate patients regarding the dangers of heavy alcohol use in the setting of HCV-associated liver damage.

*Hepatotoxicity of anti-retroviral therapy*

Several anti-retroviral agents are hepatotoxic and there have been concerns regarding the risks of severe hepatotoxicity in patients with existing liver disease such as HCV infection. Several groups have looked at this aspect. The Swiss cohort study found no increase in treatment changes in the HCV-infected patients,[66] whereas a large prospective study reported an increased incidence of hepatotoxicity in patients with HCV co-infection.[97] Many clinicians avoid didanosine and stavudine in patients about to embark on IFN and ribavirin, but otherwise use similar anti-retroviral regimens in patients with HCV co-infection and monitor the liver function tests more rigorously in this group.[98]

*Liver transplantation*

The early experience of liver transplantation for individuals with HIV infection was disappointing, with high mortality rates. Survival rates are improving with more effective anti-retroviral therapy and careful selection of patients, but liver transplantation for HIV-positive patients is only available in a limited number of centres.[99]

## Hepatitis D

### Epidemiology

As with HCV infection, hepatitis D virus (HDV) is not a major infection of homosexual men, so the combination of HIV and HDV infection is mainly seen in those infected by intravenous drug use or exposed to contaminated blood products.

### Immunopathology

HDV is thought to have a direct cytopathic effect on hepatocytes, and more rapidly progressive liver disease would be expected in immunosuppressed states.

Normally, HDV has an inhibitory effect on HBV replication, but some reports suggest that this effect is lost with HIV infection.[100] It has also been suggested that HDV can suppress HCV replication in patients with HIV infection.[101] In one cross-sectional study, 15 patients with HIV and HDV infection were compared with 29 patients with only HDV infection.[102] This study confirmed that HIV reduces the suppressive effect of HDV on HBV replication, but found no effect of HIV infection on HDV replication and no increase in the severity of the liver disease in those with HIV and HDV.

The clinical outcomes over 6.5 years in patients with chronic delta hepatitis were compared with the outcomes in those who had concurrent HIV infection, HCV infection, or both.[103] Although 52 patients remained asymptomatic, 34 developed hepatic dysfunction and 16 patients died because of liver failure. Ten patients died from AIDS and two from unrelated causes. Deaths were recorded in 4 of 20 patients from the HDV alone group, 3 of 11 patients with co-existent HCV, 3 of 12 patients with HIV and 18 of 43 patients with HCV and HIV infection. It is likely that with improved survival in patients with HIV infection, liver failure will be seen more commonly in those co-infected with HCV and HDV. With progression of HIV infection, a failure to detect anti-HDV antibodies has been reported[104] and this may complicate the diagnosis of HDV infection in this group of patients (Table 50.2).

### Treatment

The rate of successful response following IFN administration of HIV-negative individuals is disappointingly low, and there is very little published information regarding the treatment of those with HIV and HDV infection.

## Hepatitis E

Although there are reports of an increased seroprevalence of anti-hepatitis E virus (HEV) antibodies in Italian injecting drug users[105] and homosexual men,[106] it is likely that most HIV-positive patients exposed to HEV infection live in tropical areas where there are large outbreaks of HEV infection, and as yet few data are available regarding the relative seroprevalence of HIV and HEV infection or the severity of disease in HIV-infected patients. It has been suggested that false-positive tests can occur[107] in HIV-infected patients and that in homosexual men, foreign travel rather than sexual practice can predispose to HEV infection.[108] If the severity of HEV infection in pregnancy is related to immune changes, it may be that more severe disease will be seen in patients with underlying HIV-associated immunosuppression.

## Hepatitis GBV-C

There have been some interesting observations in patients with HIV and GBV-C co-infection. It is thought

that GBV-C can be transmitted sexually[109] and patients co-infected with GBV-C tend to have higher CD4 counts and some, but not all, studies have reported a survival benefit.[110,111] One recent study described a survival benefit at 5–6 years post-HIV seroconversion but not at 12–18 months.[112] GBV-C infects PBMCs, and it is not clear if the apparently beneficial effect of co-infection relates to the interaction with HIV at the cellular level or to an indirect action related to alterations in the cytokine balance promoting a T-helper-1 cytokine profile.[113]

## Conclusion

There are many epidemiological, molecular, and clinical interactions between HIV and the hepatotropic viruses. With advances in the therapy of HIV infection and improved survival of patients, these are likely to become of increasing clinical and economic importance.

# Chapter 51
# Treatment of extrahepatic diseases caused by hepatitis B and hepatitis C viruses

Philippe Merle, Christian Trepo

## Introduction

Hepatitis B (HBV) and hepatitis C (HCV) viruses are well-recognized causes of chronic hepatitis, cirrhosis and even hepatocellular carcinoma. Apart from liver disease, these viral infections are known to be associated with a spectrum of extrahepatic manifestations. Hepatotropic HBV and HCV are capable of triggering immune complex formation and autoimmune reactions. The prevalence of clinically significant extrahepatic manifestations is relatively low, but it can be associated with significant morbidity and even mortality. An awareness and recognition of these manifestations is of paramount importance in facilitating early diagnosis and in offering treatment. Such treatments may be highly successful, as for HBV polyarteritis nodosa (PAN), but they may also be less effective, and patients may continue with disabling extrahepatic manifestations.

Patients with chronic viral hepatitis commonly have immunological manifestations, including autoantibodies and concurrent immune diseases. These immunological findings may resemble those of autoimmune hepatitis and they are not disease-specific. High titre autoantibodies are uncommon in chronic viral hepatitis as are multiple concurrent autoantibodies. These findings reflect an autoimmune-predominant disorder in which the viral infection may be coincidental or facilitative. Concurrent immunological disorders may be viral antigen-driven and associated with immune complex deposition (cryoglobulinaemia, glomerulonephritis, cutaneous vasculitis and polyarteritis) or autoantigen-driven (autoimmune thyroiditis and Sjögren's syndrome) and associated with host-specific rather than virus-specific factors. Genetic predisposition influences immunological expression. Seropositivity for antinuclear antibodies is associated with HLA A1-B8-DR3, and concurrent immunological diseases are associated with the DR4 allele. Patients with chronic hepatitis B and C can have similar immune features, but patients with chronic hepatitis C more commonly have autoantigen-driven processes.

## Extrahepatic diseases caused by HBV infection

### Background

Although most patients infected with HBV remain symptom-free, a wide clinical and histopathological heterogeneity bears witness to complex interactions between the virus, the immune response and other factors: for example, hepatitis C or delta virus or human immunodeficiency virus (HIV) co-infections; consumption of cytotoxic, immunosuppressive or glucocorticoid medicines; or alcohol abuse. In acute primary HBV infection, in adults almost 75% of patients remain symptom-free. Fortunately, about 90–95% of patients recover spontaneously. However, the prognosis can be worsened by fulminant hepatitis (about 1% of acutely infected patients), or evolution to chronic infection (about 5–10% of acutely infected patients in adulthood). Chronic HBV infection affects 350 million people in the world, and 25–40% will eventually die of either cirrhosis-related complications or primary liver cancer.[1] Both acute and chronic HBV infections have been well recognized as responsible for a variety of extrahepatic manifestations including polyarteritis nodosa, glomerulonephritis, polyradiculoneuritis, essential mixed cryoglobulinaemia, porphyria cutanea tarda, polyneuritis and thyroid dysfunction.[2]

Classically, acute viral hepatitis B may be preceded by a prodromal pre-icteric phase characterized by arthralgias or arthritis and urticarian skin rashes. Rarely, other types of symptoms, including renal, central or peripheral nervous system manifestations, may also occur. Although extrahepatic manifestations do exist with all hepatitis viruses, they are more commonly associated with acute HBV infection. The most common pattern is that of diffuse polyarthralgia occurring several days

before the onset of icterus, and may be associated with fever and some urticarian maculopapular lesions. All these manifestations are usually transient and clear up as the hepatitis progresses. Rarely, extrahepatic manifestations of HBV infection may persist for months, usually reflecting the transition to chronic hepatitis. High viral replication levels and persistent infection may favour production of soluble immune complexes in antigen excess, which deposit on specific sites including skin, kidney and small/medium-calibre arteries. Different pathogenetic mechanisms have been identified in the pathogenesis of vasculitis. Immune complexes are mainly thought to be responsible for vasculitis including polyarteritis nodosa, glomerulonephritis and mixed cryoglobulinaemia. Nevertheless, other immune system factors can also participate in the development of the disease, e.g. cytokines and lymphocytes. Furthermore, glomerular deposits of HBs/HBc/HBe antigens together with immunoglobulins and C3 have been documented together with low complement levels in the serum. Immunostaining and ultrastructural findings indicate that hepatitis B 'e' antigen (HBeAg) is probably a responsible candidate antigen.[2] However, a polyarteritis nodosa case was recently reported in association with an HBeAg-negative precore mutant infection.[3]

## Manifestations

### *Polyarteritis nodosa*

Three decades ago, HBV was recognized as being associated with a significant number of patients with polyarteritis nodosa (PAN).[4,5] PAN is due to inflammation and necrosis of medium-sized arterial walls that lead to microaneurysm formation and organ infarction. Exposure to HBV before the onset of PAN is well documented in 60% of cases.[6] The immunological process responsible for PAN usually occurs within 6 months of the primary HBV infection. Hepatitis is rarely diagnosed as it remains mostly silent before the PAN becomes clinically patent. Clinical manifestations are characteristic of those commonly described with historical classical PAN, with gastrointestinal involvement (especially perforation and bleeding), malignant hypertension, renal infarction and orchiepididymitis.[6,7] The outcome of HBV-PAN is more serious unless the appropriate antiviral treatment is prescribed.[7] Sequels are the consequence of pathological damage including vascular nephropathy, as well as central and/or peripheral nervous disorders. Hepatic manifestations associated with the course of PAN are clinically moderate, and transaminase elevations are mild in most cases. Whenever performed, liver biopsies have shown a chronic hepatitis pattern in agreement with the overwhelming progression to chronicity.[2] Although most cases of PAN are associated with the wild-type HBV strains that strengthen the involvement of HBeAg in pathogenesis of PAN, a few cases challenge this view, as they have been reported to be associated with precore mutation which abrogates the formation of HBeAg. However, no autoimmune mechanism could be incriminated as antiviral therapy was successful in eradicating the disease in close connection with replication inhibition.[3]

For many years, HBV-related PAN was treated in the same way as non-virus-related PAN, and patients received corticosteroids combined with plasma exchanges. This treatment was often effective in the short term. In a prospective randomized study enrolling 71 patients, addition of cyclophosphamide was even shown to be beneficial in preventing relapses and improving the quality of the clinical response to therapy during the long-term follow-up.[8] However, exclusive immunosuppressive therapy showed the occurrence of relapses and complications related to virus persistence like chronic hepatitis or liver cirrhosis, showing that when corticosteroids and immunosuppressive agents are prescribed to HBV-related PAN, the outcome is poorer than in non-viral PAN.[9] Later, a first-generation nucleoside analogue (i.e. vidarabin) was used to treat HBV-related PAN based on its efficacy in chronic hepatitis B together with plasma exchanges commonly used in PAN, both therapies being combined in a physiopathological approach to treatment.[10] The rationale of the therapeutic sequence was: (1) to rapidly control the most severe life-threatening manifestations of PAN by an initial corticosteroid therapy; (2) to control the course of PAN and restore immune reactivity by removing immune complexes by plasma exchanges; (3) to inhibit HBV replication by vidarabin administration; and (4) to enhance immunological clearance of HBV-infected hepatocytes and favour HBe antigen to anti-HBe seroconversion by abrupt cessation of corticosteroid therapy. Thirty-three patients were treated following this schedule (1 week of 1 mg/kg/day corticosteroids, followed by a 3-week course of vidarabin combined with plasma exchanges), inducing a full clinical recovery in 75% of patients, and HBeAg to anti-HBe seroconversion in about 50% of patients, while hepatitis B surface antigen (HBsAg) to anti-HBs seroconversion was obtained in about 20% of patients. Later studies enrolling small numbers of patients replaced vidarabin by interferon (IFN)-α, allowing efficient recovery from PAN and HBeAg to anti-HBe seroconversion in about two-third of patients, and HBsAg to anti-HBs seroconversion in about half of patients, and rare relapses (about 6%) over the long-term follow-up.[6,11] The dose of IFN-α was comparable to that prescribed for hepatitis B, the duration of administration not exceeding 6 months for the majority of patients. The triple therapy combining plasma exchanges, corticosteroids and IFN-α was again shown to be successful for treating a PAN case associ-

ated with a precore promoter mutant HBV infection.[3] Other similar antiviral approaches were also successful including IFN-α alone,[12–14] or combined with famciclovir[15] or lamivudine.[16,17] Lamivudine has also been tested as a successful single first-line antiviral therapy for HBV-related PAN.[18]

In summary, although therapeutic options for HBV-related PAN must primarily inhibit HBV replication, they should also control lesions immediately due to the severe life-threatening manifestations of PAN. To this end, plasma exchanges are able to rapidly clear the immune complexes responsible for the disease. This rapid intensive intervention is the most appropriate way to minimize life-threatening disease complications and/or sequels. We can probably expect that new antiviral therapies and novel drug combinations will bring further improvement in terms of definitive suppression of the virus.

### *Glomerulonephritis*

Although most cases of glomerulopathies are idiopathic, they may be associated with a variety of chronic infections and immune complex diseases. HBV is a well known cause of membranous glomerulonephritis (MGN), membranoproliferative glomerulonephritis (MPGN), mesangioproliferative glomerulonephritis (MSPGN) and IgA nephropathy. The association between HBsAg and nephrotic syndrome is usually due to membranous GN, probably immune complex-mediated.[19] Patients commonly present with a nephrotic syndrome and microscopic haematuria. Almost half of them have hypertension and 20% have renal impairment. Remission of nephrotic syndrome parallels elimination of HBV antigens, especially HBeAg, with resolution of proteinuria occurring within 6 months of clearing the HBeAg in many cases.

There are few available data on the treatment of HBV-related GN. Treatment such as corticosteroid or immunosuppressive therapy is not effective, the renal prognosis being similar to idiopathic MPGN, and may actually increase the morbidity and mortality.[20,21] Only limited series of patients have been reported. Most cases treated with IFN-α published so far have had either membranous or mesangiocapillary GN, and response to IFN-α seems to be better in membranous as compared with mesangiocapillary GN. Chung *et al*.[22] treated four patients with HBV-associated MPGN with IFN-α for 6 months. Although two of these patients showed a transient decrease in proteinuria to less than the nephrotic range with anti-HBe seroconversion, the other two did not. Serum creatinine levels did not change significantly during the treatment. Lisker-Melman *et al*.[23] gave IFN-α to five patients with HBV-related GN for at least 6 months. The four patients with membranous GN were good responders with a 24-hour urinary protein falling to <2 g/day at 1 year. The patient with MPGN failed to obtain a sustained response. In a case report,[24] one patient with an HBV-related MPGN was shown to be in complete remission of the nephrotic syndrome after IFN-α therapy, and this persisted despite the reappearance of viral markers in the serum when IFN-α was withdrawn. In another case report,[25] one patient with HBV-related MSPGN was shown to benefit from IFN-α therapy too, corroborating data obtained from two other HBV-related MSPGN patients treated with IFN-α.[22] Proteinuria subsided with or without seroconversion to anti-HBe and loss of HBeAg. The response to IFN-α therapy found in HBV-infected patients with GN seems to be higher than seen in patients without GN. Conjeevaram *et al*.[26] have reported a series of 15 patients with chronic hepatitis B and GN (membranous 10, membranoproliferative five) treated with IFN-α, and have shown a long-term serological response with sustained loss of HBeAg and HBV DNA in eight (53%) patients. Most of these eight virological responders also showed a gradual and marked improvement in proteinuria. Lin[27] reported the effect of IFN-α therapy in 40 children with HBV-related membranous GN who failed to respond to corticosteroid treatment. All 20 patients who received IFN-α were free of proteinuria after 1 year of follow-up, and 50% of these cases showed anti-HBe seroconversion. By contrast, in the untreated group only 35% were free of proteinuria, and none showed anti-HBe seroconversion.

Disadvantages of IFN-α include expense, the requirement for subcutaneous injections, and frequent side-effects that may be severe. In contrast, the incidence of adverse events with lamivudine is similar to placebo. Lamivudine has recently been shown to be efficient for inducing remission of HBV-related membranous GN and nephrotic syndrome.[28,29]

## Extrahepatic diseases caused by HCV infection

### Background

HCV is an RNA virus that is a major cause of acute and chronic hepatitis. Both acute and chronic hepatitis C are asymptomatic in most patients. However, chronic hepatitis C is a slowly progressive disease and results in severe morbidity in 20–30% of infected persons. Chronic hepatitis C is associated with a host of extrahepatic manifestations. Patients who definitely need treatment are those with liver fibrosis progression, and/or with extrahepatic manifestations and those who can transmit the virus. Furthermore, treatment of HCV should be systematically discussed in patients co-infected with HIV and HCV. In discussing the extrahepatic manifestations of HCV, it is necessary to distinguish between syndromes

in which the role of HCV is well established (e.g. essential mixed cryoglobulinaemia and glomerulonephritis) and those in which it is still poorly understood although clinically relevant (e.g. thyroid dysfunction). Other, less common manifestations, such as other autoimmune-related disorders, are also of interest.

Between 1996 and 1997, 321 patients chronically infected with HCV were prospectively enrolled in a study designed to determine the prevalence of extrahepatic manifestations associated with HCV infection, to identify associations between clinical and biological manifestations.[30] In all, 38% of patients presented at least one clinical extrahepatic manifestation including arthralgia (19%), skin manifestations (17%), xerostomia (12%), xerophthalmia (10%) and sensory neuropathy (9%). The main biological abnormalities were mixed cryoglobulinaemia (MC; 56%), thrombocytopenia (17%) and the presence of the following autoantibodies: antinuclear (41%), rheumatoid factor (38%), anticardiolipin (27%), antithyroglobulin (13%) and anti-smooth muscle cell (9%). At least one autoantibody was present in 70% of sera. A definite connective tissue disease was noted in 14% of patients, mainly symptomatic MC and systemic vasculitis.

Few treatment-related data are available on the management of the numerous extrahepatic manifestations and autoimmune disorders associated with chronic HCV infection. Recent studies have demonstrated that antiviral therapy, as well as corticosteroids and immunosuppressive therapies, may be effective in managing extrahepatic HCV manifestations, although discontinuation often produces relapses.[31,32] Very recently, anti-CD20 (rituximab) therapy has given promising results and opened new hopes in the therapeutic management of HCV-induced vasculitis.[33] However, the potential improvement of symptoms and reduction of viraemia must be balanced against the adverse effects of medication, which include IFN-α-induced autoimmune phenomena, ribavirin toxicity and possible exacerbation of HCV infection caused by immunosuppressive agents as well as anti-CD20 therapy.[34]

## Manifestations

### *Glomerulonephritis*

HCV infection has been associated with glomerular disease, the foremost being MPGN with or without MC.[35,35] Cases of MGN and focal segmental glomerulosclerosis (FSGS) have also been reported.[36,37] Treatment of these patients with IFN-α therapy has been disappointing, with in some cases a favourable outcome, but often with relapse of viraemia and recurrence of renal disease after cessation of therapy.[38,39] The addition of the nucleoside analogue ribavirin have meant that treatment successes for HCV have improved significantly, but only a few case reports deal with treatment outcomes for HCV-associated renal diseases.[40,41] It has been shown that ribavirin could be used in combination with IFN-α in dialysis patients, the cornerstones of therapy being reduced ribavirin doses and high-dose erythropoietin treatment, as well as ensuring adequate iron stores for erythropoiesis.[42] One study involved 20 patients with HCV-associated glomerulopathy (MPGN in 85% of these cases, MGN in 10% and mesangioproliferative glomerulonephritis in 5%) who received IFN-α therapy for 12 months. In IFN-α-resistant subjects, IFN-α was combined with ribavirin. MC was not constant, and was encountered in only 60% of the cases. Twelve months of antiviral therapy combining IFN-α and ribavirin resulted in viral clearance in 25% of cases associated with significant proteinuria decrease (4 g to 1.10 g/24 h, $p = 0.001$), serum albumin increase (25 to 35.5 g/L, $p = 0.012$), and C3 and C4 concentration returning to normal.[43] The use of pegylated interferon (PEG-IFN) has recently been tested for two of seven patients treated with IFN-α and ribavirin for HCV-related renal insufficiency: two with cryoglobulinaemia, vasculitic manifestations and glomerulonephritis, four with MPGN and one with FSGS.[44] The aim of this study was to retrospectively analyze the outcome of these patients, regarding viral and renal response, as well as their tolerability to treatment, showing that IFN-α and ribavirin could with reasonable safety be used in HCV-related vasculitis and GN irrespective of renal function. Six of seven patients became HCV RNA-negative by PCR, and four of seven maintained both virological and renal remission with 12–32 months of follow-up. One of seven maintained virological and partial renal remission. One patient did not tolerate IFN-α, but was in renal remission with low-dose ribavirin. One vasculitis patient responded with complete remission, but relapsed virologically and had a minor vasculitic flare after 9 months. Only one patient with vasculitis required low-dose immunosuppression in addition to antiviral therapy. The renal outcome was favourable in all cases. In all patients, serum albumin normalized and albuminuria decreased substantially to levels <0.5 g/24 h, except for one patient. The renal damage was most probably irreversible, considering the chronic changes seen in the renal biopsy. However, the rapid loss of renal function had been halted. Haematuria was no longer detectable at follow-up in five of seven cases, and glomerular filtration rate normalized in two of seven patients, or stabilized in the remainder of the cases.

### *Sicca syndrome*

Although sicca syndrome seems to be associated with HCV, it may differ from the typical Sjögren's syndrome. It affects women preferentially and is usually not accompa-

nied by anti-SSA or anti-SSB antibodies. This syndrome is histologically detected in 15–50% of patients. The main studies that include large series of patients show that xerostomia and xerophthalmia are observed in about 15% of HCV patients.[45] Improvement of HCV-related sicca syndrome under antiviral therapy has not been clearly reported. Adequate management should include the replacement of oral and ocular fluids, and a multidisciplinary approach involving different specialities (odontology, ophthalmology, gynaecology and dermatology).

### *Pulmonary disease*

There are few data on the treatment of pulmonary alveolitis in patients with chronic HCV infection. The severity of this situation suggests the need for aggressive treatment combining antiviral and immunosuppressive therapies and plasmapheresis. Some studies have evaluated the presence of an inflammatory process of the lower respiratory tract in patients with MC associated with HCV. Bronchoalveolar lavage and pulmonary function tests including diffusion capacity for carbon monoxide (DLCO) were carried out, and indicated a subclinical T-lymphocytic alveolitis in HCV-related MC patients that was not associated with a risk of deterioration in lung function.[46] A few case reports have been published so far on symptomatic pulmonary alveolitis due to HCV-related MC, and patients may respond dramatically to plasmapheresis and the addition of high-dose corticosteroids,[47] or may be refractory to conventional immunosuppressive treatment.[48]

### *Articular manifestations*

Arthralgias are common in patients with chronic HCV infection, and were reported in 20% of patients in a large series.[49] Paracetamol medication should be considered as a first therapeutic approach, and the use of non-steroidal anti-inflammatory drugs (NSAIDs) requires individual evaluation as they are contraindicated in patients with cirrhosis.[50] Furthermore, anti-cyclooxygenase 2 drugs may be considered with a good clinical response and no worsening of liver function.[51]

Arthritis occurs less frequently than arthralgias, with a prevalence below 5%, and is usually related to a cryoglobulinaemic syndrome. They are mono- or oligoarticular and non-erosive arthritis, affecting large and medium-sized joints. In small published series, patients with HCV-related arthritis have been shown to be able to benefit from IFN-α therapy (n = 4).[52] Other studies conducted on small series of patients reported the usefulness of NSAIDs associated with low doses of prednisone (n = 3),[50] or hydroxychloroquine plus low doses of prednisone (n = 19).[53] The use of immunosuppressive agents, such as methotrexate and azathioprine, should be considered for severe and refractory arthritis in individual cases, with close monitoring of liver function, blood cell counts and HCV RNA levels.

### *Systemic lupus erythematosus*

The most frequent extrahepatic manifestations of HCV including arthralgia, myalgia, sicca syndrome and nuclear antibodies, may mimic a connective tissue disease, particularly systemic lupus erythematosus (SLE). Reports on the association between SLE and HCV infection are scarce, and to our knowledge, so far no study has reported the benefit of antiviral therapy and clearance of HCV RNA on the outcome of the presumed HCV-related SLE syndrome. A retrospective case-control study of 19 patients with SLE and anti-HCV antibodies versus 42 randomized SLE patients without anti-HCV antibodies showed that prevalence of cryoglobulin was higher in SLE patients with anti-HCV antibodies, but without MC syndrome. HCV infection had moderate signs of biochemical and liver pathological severity. One patient treated with IFN-α had a sustained virological response without SLE flare. Corticosteroid therapy did not seem to alter the HCV course.[54] Furthermore, IFN-α therapy itself, with or without combination with ribavirin, is able to induce SLE or an SLE-like syndrome in 0.15–0.7% of patients, with a generally good outcome after discontinuance of the drug.[55]

### *Thyroiditis*

Although chronic HCV infection is associated with a high prevalence of thyroid autoantibodies, only a few patients spontaneously develop autoimmune thyroid dysfunction.[56] Most HCV patients with thyroid dysfunction are middle-aged women with asymptomatic hypothyroidism and do not require specific treatment. However, no study has so far really clarified whether HCV does play a pathological role in the development of thyroid dysfunction and autoimmune thyroiditis.[57]

By contrast, thyroid dysfunctions developing in HCV-infected patients under IFN-α therapy are common (50% of cases with anti-thyroperoxidase (anti-TPO) antibodies prior to treatment) and well documented. They are different from those occurring without IFN-α.

A prospective study has recently demonstrated that the appearance of thyroid autoantibodies during treatment of HCV with IFN-α is accompanied in most cases by the occurrence of a destructive process in the thyroid gland with hyper- or hypothyroidism, and that the thyroid clinical outcome of these patients is strictly correlated to the continuation of IFN-α treatment.[58] The presence of thyroid autoantibodies before initialization of antiviral treatment should not necessarily be regarded as a contraindication for IFN-α therapy, depending

on the severity of the HCV-related hepatopathy and likelihood of response to IFN-α therapy. Screening for serum antibodies and thyroid-stimulating hormone (TSH) is highly recommended before, during and until 6 months after discontinuation of IFN-α therapy. Because most patients with increased antibody titres or thyroid dysfunction (especially hypothyroidism) under IFN-α therapy recover after completing therapy, interruption of IFN-α therapy may not always be required, although treatment must be interrupted in patients with severe symptoms or frank hyperthyroidism.[58a] After specific treatment of hyperthyroidism and recovery, IFN-α therapy may be reconsidered.

### *Skin manifestations*

Among extrahepatic disorders associated with HCV infection, dermatological diseases occupy a central part. The most frequent dermatological manifestations associated with chronic hepatitis C include MC with leukocytoclastic vasculitis, porphyria cutanea tarda and lichen planus.

Patients with HCV-associated vasculitis may present palpable purpura, urticaria or livedo reticularis, most of which present as leukocytoclastic vasculitis associated with cryoglobulinaemia.[59] The most frequent clinical situation is palpable purpura in the legs, requiring non-aggressive management consisting of changes in posture, rest and, in some cases, low doses of corticosteroids. Severe cutaneous complications, such as ulcers, necrosis and gangrene, require intensive immunosuppressive therapy with higher doses of corticosteroids, pulses of cyclophosphamide, intravenous gamma globulins or prostacyclins.

Porphyria cutanea tarda is due to uroporphyrinogen decarboxylase deficiency in the liver that may be driven, at least in part, by HCV infection. Most patients with porphyria cutanea tarda have iron overload with increased plasma iron and ferritin levels and hepatic siderosis similar to that observed in individuals with haemochromatosis. Treatment of porphyria cutanea tarda remains mainly based on low-dose choloroquine and phlebotomy. It is probable that previous phlebotomy increases the percentage of response to IFN-α when patients present with HCV infection. Although the indication for phlebotomy appears clear in patients with iron overload, the rationale for chloroquine prescription, even though proven to be useful, has not been clearly established as its therapeutic mechanism is poorly understood.[60]

Lichen planus with cutaneous eruption and sometimes mucosal lesions may be associated with HCV infection. Cutaneous biopsy specimens can show lymphoid infiltrates without CD20+ B cells. Although patients have HCV RNA in the serum, the viral genome is usually not detected by reverse transcription and polymerase chain reaction (RT-PCR) in skin biopsies, and lichen planus show an inconsistent response to IFN-α and ribavirin therapy. Thus, lichen planus appears to be related to the pattern of immune dysregulation induced by HCV, probably in a host with an underlying susceptibility to autoimmune disease, but therapeutic viral response does not correlate with clearing of lichen planus.[61]

However, other skin disorders, such as Adamantiadis-Behçet syndrome, erythema multiforme and nodosum, malacoplakia, urticaria and pruritus, may also be linked to HCV. Further studies are necessary to establish or refute any aetiopathogenetic role of HCV in these conditions. Skin manifestations are also part of the clinical picture of other extrahepatic disorders associated with HCV infection, such as thyroid dysfunction and HCV-related thrombocytopenia.

The response to IFN-α therapy in skin diseases is unpredictable with some patients ameliorating, others remaining stationary and others deteriorating. Lichen planus, psoriasis and vitiligo may be induced or exacerbated by IFN-α therapy.[62–64]

### *Idiopathic autoimmune cytopenia*

Thrombocytopenia is frequently seen in HCV-infected patients. Furthermore, to a much lesser extent, autoimmune haemolytic anaemia and neutropenia are sometimes described.[65] Although thrombocytopenia in patients with advanced liver disease can result from splenic sequestration due to portal hypertension, the degree of thrombocytopenia observed in patients with HCV appears to be significantly greater than reported in other forms of severe liver disease. This would suggest a possible immunopathic mechanism for the development of thrombocytopenia with HCV infection.[66] Thrombocytaemic patients infected with HCV share many clinical features of idiopathic immune thrombocytopenic purpura. They are characterized by the presence of autoantibodies against platelet membrane proteins, and they have large platelets on peripheral smear, and normal or increased megakaryocytes on bone marrow examination.[67] An immunopathic mechanism for the development of thrombocytopenia is also supported by numerous reports of other immunological abnormalities in patients with HCV. Treatment with steroids is effective in these patients, but poses a risk of aggravating the HCV infection. Patients with HCV-related thrombocytopenia may have a good response to corticosteroids alone (around 50% of patients), although with a higher rate of mortality observed in case of liver cirrhosis.[65] Patients who fail to respond to corticosteroids may respond to intravenous immunoglobulins or cyclophosphamide, or may require splenectomy.[68–70]

As treatment with steroids may be effective but can exacerbate the viral infection, an antiviral approach has

been tested as a therapeutic strategy for HCV-related thrombocytopenia. IFN-α is the primary therapeutic modality for HCV infection. IFN-α can be associated with the development of thrombocytopenia.[71] However, if viral replication and host immune response to the virus are responsible for the accelerated platelet clearance, then successful IFN-α treatment of the HCV could result in improvement in the platelet counts. Although IFN-α has documented efficacy in the treatment of HCV, its use in the treatment of HCV thrombocytopenia is controversial. In a small study,[72] eight patients with severe HCV-related thrombocytopenia (platelet count $<50 \times 10^9$/L) were treated with IFN-α (3 MU three times a week for 24 weeks). Only three patients tolerated the full course of treatment, and all three had improvements in their platelet counts to $>50 \times 10^9$/L. Two other patients had improvement in platelet counts to $>50 \times 10^9$/L with a shorter duration of treatment (6 and 16 weeks, respectively). Duration of response ranged from 4 to at least 18 months, with the shortest responses observed in the two patients treated with a shorter course of IFN-α. Responding patients showed improvement in hepatic transaminases, reduction in cryoglobulin and anticardiolipin antibodies, and HCV plasma RNA. Relapse was associated with an increase in these laboratory markers of HCV infection. It was concluded that IFN-α could be an effective treatment in patients with HCV-related thrombocytopenia. A larger study involving 20 patients strengthened evidence for the benefit of IFN-α for HCV-related thrombocytopenia.[73] In this study, 20 naïve HCV-infected patients with thrombocytopenia (platelet count $<140 \times 10^9$/L for at least 6 months, without portal hypertension and/or hypersplenism) received leucocyte IFN-α (3 MU three times per week for 12 months) and were followed up for 12 months. During treatment, platelet counts decreased to <10–20% of pretreatment values in most patients. Three of the four patients with a complete virological response showed a platelet increase during treatment and throughout the follow-up period.

In summary, although steroids may have a role in the short-term treatment of patients with HCV-related thrombocytopenia, their deleterious effect on HCV infection should limit their use in these patients. Antiviral therapy with IFN-α, combined with ribavirin if possible, should be attempted. A remission can be expected in virological responders. In non-responders, treatment with ribavirin alone may be considered.

### *Myositis*

HCV-related polymyositis should be considered as an extrahepatic condition of chronic HCV infection for which therapeutic management is difficult, needing careful individual evaluation when considering the use of corticosteroids and/or IFN-α. Indeed, different therapeutic options have been used, with controversial results. Some studies reported the benefit of steroids or intravenous gamma globulins in achieving a reduction in symptoms and muscular enzyme levels,[50,74] while others reported that steroids could increase hepatic transaminases leading to severe liver damage.[74] In some patients, cytotoxic agents were successfully added to steroid therapy.[75] On the other hand, some authors have used IFN-α monotherapy to treat HCV-related polymyositis with the same controversial outcome: some patients responded well, others presented severe aggravation of polymyositis after IFN-α discontinuation, and several worsened or precipitated into myositis under IFN-α therapy.[74,76]

### *Neurological manifestations*

Patients infected by HCV frequently complain of fatigue, lassitude, impaired memory and a perceived inability to function effectively, even in the absence of clinically significant liver disease. However, it is not known whether social, psychological or biological factors may cause these complaints. HCV infection itself very likely affects cerebral functions, as demonstrated by proton magnetic resonance spectroscopy, showing elevations in basal ganglia and white matter choline/creatine ratios in patients with histologically mild hepatitis C, compared with healthy volunteers and patients with hepatitis B.[77] Corroborating these findings, several studies have shown that patients with HCV infection score worse than matched controls on health-related quality of life indices, and their scores improve with successful antiviral treatment.[78] The mechanisms involved are poorly understood, but HCV can infect cells of monocytic lineage, raising the possibility that HCV may infect brain cells as well. An alternative explanation is a centrally mediated effect of peripherally derived cytokines.[79] In a much more severe manifestation, although exceptional, patients with HCV infection may present central nervous system (CNS) vasculitis related to cryoglobulinaemia, for which intravenous pulse and oral corticosteroid therapy combined with cyclophosphamide, followed by warfarin and IFN-α, was shown to be effective in some case reports.[80,81]

More frequently, HCV-infected patients may develop peripheral neuropathy (PN), generally due to MC. However, PN may be associated with HCV infection without MC, for which mechanisms are even less understood and might involve vasculitis and even PAN.[82] In contrast to other HCV-related extrahepatic manifestations, PN does not respond as favourably to the different therapeutic regimens. In addition, it has been reported that IFN-α may cause a worsening of PN in patients with HCV-related MC, despite the improvement of hepatic function.[83] Among patients with HCV-related PN in which a virological response to IFN-α therapy was reported,

only a few of them presented a favourable response for the PN.[30,40,82,84,85] Addition of ribavirin to IFN-α in patients resistant to other therapies (IFN-α monotherapy, corticosteroids, immunosuppressive agents), showed a stabilization or a slight improvement in two of the four treated patients.[40] The best result was obtained when plasmapheresis was added to IFN-α and/or immunosuppressive agents. Finally, the management of HCV-related PN should be based on its severity and response to treatment. Combined antiviral therapy (ribavirin and IFN-α) should be considered as the initial option in patients with slight to moderate neuropathy, with addition of corticosteroids in the case of non-response or worsening of the PN. Patients who fail this triple therapy should be considered for intravenous immunoglobulins, keeping in mind that plasmapheresis seems to be the best option in severe or refractory cases.

### *Cryoglobulinaemia and systemic vasculitis*

MC is a chronic immune complex-mediated disease.[86] MC is the most frequent biological peculiarity in chronically HCV-infected patients, found in >50% of patients, and there seems to be a south–north gradient in the prevalence of HCV-associated cryoglobulinaemia. It is only symptomatic in less than one-third of cases – i.e. vascular, renal and neurological lesions.[87] Oligoclonal or monoclonal B-cell expansions are significant molecular features of bone marrow[88] and liver.[89] It is estimated that almost 10% of patients with MC progress to frank B-cell non-Hodgkin's lymphoma.[90]

Cryoglobulins are cold precipitable immunoglobulins that are accounted for by two or more immunoglobulin isotypes.[91] In type II MC, cryoglobulins are composed of a monoclonal rheumatoid factor (usually, IgM kappa) against polyclonal IgG. In type III MC, all components are polyclonal. The different autoantibodies and circulating immune complexes produced, including the cryoglobulins, deposit in small vessels and are responsible for systemic vasculitis and damage of various organ. The primary role of HCV in the mechanism of cryoprecipitation is mainly suggested by its selective concentration in cryoglobulins.[92,93] The association of haplotype human leucocyte antigen (HLA) B-8 and DR-3, MC and HCV infection has been demonstrated.[94]

Although HCV is increasingly recognized as a cause of systemic vasculitis, limited data are available regarding the optimal treatment of this potentially serious condition. Based on the close correlation between HCV infection and MC, treatment with IFN-α has been strongly advocated.[95] IFN-α produces significant clinical improvement in 40–70% of MC patients.[38,96–98] Its efficacy is closely associated with inhibition of HCV replication. Reduction of HCV RNA in responsive patients usually precedes a decline of cryopricipitates. However, the improvement is generally short-lived and >80% of responders have a relapse within 6 months.[98] In addition, in patients with cryoglobulinaemic neuritic or nephropathic complications or active skin ulcers, IFN-α frequently precipitates neuropathies or aggravates renal failure and delays ulcer healing.[99]

As a small fraction of patients with HCV-positive MC achieve long-term recovery after IFN-α therapy, the effectiveness and safety of combination therapy with IFN-α and ribavirin was tested in non-responders or those who relapsed after one or more courses of IFN-α. A retrospective study[100] analyzed 27 patients with chronic hepatitis C complicated by systemic vasculitis, and treated by IFN-α plus ribavirin therapy for at least 6 months. At the end of the combined therapy, 16/27 (59%) patients were negative for HCV RNA, and 15/27 (55%) were complete clinical responders. Among the remaining 11 virological non-responders at the end of therapy, 8/11 (73%) had at least a partial clinical response. Only 14 patients had a 6-month follow-up after discontinuation of IFN-α plus ribavirin therapy. Among them, 9/14 (64%) showed a virological, clinical and immunological sustained response 6 months after the end of therapy. All (nine of nine) virological sustained responders and a few virological non-responders (one of five) were also clinical and immunological complete responders. However, three of five non-responders could benefit from the therapy and had partial clinical and immunological responses. This study demonstrated that IFN-α plus ribavirin can achieve a complete clinical response in a substantial proportion of patients with HCV-related systemic vasculitis, and that complete clinical response correlates with the eradication of HCV.[100] A more recent and prospective study involving 27 patients with HCV infection and MC did not show such a high efficiency of IFN-α plus ribavirin combined therapy administered for 1 year, as only 18.5% of patients completely recovered (viral clearance and all symptoms of the disease). However, most patients (85%) improved clinically during the combined therapy.[101]

This prompted a search for innovative therapeutic strategies with the aim of reducing or depleting the B-cell clonal expansion that sustains production of IgM rheumatoid factor molecules. One such approach involves the use of monoclonal antibodies directed to CD20 antigen, a transmembrane protein expressed on pre-B lymphocytes and mature lymphocytes.[102] Rituximab, a humanized murine monoclonal antibody of this kind, is highly effective for *in vivo* B-cell depletion.[103] Peripheral blood B lymphocytes become undetectable after a single infusion and recover 6–9 months after discontinuation of treatment.[104] Rituximab was originally approved for the treatment of low-grade B-cell non-Hodgkin's lymphoma,[105] and has since become a promising therapeutic approach for diffuse large B-cell lymphomas, mantle cell

lymphoma,[106] hairy cell leukaemia[103] and chronic lymphocytic leukaemia.[107] It has also been used in several other haematological disorders including pure red cell aplasia and haemolytic anaemia,[108] primary cold agglutinin disease,[109] post-transplantation B-lymphoproliferative disorder,[110] Waldenström's macroglobulinaemia,[111] and idiopathic thrombocytopenic purpura.[112] A recent controlled Italian study involving 20 patients with MC and HCV-positive chronic active liver disease, resistant to IFN-α therapy and non-improved by low or moderate doses of corticosteroids, has revealed that an intravenous infusion of 375 mg/m$^2$ rituximab once a week for 4 consecutive weeks could safely induce a rapid improvement of clinical signs and complete response in 80% of patients (disappearance of purpura, weakness arthralgia, improvement of peripheral neuropathy, and decline of cryoprecipitates).[33] This complete response was maintained in 75% of patients during the whole of follow-up (12 months). Complete response was associated with a significant reduction of rheumatoid factor activity and anti-HCV antibody titres. Decline of IgG anti-HCV titres in the cryoprecipitates was usually associated with a favourable response. Molecular monitoring of the B-cell response revealed disappearance/deletion of peripheral clones in the responders and stability in the non-responders. However, complete response was associated with an increase of HCV RNA titres, suggesting that combination of anti-CD20 therapy together with antiviral combination could be of optimal benefit.

### *Non-Hodgkin's lymphoma*

In connection with MC, which is a low-grade benign lymphoproliferative disorder (LPD), HCV infection may be associated with other lymphoproliferative disorders (LPDs), especially malignant B-cell non-Hodgkin's lymphoma.[113] The association between HCV and B-cell non-Hodgkin's lymphoma has been controversial. There is increasing evidence of the pathogenesis of HCV-associated lymphoma.[114] Another clue pointing towards the relationship between B-cell non-Hodgkin's lymphoma and HCV has been brought by the establishment, from a HCV-associated human lymphoma, of a B-lymphoma cell line which continuously produces HCV.[115] MC is characterized by the clonal expansion of B cells that may evolve into low-grade or high-grade non-Hodgkin's lymphoma.[116] HCV infection is most frequently encountered in patients with lymphoplasmocytoid lymphoma or immunocytoma-lymphoma, marginal zone lymphomas of the lymph node, diffuse primary hepatosplenic large B-cell lymphomas and splenic lymphomas with villous lymphocytes.[117] However, the pathogenetic mechanisms involved are still poorly understood. A direct role of HCV infection in the genesis of these B-cell lymphoproliferative disorders was suggested initially by epidemiological studies and is supported by recent studies, which analyzed the monoclonal B cells that proliferate in these disorders. How HCV induces B-cell lymphoproliferative disorders is still unclear. It is probably not due to a direct change of phenotype in B cells after viral infection, but it may be due to an HCV antigen-driven process. Support for this hypothesis comes from the analysis of monoclonal B cells found in these disorders, which use a restricted repertoire of immunoglobulin variable region genes that are similar to those used by B cells that secrete anti-HCV antibodies. The fact that monoclonal IgM is resolved in HCV-infected patients who responded to antiviral treatment supports the linkage between antigen persistence and B-cell proliferation. Finally, the linkage between benign B-cell proliferation and overt lymphoma is supported by the identification of a pre-malignant B-cell clone that subsequently converted to an overt B-cell lymphoma. The molecular basis for viral-induced B-cell proliferation is still unknown. One possibility is that HCV stimulates the proliferation of monoclonal B cells via their HCV-specific B-cell receptor on the cell surface. Binding of the HCV envelope proteins to a cellular ligand, CD81, may also enhance this antigen-driven process. A recent report on regression of splenic marginal zone lymphoma after antiviral treatment with IFN and ribavirin has significantly strengthened the cause–effect relationship between HCV infection and lymphoma.[118]

A significantly higher prevalence of bcl-2 recombination [t(14;18) (q32;q21)] – a B-lymphocyte-specific chromosomal rearrangement – was shown in peripheral blood mononuclear cell (PBMC) samples from HCV-infected patients, especially in the case of HCV-related MC, as well as clonal expansion of translocated B lymphocytes, suggesting that inhibition of B-lymphocyte apoptosis by bcl-2 overexpression plays a key role in LPD pathogenesis.[119] The pathogenetic importance of t(14;18) in LPDs has been supported by animal studies. Mice transgenic for t(14;18) develop an indolent polyclonal follicular lymphoproliferation that progresses to a monoclonal high-grade malignancy.[120] However, in humans the t(14;18) translocation is not sufficient to induce clinical neoplasm and may be found in apparently healthy people, with its prevalence increasing with age. In some individuals, however, t(14;18) may represent an early stage in a complex, multi-step process that leads to malignant lymphoma, and inhibition of abnormal B-cell expansions at earlier stages of the pathogenic process may prevent the development of some neoplasias.[121,122]

Limited data are available with respect to the effects of antiviral treatment on clonal HCV-related B-cell expansion. These data generally refer to patients with frank LPDs, especially MC with or without non-Hodgkin's lymphoma.[119,123,124] One study has investigated the effect of antiviral treatment on immunoglobulin heavy-chain gene (IgH) rearrangement and t(14;18) translocation in

the PBMCs of 29 HCV-infected patients. Fifteen of 29 patients were treated with either IFN-α or combination therapy with IFN-α and ribavirin for 6–12 months. IgH rearrangement became negative in seven of nine treated patients compared with only one of eight of non-treated patients ($p$ <0.02). The t(14;18) translocation became negative in six of seven treated patients compared with one of six non-treated patients ($p$ = 0.03). Disappearance of IgH rearrangement or t(14;18) translocation was strongly associated with virological response to treatment. Two t(14;18)+ patients developed B-cell lymphoma during follow-up. Antiviral treatment appeared to be effective in eliminating the clonal proliferation of B cells in patients with chronic HCV infection and might have prevented the subsequent development of lymphoma.[123]

Furthermore, antiviral therapy has shown anti-oncogenic activity on malignant B lymphocytes. Twenty patients with HCV infection and MC had a bone marrow biopsy, showing a massive monomorphous infiltration by plasmacytoid lymphocytes, indicating the presence of low grade non-Hodgkin's lymphoma in six of twenty patients. After IFN-α therapy for 1 year and a subsequent few months' follow-up after therapy withdrawal, bone marrow examination showed that B-lymphocytic monoclonal infiltrate had disappeared in three patients.[124] In another study, IFN-α with or without ribavirin was shown to induce complete remission of eight of nine HCV-related splenic lymphomas with villous lymphocytes after the loss of detectable HCV RNA, while none of the six HCV-negative patients had a response to IFN-α therapy.[117]

## Conclusion

Hepatitis B and C infections are a major public health problem worldwide, as they may lead to liver failure and/or primary liver cancer. Furthermore, although to a much lesser extent, these infections may induce extrahepatic lesions, with a significant impact on morbidity and mortality of HBV- or HCV-infected patients. As limited data are available, more information is needed before definitive therapeutic recommendations for the extrahepatic HBV or HCV features can be established.

PAN is the most dramatic manifestation of primary HBV infection, while glomerulonephritis and nephrotic syndrome may develop during chronic HBV course. The pathogenesis of both vasculitis and glomerulonephritis is still believed to be mediated by circulating immune complexes, the formation of which is favoured by high HBV replication. No evidence for an autoimmune pathogenic mechanism can be substantiated in PAN, contrary to other types of systemic vasculitis unrelated to HBV. The spectacular immediate and long-term benefits of combining plasma exchange with antiviral therapy add further support to this in the treatment of PAN. Antiviral therapy alone without plasma exchange may control HBV-related glomerulonephritis. Traditional immunosuppressive and corticosteroid therapy should no longer be used.

The optimal treatment strategy for HCV-related extrahepatic manifestations remains to be defined. Both antiviral and immunosuppressive therapies, either alone or in combination, seem likely to have an important role, although these treatments should be administered with caution, and the exacerbation or precipitation of autoimmune symptoms should be monitored closely. The first goal of the treatment should be the definitive eradication of HCV by combined therapy with IFN-α and ribavirin without adding immunosuppressive drugs if possible. HCV eradication may be enough to suppress extrahepatic manifestations. However, persistence or relapse, and sometimes worsening, of extrahepatic lesions may occur, and conventional corticosteroid therapy, immunosuppressive agents, intravenous immunoglobulins and/or plasmapheresis should be added in specific severe cases. Anti-CD20 therapy is a new potentially promising therapeutic approach for MC-mediated lesions, but data have to be confirmed in large cohorts of patients, alone if antiviral therapy is contraindicated or combined with antiviral therapy to prevent high viral replication rates and subsequent possible worsening of the liver disease. When long-term immunosuppressive therapy becomes warranted, this will require very close monitoring of liver function and HCV levels, and combined antiviral therapy should be added if at all possible. The search for new antiviral drugs, possibly combined with immunosuppressive agents, is urgently needed because of the significant morbidity and mortality associated with some HCV-related extrahepatic manifestations.

# Chapter 52
# The histologist's role in the diagnosis and management of chronic hepatitis B and C

Robert Goldin, Geoffrey M Dusheiko

The role of the histopathologist in the diagnosis and management of viral hepatitis has changed significantly in recent years and will no doubt continue to evolve in the future, as more effective antiviral drugs and new diagnostic techniques become available. The objectives of this chapter are to outline the current role of histopathology and to suggest how this is likely to change.

## Diagnosis

The actual diagnosis of hepatitis B (HBV) and C (HCV) is almost always made before the liver biopsy is taken and is usually done by a combination of serology and polymerase chain reaction (PCR). Very occasionally, unsuspected HBV is diagnosed by the histopathologist by the presence of ground-glass cells (and confirmed by immunohistochemistry) or HCV by the presence of the combination of the characteristic features described below. In contrast hepatitis D (HDV) is frequently first diagnosed (or at least confirmed) on liver biopsy (see below). More common than diagnosing chronic viral hepatitis on liver biopsy is making the diagnosis of another form of liver disease in a patient known to have chronic viral hepatitis. This has important implications for managing these patients and will be discussed in the next section.

### Histopathological features of chronic viral hepatitis

#### *HBV*

(See Plates 52.1–52.3, found between p.786–7.)The specific histopathological features of HBV are: the presence of immunopathic liver damage, ground-glass cells and the immunohistochemical demonstration of HBV antigens in the liver.[1,2] As the damage in HBV is immune-mediated, a common finding in HBV is the presence of lymphoid cells in close apposition to hepatocytes showing degenerative changes. The ground-glass cells seen in HBV need to be distinguished from those seen, much less frequently, in other conditions, such as Lafora bodies in mycoclonic epilepsy. More frequently, they need to be distinguished from the effects of drugs, especially anticonvulsants such as diphenylhydantoin, which induce the smooth endoplasmic reticulum ('turned on hepatocytes'). This is easily done by staining for hepatitis B surface antigen (HBsAg). There is a limited but significant role for immunohistochemical staining in cases of HBV in addition to confirming the diagnosis. It is only necessary in a very small number of cases. Staining with hepatitis B core antigen (HBcAg) (or hepatitis B 'e' antigen; HBeAg) can be used to assess disease activity.[3] Active disease is characterized by more widespread staining with more cytoplasmic (rather than purely nuclear) staining. In cases with the precore, mutant staining for HBeAg will be negative; HBeAg staining correlates to the presence of wild-type virus. In immunosuppressed patients, there may be decreased necroinflammatory activity in the presence of large amounts of viral antigen.[4] Immunohistochemistry is especially useful, as some of these patients may in the past have been considered to have cleared HBV and even be HBsAb-positive.

#### *HDV*

(See Plates 52.4 and 52.5, found between p.786–7.) HDV is associated with increased histological activity with prominent cytopathic changes.[1,2,5,6] The histopathologist may see unusually active lobular inflammation with prominent apoptosis in a patient with HBV and confirm the diagnosis of HDV using immunohistochemistry. Even if the clinician is the first to raise the possibility of HDV, the definite diagnosis may first be made by immunohistochemical staining of a liver biopsy, as the demonstration of HDV antigen in the liver biopsy remains the gold standard for making the diagnosis.[7] Furthermore, this can usually be done more rapidly than the corresponding serological tests. Reliable anti-HDV antibodies are, however, not commercially available.

### *HCV*

(See Plates 52.6 and 52.7, found between p.786–7.) There are no diagnostic features of HCV. However, as compared with other causes of chronic hepatitis the presence of two or more of the characteristic changes (lymphoid aggregates/follicles, hepatitic bile duct damage and large droplet fatty change) strongly suggests the diagnosis.[1,2,8,9] Lymphoid aggregates may, however, also be seen in HBV and autoimmune hepatitis. Although hepatitic bile duct damage is very often seen, bile duct loss is not a feature of HCV, and if present, the usual causes of ductopaenia need to be excluded.[10] The presence of canalicular cholestasis should always suggest a superimposed pathological process. Excess alcohol intake is not uncommon in patients with HCV. Fatty change is particularly associated with infection with HCV genotype 3.[11] Ballooning degeneration, neutrophils, etc. are only seen when there is significant alcohol-induced liver disease in addition to the HCV. Biopsies from patients with HCV often show relatively mild portal and periportal inflammation with more prominent lobular changes as compared with cases of HBV. Granulomas for which no other cause can be found are more common with HCV than HBV.[12] Plasma cell-rich inflammatory infiltrates may be seen in cases of HCV, and this is often associated with positive serum antinuclear antibodies, although their presence does not seem to be associated with an impaired responsiveness to antiviral treatment.[13] Unfortunately, there is still no routinely available immunohistochemical technique for demonstrating HCV in formalin-fixed, paraffin-embedded tissue.[14] However, it is possible to assay by PCR and even genotype HCV from formalin-fixed, paraffin-embedded liver biopsies.[15] There has been considerable debate about the effect of co-infection with HGV in patients with HCV. A recent Japanese study has suggested that HGV RNA-positive patients show significantly more severe bile duct damage, perivenular fibrosis, pericellular fibrosis and 'irregular regeneration' of hepatocytes than the livers of the HGV RNA-negative patients.[16] Overall, however, most studies have suggested that there is no significant impact of HGV co-infection on disease severity.[17]

## Histopathology of chronic viral hepatitis in liver transplant patients

### *HBV and HDV*

Biopsies taken from patients with recurrent HBV in their liver grafts show a spectrum of histopathological appearances.[18] Over three-quarters of them show the changes of chronic hepatitis or cirrhosis, often with ground-glass cells. This is usually indistinguishable from HBV in non-transplant patients. The second commonest finding is of a mild, non-specific hepatitis. A fibrosing cholestatic hepatitis is seen in a minority of patients.[19] This is characterized by fibrosis (both portal and perisinusoidal), cholestasis (intracellular and canalicular), severe ballooning of hepatocytes and mild portal inflammation. Overall, the severity of the pathological changes is more severe than in patients with recurrent HCV. This is associated with high levels of HBsAg and HBcAg expression. It should be noted that recurrent HDV may recur without demonstrable markers of HBV infection. In these circumstances HBV is not necessarily cytopathic. Coagulative necrosis of zone 1 associated with fibrinoid necrosis of hepatic arteries has also been described.

### *HCV*

(See Plate 52.8, found between p.786–7) The nature of the pathological changes may be the same as in non-transplant patients and a chronic hepatitis is seen in 80%.The pathological changes tend to be milder than is the case with HBV; only 5–10% progress to cirrhosis. The severity, in terms of both inflammation and fibrosis, tends to be more severe than in non-transplanted HCV patients. A match at one or two HLA DQ loci has been strongly associated with the severity of the damage seen. HCV has a direct cytopathic effect on bile duct epithelium. The level of liver injury does not correlate with the levels of HCV. One-third of treated patients develop ductopaenic rejection. Atypical features include severe bile duct injury and bile duct proliferation. This may be so marked as to mimic large duct obstruction. Features resembling the fibrosing cholestatic hepatitis seen with HBV may also be observed.[20] Nodular regenerative hyperplasia has also been described. When recurrence occurs within 6 weeks the differential diagnosis includes acute cellular rejection. Multiple biopsies help with this differential diagnosis as the portal inflammation, with lymphoid aggregate formation, and the lobular inflammation characteristic of HCV, develop with time. In cases which are difficult to categorize as either recurrent HCV or acute rejection, it is likely that each of these processes may be occurring together. In atypical cases, other causes of chronic hepatitis need to be considered. Unless it is certain that all the changes seen are all ascribable to HCV, they should not be scored (see below).

## Assessment of disease severity

Assessment of disease severity is, perhaps, the most important contribution the histopathologist makes to patient management. This involves the separate assessment of necroinflammatory activity (the *grade* of the biopsy) and the fibrosis (the *stage* of the biopsy). The terms grade and stage were coined by Scheuer, by analogy to tumour pathology, and represented a significant advance over the older nomenclature in which biopsies were subdivided according to the presence or absence of piecemeal necrosis alone (chronic persistent hepatitis or chronic active

hepatitis) with cirrhosis being a separate category.[21] In terms of nomenclature, many people prefer the term 'interface hepatitis' to 'piecemeal necrosis' as this is a more accurate description of the pathological process, which is apoptosis rather than necrosis. Still others prefer the less committed expression 'periportal inflammation'. Stage is usually considered the more important, as the severity of the inflammation may vary while, at least until recently, fibrosis was considered an irreversible process. [22,23]

Grade and stage are usually assessed using a semi-quantitative scoring system, although this can also be done by simply describing the severity of the necroinflammatory and fibrotic changes in words. In the hospital setting, the decision as to whether to score biopsies or not depends on agreement between clinicians and pathologists, which in turn depends on whether the actual scores are used to determine whether the patient is treated or not. Furthermore, when comparing sequential biopsies on the basis of their scores, it is highly desirable that they are scored by the same pathologist and at the same time. In clinical trials, some form of scoring system is almost always used. Either way, the biopsy must be of adequate size (see below) and be stained using both a conventional haematoxylin and eosin stain, which is used to assess the necroinflammation, and a histochemical stain that highlights the connective tissue present. This is usually done using the silver stain Gordon and Sweets reticulin (especially in the UK) or trichrome stain, such as Masson's trichrome (especially in the USA).

It has been shown that the sampling error depends partly on the size of the liver biopsy taken.[24,25] This will depend on the size and gauge of the needle. In one study, successive 5-mm portions of liver biopsies were uncovered. In 20 biopsies in which cirrhosis was diagnosed when 25 mm of the biopsy was exposed, it was only diagnosed in 14 when 20 mm was exposed and in 11 when 10 mm was exposed. In another study in which needle biopsies were taken just before post-mortem, even 25-mm biopsies may not be big enough. 100% diagnostic precision was only obtained when three 25-mm biopsies were taken. Although the length of the biopsy is important, it is really the number of portal tracts that is critical. It is generally regarded that the biopsy must contain at least three portal tracts to be assessed at all. It should be pointed out that 16 gauge needles are needed if whole cirrhotic nodules are to be included in the biopsy. The way in which the liver tissue is actually obtained is also important.[26] Suction needles (such as Menghini needles) tend to produce fragmented samples, especially from livers with advanced fibrosis, in which nodules of hepatocytes are obtained, leaving behind much of the fibrous tissue. This can make the confident diagnosis of cirrhosis very difficult. For the same reason, biopsies taken with suction needles are particularly unsuitable for image analysis. On the other hand, cutting needles (such as a Tru-cut needle) remove both fibrous tissue and parenchyma and make the assessment of fibrosis much easier. It should be noted that as the changes in HCV tend to be more focal than those in HBV, sampling error is more significant. The subjective nature of the process can also be minimized if the scoring is done by a small number of experienced histopathologists, especially if they are given the opportunity to get together to discuss the scoring system before using it.

There are several semi-quantitative scoring systems that have been used to assess fibrosis and inflammation in patients with any of the causes of chronic hepatitis. The most established is the histological activity index – HAI (Knodell) system.[27] In its original form the scores for portal, inflammation, piecemeal necrosis (including confluent necrosis) and lobular inflammation were added together to give the HAI. Later, when it was considered incorrect to combine scores for necroinflammation and fibrosis, the system was modified to keep them separate. An idiosyncrasy of this scoring system is that, in all the categories, the scores are discontinuous. For example, the scores for fibrosis are: 0 = normal, 1 = portal tract expansion, 3 = bridging fibrosis and 4 = cirrhosis. In other words, there is no score of 2 in this system. Although this feature has come in for much criticism, it has the practical effect of dividing fibrosis into two categories: normal/portal tract expansion and bridging fibrosis/cirrhosis, which many recent publications base their analysis of drug trials on even if they use other scoring systems. Because the HAI has been used for many years, it is useful for comparing the results of different studies and it continues to be used in many current trials.

The modified HAI (Ishak) system was developed to take into account many of the criticisms made of the HAI. Necroinflammatory scores and fibrosis scores are separated and the scoring system is continuous.[28] In addition, it offers a wider range of scores, especially for fibrosis. In essence, however, it is similar. The Scheuer scoring system, important conceptually as being the first to separate grade and stage, is used mainly in Australia. This scoring system is now widely used.[21] The French METAVIR scoring system is the best validated of all the scoring systems but has not been widely used outside France.[28a] Again, necroinflammation and fibrosis are assessed separately. In terms of grade, only piecemeal necrosis and lobular inflammation are considered important and then, using a cross table, combined to give an overall necroinflammatory grade. Many centres use their own modified versions of one of these scoring systems. Even if different pathologists use the same scoring system, their interpretations of the definitions used for particular aspects are often quite different (partly because of the ambiguities that some of the scoring systems contain) and this adds another source of variation. Regardless of the scoring system used, when the

results come to be analyzed it is common for fibrosis to be divided into only two categories: normal/portal tract expansion and bridging fibrosis/cirrhosis. This is based on the idea that it is only a change from one of these broader categories to another that is clinically significant. It should be noted that this is essentially what the often criticized HAI system does!

There are a number of generic problems with all these scoring systems. Firstly, the data they produce is ordinal (categorical) but not numerical, i.e. the increasing scores for any feature represent progressively more severe changes but the differences between consecutive scores are not equal. For example, a score of 4 does not mean that the changes seen are twice as severe as those seen if the score was 2. This problem is especially acute with the HAI scoring system because it is discontinuous. In any case, this means that adding scores together, as is done by adding the different inflammatory scores together to give the overall grade, is statistically invalid, although it is regularly done! Adding the scores of the three (or four) categories of necroinflammation to give a single number loses information and may be misleading. For example, if there is a biopsy with marked portal inflammation but only mild piecemeal necrosis and lobular inflammation, it may have the same overall score for grade as a biopsy with mild portal tract inflammation and more marked piecemeal necrosis and lobular inflammation. Most people would agree that the second biopsy actually represents more active disease. Also, when analyzing the data generated by a study, non-parametric tests need to be employed. Furthermore, the scores obtained from different studies are not suitable for meta-analysis. Secondly, there are problems with inter- and intra-observer variation. This has been examined and, overall, experienced liver pathologists have a reasonable level of agreement with most studies, indicating that this is better for stage than grade.[29] The METAVIR group have also shown that pairs of pathologists give more reproducible results than single pathologists. This is, however, rarely a practical possibility either in clinical practice or in trials, as it is so time-consuming (and expensive). Those scoring systems which allow a more detailed assessment of the pathological changes are inherently more likely to produce increased inter-observer variation. For this reason, it is preferable to use the simplest scoring system which will provide the information required. It is salutary at the end of a study to undertake an audit to assess the degree of intra-observer variation to get a feel for the reliability of the results. Thirdly, it is important to consider what difference in scores will be considered significant. Empirically, it is usually considered that a difference of 2 or more is clinically important. This makes some allowance for sampling and observer error. It is clearly essential that the scoring be done without knowledge of the sequence of the biopsies and all other clinical information. A way of comparing biopsies which obviates this problem (and which does not depend on using a particular scoring system) is to make a direct comparison between biopsies which have been blinded as to sequence with grade and stage being assessed separately. The small number of possible results makes this a statistically powerful approach. Another way of assessing fibrosis and inflammation, which is especially useful in small studies, is to rank all the biopsies after they have been blinded as to which patients they are from and to sequence. Finally, it needs to be questioned what the scores mean for the patient. Although it is accepted that higher grade or stage disease is more likely to progress, there are no data to suggest that any of these scoring systems predict this more accurately than any of the others.[30] Scoring adds time and cost to the liver biopsy evaluation, but may provide a useful means of training in biopsy interpretation, and can assist clinical decisions, as well as providing a means of validating surrogate markers of fibrosis.

If three or more consecutive biopsies are available from a particular patient, and it is known when they were taken, it is possible not only to look at the differences in fibrosis scores between the biopsies but also the changes in the rate of fibrosis, which also takes into account how far apart they were taken. Studies using this approach have provided valuable information on the rates of disease progression (e.g. Wright *et al*.[31]). Some studies have suggested a linear increase in fibrosis, while others have supported a non-linear increase. It is not clear if the differences are artefacts of the different scoring systems used in these studies.

Immunohistochemical techniques can also be used to assess fibrosis or hepatocyte damage. For example, the presence of activated stellate cells can be quantified using immunohistochemical markers, for example, to α-smooth muscle actin or synaptophysin.[32] Alternatively, the deposition of a particular type of collagen, for example, the C-terminal procollagen α 1 peptide or other extracellular matrix protein, can be directly demonstrated. The degree of liver damage can also be assessed directly by using markers for cell damage (such as TUNEL staining or Fas antigen [CD95] expression)[33,34] or indirectly by assessing liver cell proliferation (using cell cycle markers such as PCNA). In the case of hepatitis B, immunohistochemical demonstration of the presence, distribution (nuclear ± cytoplasmic) and extent of HBcAg or HBeAg expression can add useful information about disease activity (see above).

Many people feel that image analysis can overcome many of the disadvantages of the semi-quantitative scoring systems when it comes to assessing fibrosis.[36] It has been claimed that it is more objective, sensitive and reproducible, although this is not accepted by everyone. For image analysis, sections are stained with a collagen

stain, most frequently Sirius red, and the amount of 'redness' in the section is measured using a computer attached to a video camera. Sirius red binds to collagen stochiometrically, and it has been shown that this binding correlates with the amount of collagen in the tissue as measured chemically by its hydroxyproline content.[58] Other stains which have been used for image analysis are Mallory's trichrome and aniline blue. Fast green binds to non-collagen proteins and can be used to complement Sirius red staining. Image analysis has been applied to biopsies from patients with chronic viral hepatitis. For example, a decrease in the collagen content, especially in the space of Disse, has been demonstrated in patients with HCV after they have been treated.[37]

Image analysis can also be applied to the immunohistochemical stains, including those described in the previous paragraph. For example, in one study the relationship between hepatocyte proliferation and DNA ploidy patterns was examined using a TV image analysis method. The authors concluded that the higher G1 and lower S cell cycle phase fractions observed in patients with HCV reflected decreased hepatocyte proliferation. In addition, they suggested that the near-aneuploid DNA content of the HCV-infected liver samples may be a sign of increased genetic instability which may, in turn, contribute to the increased risk of liver cancer.[38]

There are, however, three major drawbacks to image analysis. Firstly it requires equipment that is not universally available and it is very time-consuming. Secondly, it is only the total amount of collagen present that is being measured, and no account is taken of its distribution. For example, a high score may be obtained in a biopsy with normal architecture because of the presence of septal portal areas and a low score from a cirrhotic liver because only fragments of parenchyma surrounded by wisps of connective tissue have been obtained. Furthermore, critical changes in liver architecture, such as bridging fibrosis which is the morphological basis of porto-systemic shunting, are best assessed by eye. Thirdly, as part of the process it is necessary to set a threshold above which fibrosis will be considered to be present. This is often done 'by eye' and therefore remains very subjective. Even when a computer programme is used to minimize this problem, it has been shown that the semi-quantitative scoring systems are actually a more robust measure of fibrosis. Image analysis should be used only in the research setting, and even here should be seen as complementing routine histological examination and not replacing it.[39,40]

## Role of liver biopsy[41]

### HBV

At the time of the initial assessment of patients with HBV a liver biopsy is recommended.[42] This is done to assess the degree of liver damage and to exclude other causes of liver disease. It has also been suggested that the histological findings may predict prognosis. Following treatment, or spontaneous HBeAg seroconversion, the histology improves. Conversely, the histological changes may transiently deteriorate at the time of this seroconversion with an increase in lobular inflammation when the HBeAg-expressing cells are being cleared. The pathology may also deteriorate following reactivation of the disease. In following up patients not initially considered for treatment, in those who have a serum HBV DNA level of $>10^5$ and continuingly abnormal liver function tests, a further liver biopsy may be indicated. Liver biopsy remains an important part of the investigation of patients with chronic hepatitis B. The dynamic fluctuations in biochemical and seriological markers may not provide reliable information regarding the cumulative liver damage.

### HCV

The value of the liver biopsy in managing patients with HCV has been reviewed recently .[43–45] The possible roles of the liver biopsy include the following.

**1** To assess how urgently treatment is needed.
**2** To provide a baseline for assessing disease progression.
**3** To exclude co-existing liver diseases.
**4** To predict the likely response to antiviral treatment.

It should be noted that conventional liver function tests do not reliably predict the severity of the underlying disease. For example, in a group of 19 patients with normal aspartate aminotransferase (AST)levels two showed non-specific reactive hepatitis and 14 showed the features of chronic hepatitis.[46]

#### *1. To assess how urgently treatment is needed*

Treatment of HCV is unpleasant, expensive and associated with significant side-effects. More than this it is only effective, long term, in approximately 50% of patients. Currently, therefore, many management protocols require a liver biopsy to select those patients most urgently in need of treatment. As most patients only come to clinical attention many years after contracting the disease, the biopsy allows the assessment of the long-term impact of the disease on the liver. A small number of studies have been carried out using histological assessments of stage and grade to predict disease progression. It has been shown, for example, that mild disease progresses very slowly, if at all, when followed up for over 10 years, while patients with moderate or severe disease progress to cirrhosis over 20 years and 10 years, respectively. Some studies on the cost-effec-

tiveness of treatment have, however, suggested that it is worthwhile to treat even patients with mild disease. This conclusion has not been universally accepted. In any case, these studies need to be repeated with the new generation of antiviral agents.

### *2. To provide a baseline for assessing disease progression*

Another reason put forward for performing a liver biopsy is to act as a baseline against which disease progression can be assessed. Related to this is the question of how long to wait before rebiopsying patients who have not been treated to see if treatment is now indicated. Although a wait of 3 years has been widely suggested, if a rebiopsy is considered necessary at all, then, given the information that has been obtained from disease progression studies, an interval of 5 years may be more sensible. The differences between the baseline and subsequent biopsies can be assessed by comparing the scores, obtained using one of the semi-quantitative scoring systems, of the respective biopsies. It is generally considered that a difference in scores of 2 or more points is significant. This allows for some degree of sampling error. It can also be done by making a direct comparison of the stage and grade of the biopsies. When this is done as part of a clinical trial, it is clearly essential that the biopsies are blinded as to their sequence. When making any of these comparisons, it is highly desirable that this be done by the same experienced liver pathologist. The management of patients with normal alanine aminotransferase (ALT) remains controversial. The majority of these patients tend to have mild disease (F0 to F4) and the rate of progression of patients with normal ALT levels (which tend in fact to be at the upper limit of normal) is slower, or even stable. However, progression can be observed with longer follow-up, particularly in those with F2 rather than F0 or F1 disease at baseline. The risk of progression is to some extent dependent upon the definition of persistently normal ALT. There is a relationship between age, steatosis and the presence or absence of ALT flares. Liver biopsy, or perhaps serum markers of fibrosis, may be important in deciding upon treatment.[47]

### *3. To exclude co-existing liver diseases*

(See Plate 52.9, found between p.786–7.) The commonest liver diseases co-existing in patients with chronic viral hepatitis are due to iron overload or alcohol. These diseases are important in two different ways. Firstly, they may need to be treated in their own right. Secondly, they are associated with accelerated progression of the HCV and/or impaired response to treatment. One study found that 2% of patients with HCV had a clinically suspected other diagnosis and an equal number had a clinically unsuspected second disease, and another study demonstrated that the iron in Kupffer cells correlates with disease activity and that it decreases with successful treatment. Parenchymal iron disposition is more significant and underlying haemochromatosis should be excluded. In patients who have thalassaemia in addition to their HCV, parenchymal iron deposition is likely to be associated with the effects of the underlying ineffective erythropoiesis.[48] There are no prospective studies analyzing the clinical importance of excluding co-existing liver diseases.

### *4. To predict the likely response to antiviral treatment*

The more advanced the fibrosis in a liver biopsy, the less likely the patient is to respond to antiviral therapy. This difference is less marked in patients treated with the newer pegylated interferons (PEG-IFNs), especially when used in combination with ribavarin. A significant difference in response rates between patients without significant fibrosis (either no fibrosis or only portal tract expansion) and those with significant fibrosis (bridging fibrosis or cirrhosis) who have been treated with these agents has been demonstrated ($p<0.01$ for a sustained viral response in a multiple regression analysis). The effect of histology on the responsiveness to antiviral treatment has to be interpreted in the light of other factors that also influence it. These factors include: viral genotype, drug dosage and duration of treatment. Overall, the histology is not a sufficiently significant factor in predicting responsiveness to antivirals to influence treatment decisions on its own.

The determination of hepatitis C in biopsy tissue using sensitive PCR suggests that cryptic hepatitis C infection may be more common than previously thought to be the case.[49]

## Assessment of the risk of malignant change

(See Plate 52.10, found between p.786–7) The development of liver cell cancer is one of the most important complications of chronic viral hepatitis, and a number of protocols have been recommended to assess the risk. Liver biopsy may provide information about which patients are at increased risk for developing malignant change. The presence of large cell dysplasia and small cell dysplasia are both associated with an increased risk of developing liver cell cancer but are fundamentally different processes.[50–52] The terms large and small cell dysplasia (or change) should be used for lesions up to 1 mm in diameter. For larger lesions the expression dysplastic (macroregenerative) nodule is preferred.[53,54] Large cell dysplasia is characterized by groups of cells with large nuclei and prominent nucleoli set

in cells with more than the usual amount of cytoplasm.[55] Consequently, they have normal nuclear:cytoplasmic ratios. Large cell dysplasia is associated with an increased risk of malignant change, but these cells have a lower proliferation index than the other cells in the liver and do not themselves become malignant and appear to be terminally differentiated hepatocytes. Large cell dysplasia should therefore be considered as a *marker* for malignant change but not as a precursor lesion.[56] For this reason, the term large cell *change* is preferred by some. Its presence should act to encourage closer follow-up of patients.

Small cell dysplasia, conversely, is characterized by cells with normal, or even smaller than normal, nuclei within cells with decreased amounts of cytoplasm which is often basophilic. These cells, therefore, have increased nuclear: cytoplasmic ratios and the cells are more crowded together than normal. Small cell dysplasia is a *precursor* lesion for the liver cell cancer and, practically, it may be very difficult to distinguish it from a well differentiated liver cell cancer.[51] Staining for reticulin and CD34 may help with this differential diagnosis. Because of this link, the term small cell dysplasia is more informative than the more neutral small cell change. Small cell dysplasia appears to be commoner in Japan than in Western countries.

Although hepatocellular carcinoma is the commonest neoplasm seen in patients with HCV, there are a number of recent reports of cholangiocarcinoma developing in these patients.[57]

## Extrahepatic manifestations of hepatitis infection

Histopathologists may also make important contributions to patient management with reference to the extrahepatic manifestations of HCV, especially those involving the kidney. Extrahepatic disease is seen in approximately 40% of cases. They include renal disease, neuropathy, lymphoma and Sjögren's syndrome with or without mixed cryoglobulinaemia, which are all strongly associated with HCV infection. Porphyria cutanea tarda and diabetes have also been linked to HC.[58,59]

## The future of liver biopsies in the management of chronic hepatitis

### Non-invasive tests for hepatic fibrosis

Serum glycomics test based on serum N-glycans profiles distinguishes cirrhotic patients from non-cirrhotic patients. Compensated cirrhosis was detected with 86% specificity and 79% sensitivity. Although scientifically interesting, the current methodology does not detect early fibrosis easily, which is easily seen on liver biopsy.[60]

There is considerable interest in biochemical tests that predict stages of fibrosis. The FibroTest, developed by Poynard and co-workers, utilizes the fibrosis index, which combines the blood measurement of five indirect markers of fibrosis (alpha 2 macroglobulin, haptoglobin, apolipoprotein A1, total bilirubin and gamma-glutamyl transpeptidase; PGGT), adjusted for age and sex. The test results are obtained by automated measurement. The diagnostic value of this matrix index has been assessed. High area under the curve statistics (AUROC) of the order of 0.8 for METAVIR F3 and F4 fibrosis have been reported in patients with chronic hepatitis C. A high negative predictive value for excluding METAVIR F1 or Ishak F2 fibrosis has been reported. The role and cost-effectiveness of FibroTest as an alternative to liver biopsy in selected patients with chronic hepatitis C requires assessment. The limitations of the test require continuing independent assessment. The test has not been evaluated in patients with post-transplant hepatitis or renal disease, or in patients younger than 18 years.[61–65] False-positive tests may occur with haemolysis or Gilberts syndrome.

Other predictive models utilizing, for example, age, GGT, cholesterol, platelet count and prothrombin time,[66] platelets, aspartate aminotransferase (AST) and alkaline phosphatase (using a novel index, AST to platelet ratio index, APRI), have been developed.[67] These may exclude F2–F4 fibrosis with high accuracy. However, all these indices have been validated mainly in patients with hepatitis C and give different results in different populations of patients being studied. There has been a single study in patients with HBV.[68] At best, biochemical markers of fibrosis are surrogate tests and do not reflect the processes of fibrogenesis and fibrinolyis occurring in the liver. They remain less useful, for example, in liver transplant patients, and those with genotype 3 and hypercholesterolaemia, and HIV co-infection.

Ultrasound examination of the surface of the liver, its echotexture and the resistance within the hepatic artery may provide a useful assessment of the presence of cirrhosis, but it remains a crude assessment of advanced disease. Staging of fibrosis is not possible with ultrasound imaging.[69–71] Newer techniques (such as microbubble transit times) can provide, by non-invasive means, a diagnosis of cirrhosis with some sensitivity.[71a] Beaugrand *et al*.[71b] have recently evaluated a new non-invasive device to quantify liver fibrosis: the shear elasticity probe or fibroscan. The device is based on one-dimensional transient elastography, a technique that uses both ultrasound and low-frequency elastic waves, whose propagation velocity is directly related to elasticity. Fibrosis of the liver is related to liver elasticity. Liver elasticity measurements, obtained in minutes, are reproducible, with an AUROC of 0.88 and 0.99 for the diagnosis of F4 cirrhosis. The technique can fail in obese subjects.[74]

### Liver biopsy

Recent advances in the management of viral hepatitis,

especially HCV, are causing the role of the liver biopsy to be reassessed. The development of more effective antiviral therapies (such as the introduction of the PEG-IFNs), together with the use of combination therapy coupled with improved patient selection (including the observation that patients with HCV genotypes 2 and 3 have higher response rates), has led some to suggest that liver biopsies should no longer be considered essential. Liver biopsies add to the cost of investigation and treatment for hepatitis C. Although hitherto, biopsies have been considered an integral part of the investigation of chronic hepatitis C, the need for routine biopsies may change in the future. Liver biopsies are associated with slight risk, and can cause discomfort, pain and anxiety for patients. Direct and indirect costs of the procedure add to the cost of a relatively costly treatment. The cost-effectiveness of liver biopsy needs evaluation. Prior studies have examined the cost-effectiveness of a baseline liver biopsy and viral genotype to ascertain patients least likely to respond. Strategies involving a liver biopsy were more expensive, as fewer patients needed treatment to achieve a higher sustained virological response rate. However, this study was based on the results achieved with a 6-month course of IFN-α monotherapy, and is dated.[75] A more recent study compared the cost-effectiveness of immediate antiviral therapy with biopsy every 3 years plus combination therapy with IFN-α and ribavirin. Immediate antiviral therapy was thought to increase life expectancy by 1.0 quality life year compared with biopsy management and was considered cost-effective compared with biopsy management.[76]

Thus, a liver biopsy before treatment is likely to increase the lifetime costs of treatment, and may be unduly restrictive and a barrier to treatment. However, physicians and patients may continue to value the diagnostic and prognostic information provided by a liver biopsy. It is believed that not everyone who is a candidate for treatment needs to undergo the procedure, and there is a move towards selective rather than routine use of the biopsy. For patients with mild disease (defined histologically as the absence of hepatic fibrosis or minimal fibrosis), empirical treatment for those with a high likelihood of response, i.e. genotype 2 and 3, is being applied in several countries, following the recommendations of recent French and American Consensus Conferences. The incremental cost-effectiveness of this approach has not yet been proven, however. Studies that have examined periodic biopsy to monitor the progression of mild disease need evaluation against treatment results for a combination of PEG-IFN and ribavirin, and against the use of serum non-invasive tests or perhaps ultrasonagraphic assessment compared with periodic biopsy. Narrowing the focus of treatment to those most likely to progress to sequelae of chronic liver disease remains a critical challenge to maximize the available resources for treatment.

# Chapter 53
# Disinfection and sterilization

Martin S Favero, Walter W Bond

The purpose of this chapter is to discuss disinfection and sterilization strategies used in health-care and laboratory settings to prevent the transmission of infectious agents from contaminated medical devices and environmental surfaces to patients and health-care workers. Although these strategies are those used generally in health-care facilities to accomplish disinfection and sterilization for all groups of pathogenic micro-organisms, emphasis will be placed on the efficacy of these procedures against the human hepatitis viruses.

The effective use of antiseptic, disinfectant and sterilization procedures in health-care settings is important in the prevention of hospital-acquired infections. Historically, the use of physical agents, such as moist heat in the form of steam autoclaves or dry heat applied using convection or forced air ovens, has played the predominant role in sterilizing instruments, equipment and supplies in hospitals. In the 1960s, a number of heat-sensitive medical instruments requiring sterilization by low temperature methods were developed. Ethylene oxide was used for this purpose for many years, but increasing concerns about acute and residual toxicity to humans and the environment and very long sterilization cycles stimulated the development of a number of alternative low temperature sterilization technologies. These include systems employing hydrogen peroxide gas plasma or ozone, and in some parts of Europe, steam/formaldehyde. Liquid chemical germicides formulated and marketed as 'total immersion' sterilants have also been available for many years, but they are used almost exclusively to disinfect rather than sterilize heat-sensitive medical devices.[1–3]

The choice of which sterilization or disinfection procedure or which specific chemical germicide should be used for sterilization, disinfection or antisepsis or for environmental sanitization depends on several factors. No single chemical germicide or sterilization procedure is adequate for all purposes. Factors that should be considered in the selection of a specific sterilization or disinfection procedure include (1) the degree of microbiological inactivation required for the particular device, (2) materials compatibility of the device with the disinfection or sterilization procedure based on the device's nature and physical composition, (3) the cost and ease of using a particular procedure, and (4) acute and residual toxicity concerns for the patient, the health-care worker and the environment. As will be pointed out below, the efficacy of various chemical and physical agents against the human hepatitis viruses are difficult to determine because only hepatitis A virus (HAV) can be grown in tissue culture. However, it is clear that all the human hepatitis viruses are relatively susceptible to common sterilants and disinfectants. Consequently, extraordinary procedures or preparations are not needed to process medical devices or for housekeeping purposes or laboratory decontamination.[4]

## Regulation of chemical germicides

Chemical germicides used as disinfectants or antiseptics in most countries are regulated by the federal or central government and usually by the Public Health Service or Ministry of Health.

In the United States, chemical germicides are regulated by two federal government agencies: the Environmental Protection Agency (EPA) and the Food and Drug Administration (FDA). Chemical germicides formulated as sterilants or disinfectants had historically been regulated by the EPA, but recently the EPA and FDA agreed that sterilants or disinfectants used on medical devices (e.g. haemodialysis machines, endoscopes, high-speed dental hand-pieces, etc.) will be regulated by the FDA. The EPA requires manufacturers of chemical germicides formulated as sanitizers, disinfectants, hospital disinfectants or sterilant/disinfectants (sporicides) to test these products using specific, standardized assay methods for microbicidal potency, stability and toxicity to humans. For chemical germicides intended for use on medical instruments (as opposed to environmental or housekeeping surfaces), the FDA requires that manufac-

turers submit a pre-market application that may include additional specific microbicidal activity data, device/chemical compatibility data and detailed instructions to the user regarding the 'safe and effective use' of the product. The FDA also regulates all sterilization devices such as ethylene oxide, ozone and hydrogen peroxide gas plasma sterilizers, steam autoclaves and dry heat ovens.

In addition to pharmaceutical drugs, the FDA regulates chemical germicides formulated as antiseptics, used to inhibit or kill micro-organisms on the skin or in tissue. These types of chemical germicides are categorized basically by use pattern (e.g. antimicrobial handwashes, patient preoperative skin preparations, skin wound cleansers, skin wound protectants and surgical hand scrubs) and are not regulated or registered in the same fashion that the EPA regulates and registers a disinfectant. Currently, data are not available to accurately assess the efficacy of many of the antimicrobial antiseptic formulations on the market. Consequently, health-care workers must make product selection decisions based on information derived from the manufacturer, published studies in the literature and guidelines from expert groups.[5]

The US Centers for Disease Control and Prevention (CDC) does not approve, regulate or test chemical germicides formulated as disinfectants or antiseptics. Rather, the CDC recommends broad strategies for the use of sterilants, disinfectants and antiseptics to prevent transmission of infections in the health-care environment.[1,6,7]

## Definitions

The definitions of sterilization, disinfection, antisepsis and other related terms such as decontamination and sanitization are generally accepted in the scientific community, but some of these terms are misused. It is important not only to understand the definition and implied capabilities of each procedure, but also to understand how to achieve and in some cases monitor each state.

### Sterilization and disinfection

The term *sterilization* is one that students and professionals have memorized and recited seemingly for ever. It can be the simplest and the most complex concept depending on how it is viewed and how it is applied. The definition of sterilization can change depending on the user's vantage point. We choose to view this term somewhat like a hologram and will define it in the context of:

**1** the *state* of sterilization,
**2** the *procedure* of sterilization,
**3** the *application* of sterilization.

Any item, device or solution is considered to be sterile when it is completely free of all living micro-organisms. This state of sterility is the objective of the sterilization procedure and, when viewed in this context, the definition is categorical and absolute, i.e. an item is either sterile or it is not.

A sterilization *procedure* is one that kills all micro-organisms, including high numbers of bacterial spores, representatives of the most resistant microbial forms. Sterilization can be accomplished by heat, ethylene oxide gas, hydrogen peroxide gas plasma, ozone or radiation (in industry). From an operational standpoint, a sterilization procedure cannot be categorically defined. Rather, the procedure is defined as a process, after which the probability of a micro-organism surviving on an item subjected to the sterilization procedures is less than one in one million ($10^{-6}$). This is referred to as the 'sterility assurance level,' and it is this approach that is used by the medical device industry to sterilize large quantities of medical devices. Some criteria used in the production and labelling of a sterile device are listed in Table 53.1.

The *application* of sterilization principles in industry is much more sophisticated and controlled than sterilization procedures used in hospitals. However, steam autoclaves, ethylene oxide gas sterilizers, hydrogen peroxide gas plasma sterilizers and dry heat sterilization ovens used in health-care facilities have operational protocols that are validated by the manufacturer to accomplish sterilization, and all the variables that control for the inactivation of micro-organisms are either automated or built into simple controls in the devices. In addition, the sterilization cycles can be monitored with mechanical, chemical and/or biological indicators.

The *application* of the sterilization process takes into account additional considerations. This approach involves the use strategy associated with a particular medical device (or medical fluid) and the context of its degree of contact with patients. Spaulding in 1972[1] proposed that instruments and medical devices be divided into three general categories based on the theoretical risk of infection if the surfaces are contaminated at time

**Table 53.1** Criteria used in producing sterile devices

| |
|---|
| Good manufacturing practices |
| Use of biological indicators |
| Validated sterilization process |
| Sterility testing of a subsample of the batch subjected to the sterilization process |
| Process controls |
| Quality control of materials |
| Post-sterilization testing of devices for function |

of use. Briefly, medical instruments or devices that are exposed to normally sterile areas of the body require sterilization; instruments or devices that touch mucous membranes may be either sterilized or disinfected; and instruments, medical equipment or environmental surfaces that touch only intact skin or come into contact with the patient only indirectly can be either cleaned and then disinfected with an intermediate-level disinfectant, sanitized with a low-level disinfectant or simply cleaned with soap and water. These instruments or other medical surfaces are termed (with respect to their need to be sterile at time of use) 'critical', 'semi-critical' or 'non-critical', respectively. Selection of the appropriate disinfecting procedure in the last category (non-critical) will include consideration of the nature of the surface, as well as the type and degree of contamination, as shown in Table 53.2.

In the context of these categorizations, Spaulding (1972) also classified chemical germicides by activity level. The activity levels are listed in Table 53.3 and are as follows.

**1** *High-level disinfection*. This is a procedure that kills all viruses, fungi and vegetative micro-organisms but not necessarily high numbers of bacterial spores. These chemical germicides, by Spaulding's definition, are those that are capable of accomplishing sterilization (e.g. killing of all microbial forms including high numbers of bacterial spores) when the contact time is relatively long (6–10 hours). When used as high-level disinfectants, the contact times are comparatively short (5–45 minutes). These chemical germicides are very potent sporicides and, in the United States, are those registered with the FDA as sterilant/disinfectants or simply, high-level disinfectants.

**2** *Intermediate-level disinfection*. This is a procedure that kills vegetative micro-organisms including comparatively resistant vegetative microbial forms such as *Mycobacterium tuberculosis*. All fungi and most viruses are also killed. These chemical germicides often correspond

**Table 53.2** Relationship of germicide type, type of device or surface and process

| Type of germicide | Type of device or surface | Process |
|---|---|---|
| Sterilant/disinfectant | Critical (heat-sensitive rigid endoscopes) | Sterilization (sporicidal chemical, prolonged contact time) |
| | Semi-critical (medical instruments, re-usable heat-sensitive anaesthesia circuits, endotracheal tubes, laryngoscope) | High-level disinfection (sporicidal, chemical, short contact time) |
| Hospital disinfectant (with label claim for tuberculocidal activity) | Non-critical (medical equipment, blood-contaminated control knobs of medical equipment) | Intermediate-level disinfection |
| Hospital disinfectant/sanitizer | Non-critical (environmental surfaces: exteriors of machines, floors, walls, other housekeeping surfaces) | Low-level disinfection to soap and water washing |

**Table 53.3** Levels of disinfectant action according to type of micro-organism

| | Bacteria | | | Virus | | |
|---|---|---|---|---|---|---|
| Level of action | Spores | *Mycobacterium* spp.* | Vegetative cells | Fungi† | Non-lipid, small | Lipid, medium-sized |
| High | +‡ | + | + | + | + | + |
| Intermediate | –§ | + | + | + | ±¶ | + |
| Low | – | – | + | ± | ± | + |

Plus sign indicates that a killing effect can be expected; a minus sign indicates little or no killing effect. Adapted from Favero and Bond.[1]

*Laboratory potency tests usually employ *M. tuberculosis* var. *bovis*.

† Includes asexual spores but not necessarily chlamydospores or sexual spores.

‡High-level disinfectants are chemical sterilants (sporicides); inactivation of high numbers of bacterial spores can be expected only when extended exposure times are used, e.g. 6–10 hours for sterilization vs 5–45 minutes for high-level disinfection.

§Some intermediate-level disinfectants (e.g. hypochlorites) may show some sporicidal activity, while others (e.g. alcohols, phenolics) have none.

¶Some intermediate-level disinfectants (e.g. certain phenolics, isopropyl alcohol) may have limited virucidal activity, even though they readily inactivate *Mycobacterium* spp.

to EPA-approved 'hospital disinfectants' that are also 'tuberculocidal'.

**3** *Low-level disinfection*. This is a procedure that kills most vegetative bacteria, some fungi, and some viruses. Comparatively resistant vegetative forms such as *M. tuberculosis* are *not* killed. These chemical germicides are often ones that are approved in the USA by EPA as hospital disinfectants or sanitizers. General use strategies of sterilization and disinfection using a variety of physical or chemical agents (with specific reference to hepatitis viruses) are shown in Table 53.4.[1]

Spaulding's system for classifying devices and strategies for disinfection and sterilization is quite conservative. There is a direct relationship between the degree of conservatism as expressed by the probability of a micro-organism surviving a particular procedure and the microbicidal potency of the physical or chemical germicidal agent. For example, a sterilization procedure accomplished by steam autoclaving, ethylene oxide gas, or hydrogen peroxide gas plasma sterilization, by design and definition, will result in a one-in-one million probability of a surviving micro-organism if the procedure

**Table 53.4** Some physical and chemical methods for inactivating hepatitis viruses*

| Class | Class concentration or level | Activity |
|---|---|---|
| *Sterilization* | | |
| Heat | | |
| Moist heat (steam under pressure) | 250 °F (121 °C), 15 min | |
| | Prevacuum cycle 270 °F (132 °C), 5 min | |
| Dry heat | 170 °C, 1 h | |
| | 160 °C, 2 h | |
| | 121 °C, 16 h or longer | |
| Ethylene oxide | 450–500 mg/L, 55–60 °C | |
| Hydrogen peroxide gas plasma | Manufacturer's instructions | |
| *Disinfection* | | |
| Heat | | |
| Moist heat | 75–100 °C | High |
| Liquid† | | |
| Glutaraldehyde, aqueous‡ | Variable | High |
| *Ortho*-phthalaldehyde | 0.55% | High |
| Hydrogen peroxide, stabilized | 6–10% | High |
| Formaldehyde, aqueous§ | 3–8% | High to intermediate |
| Iodophors¶ | 40–50 mg/L free iodine at use-dilution | Intermediate |
| Chlorine compounds** | 500–5000 mg/L free available chlorine | Intermediate |
| Phenolic compounds†† | 0.5–3% | Intermediate |
| Quaternary ammonium compounds‡‡ | 0.1–2% | Low |

*Adequate precleaning of surfaces is vital for any disinfecting or sterilizing procedure. Short exposure times may not be adequate to disinfect many objects, especially those that are difficult to clean because of narrow channels or other areas that can harbour organic material. Although alcohols (e.g. isopropanol, ethanol) have been shown to be effective in killing HBV, we do not recommend that they be used generally for this purpose due to rapid evaporation and consequent difficulty in maintaining proper contact times. Immersion of small items in alcohols could be considered.

†This list of liquid chemical germicides contains generic formulations. Other commercially available formulations based on the listed active ingredients can also be considered for use. Information in the scientific literature or presented at symposia or scientific meetings can also be considered in determining the suitability of certain formulations. The following US FDA site lists cleared formulations: http://www.fda.gov/cdrh/ode/germlab.html.

‡Manufacturer's instructions regarding use should be closely followed.

§Because of the controversy regarding the role of formaldehyde as a potential occupational carcinogen, the use of formaldehyde is recommended only in limited circumstances under carefully controlled conditions of ventilation or vapour containment, e.g. disinfection of certain haemodialysis equipment.

¶Only those iodophors designed as hard surface disinfectants should be used, and manufacturer's instructions regarding proper use-dilution and product stability should be closely followed. Check product label claims for demonstrated activity against *Mycobacterium* spp. (tuberculocidal activity) as well as a spectrum of lipid and non-lipid viruses.

**See text.

††Check product label claims for demonstrated activity against *Mycobacterium* spp. (tuberculocidal activity) as well as a spectrum of lipid and non-lipid viruses.

‡‡Quaternary ammonium compounds are not tuberculocidal and may not have significant effect against a variety of non-lipid viruses. This class of germicide is used primarily for routine housekeeping throughout health-care facilities.

had initially been challenged with $10^6$ highly resistant bacterial spores. The risk of infection resulting from the use of an item that was subjected to this type of procedure, assuming that the procedure had been carried out properly, would appear to be zero. Correspondingly, the probability of contamination and the theoretical probability of infection associated with sterilization or high-, intermediate- or low-level disinfection with liquid chemical agents would increase as the overall germicidal potency of the selected germicidal agent or procedure decreased.

A process of liquid chemical sterilization would, at best, be three orders of magnitude less reliable than a conventional sterilization procedure. From a practical standpoint, this means that there is a lower level of confidence with such procedures, and if and when mistakes are made there is a higher chance of failure than with a sterilization procedure. When operational errors are made, the consequences are magnified when a procedure of lower overall potency is used. When less reliable sterilization procedures such as this are used, they should invariably be accompanied by very precise protocols, policies and quality assurance monitoring.

### Decontamination

Another term quite often used in health-care facilities is *decontamination.* A process of decontamination is one that renders a device or items safe to handle, i.e. safe in the context of being reasonably free from disease transmission risk. In many instances, this process is a sterilization procedure such as steam autoclaving, and this is often the most cost-effective way of decontaminating a device or item. Conversely, the decontamination process may be ordinary soap and water cleaning of an instrument, a device or an area. When chemical germicides are used for decontamination, they can range in activity from concentrated oxidative agents such as sodium hypochlorite, hydrogen peroxide or chlorine dioxide, which may be used to decontaminate spills of cultured or concentrated infectious agents in research or clinical laboratories, to low-level disinfectants or sanitizers when general housekeeping of environmental surfaces is the objective.

### Antiseptic

The term *antiseptic* is used to describe a substance that has antimicrobial activity and is formulated for use on or in living tissue to remove, inhibit growth of or inactivate micro-organisms. Quite often, the distinction between an antiseptic and a disinfectant is not made. However, the differences between a disinfectant and an antiseptic are very great and applications are significantly different. A disinfectant is a chemical germicide formulated for use solely on inanimate surfaces such as medical instruments or environmental surfaces. An antiseptic is formulated for use solely on or in living tissues. Some chemical agents such as iodophors can be used as active ingredients in chemical germicides that are formulated either as disinfectants or antiseptics. However, the precise formulations are significantly different, use patterns are different and the germicidal efficacy of each formulation differs substantially. Consequently, disinfectants should never be used as antiseptics and antiseptics should never be used to disinfect instruments or environmental surfaces.

## Factors that influence germicidal activity

Micro-organisms vary widely in their resistance to sterilants and disinfectants. The most resistant microbial forms are bacterial spores (e.g. typically from the aerobic spore-forming genera, *Bacillus* and *Geobacillus*) and few, if any, other micro-organisms approach the broad resistance of these organisms to either heat, chemicals or radiation. A number of factors, some of which are associated with micro-organisms themselves and others with the surrounding physical and chemical environment, can significantly influence the antimicrobial efficacy of chemical germicides.

Some factors are more important than others, but all should be considered when planning sterilization and disinfection strategies for medical and surgical devices and materials. Briefly, these factors are as follows.

### Type of micro-organism

Bacterial spores are more resistant than mycobacteria, fungi, vegetative bacteria and viruses. Some types of viruses are more resistant to germicides than others. As a general guide, one should define the state or degree of inactivation needed (i.e. sterilization or various levels of disinfection) and then choose the most appropriate germicidal agent and method of application.

### Number of micro-organisms

All other factors being equal, the greater the number of micro-organisms on a device, the longer it takes to kill this microbial population. It is for this reason that devices, especially those that are disinfected, should be thoroughly cleaned prior to being sterilized or disinfected.

### Intrinsic resistance of micro-organisms

Bacterial spores have already been mentioned, but very few species in the genera *Bacillus*, *Geobacillus* or *Clostridium* are actually responsible for hospital-acquired infections. However, organisms such as *M. tuberculosis* var. *bovis* and non-tuberculous mycobacteria, as well as naturally occurring gram-negative water bacteria such as *Pseudomonas aeruginosa* and other pseudomonads can, under some circumstances, be relatively resistant to chemical disinfectants. After bacterial spores, *Mycobacterium* spp. are considered one of the more resistant classes of micro-organisms. It is for this reason that chemical germicides approved as 'tuberculocides' are sometimes recommended for purposes of decontamination or disinfection when a higher activity germicide is sought. It is usually not a concern for transmission of *M. tuberculosis* (*M. tuberculosis* is transmitted via contaminated aerosols but not by surfaces), but rather a definition or specification that can be used to describe a germicide with a relatively broad range of germicidal activity. Resistance of certain non-lipid viruses is similar to that of mycobacteria.[8]

### Amount of organic soil present on the item to be disinfected or sterilized

Blood, faeces or other organic soil may contribute to failure of a disinfecting or sterilizing procedure in three ways. Organic soil may contain large and diverse microbial populations, may prevent penetration of germicidal agents or may directly inactivate certain germicidal chemicals. This factor, perhaps even more than others, underscores the necessity of precleaning items thoroughly prior to disinfection or sterilization.

### Type and concentration of germicide

Generally, with all other factors being constant, the higher the concentration of a germicide, the greater is its effectiveness and the exposure time necessary for disinfection or sterilization can be shorter. If a chemical agent is reused over a period of time, the product effectiveness may be reduced due to a variety of factors such as dilution or organic contamination.

### Time and temperature of exposure

With few exceptions, the longer the exposure times to a given chemical agent, the greater is its effectiveness. An increase in temperature will significantly increase germicidal effectiveness, but deterioration or evaporation of the agent along with an increase in corrosiveness may also occur.

### Other product- or process-related factors

The presence of organic or inorganic loads, pH and the degree of hydration of biological material may significantly affect the potency of certain chemical germicides. For these as well as other factors given above, care should be taken to examine closely and follow label instructions of proprietary germicides.

### Device-related factors

The device or item being disinfected or sterilized must be physically and chemically compatible with the chosen procedure to ensure effectiveness and continued function of the device or item. Also, factors such as ease of access and cleaning as well as the size of the device or item are important considerations. The manufacturer of the item being reprocessed is the best source of pertinent information in this regard.

## Inactivation of hepatitis viruses

Germicidal activity of physical and chemical agents against the human hepatitis viruses has been difficult to establish because most (HBV, HCV, HDV and HEV) have not yet been grown in tissue culture. With the exception of HAV, comparative virucidal testing, for the most part, has not been performed as it has for other types of viruses that can be conveniently cultured and tested in the laboratory.

### HAV

HAV appears to have the same degree of resistance to chemical germicides and reagents as other picornaviruses.[8,9] Table 53.5 presents activity against HAV by various physical and chemical agents.[9,10] These data underscore the importance, in practice, of thorough cleaning of surfaces to remove gross organic soil and, at the same time, reduce the level of viral contamination.

### HBV and HCV

As pointed out in other parts of this book, hepatitis B and C are diseases of major public health significance. Both viruses can be transmitted in health-care settings from patient to patient and from patient to staff member, and HBV has been shown to have an environmentally mediated mode of transmission. This is due, at least in part, to the comparatively high numbers of HBV in the blood of certain infected pa-

**Table 53.5** Effects of chemical agents and heat on HAV viability

| Inoculum/exposure conditions | Agent (exposure time) | Result (log reduction) |

tients (sometimes as high as $10^8$–$10^9$/mL) and also, the ability to survive for a period of time after drying.[11] However, as these viruses cannot be grown in tissue culture, data used to verify disinfection and sterilization procedures have been deduced from experiments using human volunteers, blood products that received some degree of treatment and where disease or infection was followed in human recipients, or experiments in which chimpanzees were used to determine HBV inactivation using infectivity as a criterion. In addition, there have been other experimental approaches to demonstrate that certain physical and chemical agents can alter the immunological reactivity of hepatitis B surface antigen (HBsAg) as well as the morphological alteration of various components of the intact virus.

We have used HBsAg as a marker for HBV in order to determine the potential for environmentally mediated modes of transmission as well as inactivation capabilities of various chemical and physical agents.[12,13] Detection of HBsAg on environmental surfaces does not indicate positively the simultaneous presence of viable HBV, but it does serve as an indicator of contamination with potentially infective material. We and others have shown that HBsAg can be quantified and traced in environmental surfaces as an adjunct to longitudinal or epidemic investigations.[13–18]

Because there is no evidence to suggest that the resistance level of HBV is equivalent to or even approaches the demonstrated stability of the immunological reactivity of HBsAg, we proposed in 1977 that the immunological reactivity of HBsAg is much more resistant to physical and chemical stresses than is the infectious virion. Consequently, those chemical and physical stresses that were shown to destroy the immunological reactivity of HBsAg can be assumed to be effective against HBV. We further proposed that the resistance level of HBV be considered equivalent to that of *M. tuberculosis*, i.e. less resistant than bacterial spores but more resistant than most micro-organisms. Subsequently, even this assumption was shown to be overly conservative when a number of intermediate- to high-level disinfectants were shown to be effective against HBV.[4]

HBV has been shown to be inactivated by several moderately potent disinfectants, including 0.2% and 0.1% glutaraldehyde, 500 p.p.m. free chlorine from sodium hypochlorite, an iodophor disinfectant and isopropyl or ethyl alcohol.[11,19] Table 53.6 gives a summary of some of the inactivation potentials of various physical agents and germicides in tests using titred inocula and chimpanzee infectivity assays.[11,19,20]

As infectivity experiments using chimpanzees are not suitable for the quantitative determination of HBV inactivation, more reliance has been placed on other avenues of experimentation. Thraenhart *et al*.[21,22] developed a test referred to as the 'morphologic alteration and disintegration test' (MADT). This has been standardized and used in Germany for determining the effect of chemical germicides and physical agents on HBV. The hypothesis of MADT is that the physical destruction of intact HBV virus particles is correlated with the inactivation of infectivity using chimpanzee infectivity tests.[22] The MADT uses the human HBV but the test procedure is too complicated and cumbersome for routine use. It requires expensive equipment and personnel with considerable experience and skill in electron microscopy. The HBV suspensions required need to be highly concentrated and pure enough to allow the viral particles to be readily visualized and counted under the electron microscope. And some chemical germicides such as glutaraldehyde and alcohol act by fixing proteins and preserving the structural integrity of the material being treated. Virus particles exposed to them may appear morphologically unaltered, although being non-infectious. This could lead to false-negative results.

Testing based on HBV polymerase inactivation has also been used to test germicides.[23] This testing method has not been widely accepted because it is based on an indirect measure of virus infectivity and requires highly purified virus preparations. The sensitivity of the test is also questionable.

There have been recent studies that propose the use of animal hepatitis viruses as surrogates in germicide testing protocols. The Peking duck virus resembles HBV closely in viraemia, carcinoma production,[24] and inactivation profiles.[25,26] The duck hepatitis B virus (DHBV) infects primary duck liver cells *in vitro*, thus making the test more cost-effective compared with the use of chimpanzees or even ducklings as experimental animals.[25] The US EPA issued guidelines in August 2000[27] on protocols for testing the efficacy of disinfectants that use DHBV as a surrogate for HBV. Pugh and co-investigators[28] inoculated carriers with DHBV, dried them and then exposed them to specific germicides. After a specified contact time, the disinfectant–virus mixture is eluted off the test carriers, neutralized and then serially diluted for culture in duck hepatocytes. Detection of DHBV replication is performed either by immunofluorescence or by nucleic acid detection methods.

Chan-Myers and Roberts[20] tested *ortho*-phthalaldehyde (OPA), for efficacy against DHBV and bovine viral diarrhoea virus (BVDV), a surrogate for HCV. The virus cultures containing 5% horse serum as organic soil load were dried onto the bottom of petri dishes and a

quantity of known concentration of OPA solution was added. After an exposure of 5 minutes at 20 ºC, the virus was recovered and titrated on monolayers of either duck hepatocyctes or bovine turbinate cells for infectivity. The results showed that dilute OPA (0.31%; the use concentration of OPA is 0.55%) completely inactivated both DHBV and BVDC in 5 minutes at 20 ºC.

Testing against HCV is also difficult because the virus cannot be visualized or effectively grown in tissue culture. HCV replicate in Vero cells without producing any cytopathic effects. However, BVDC has some properties similar to HCV and has been used in the blood product industry as a surrogate for HCV.29–31 Recent studies show that the enveloped nature of HCV makes it relatively susceptible to inactivation by phenolics and chlorine.[32]

### Other hepatitis viruses

The effects of physical and chemical agents on other human hepatitis viruses, HDV and HEV, have not been studied extensively but, as mentioned previously, we are aware of no evidence to suggest that any of these viruses are intrinsically more resistant to physical or chemical agents than most viruses or that the general resistance levels can even approach that of bacterial spores. Consequently, we continue to propose that the resistance levels of the human hepatitis viruses that have not been studied in great detail be considered near that of *M. tuberculosis* var. *bovis* and non-lipid viruses (e.g. poliovirus), but much less than that of bacterial spores.

## Sterilization, disinfection and housekeeping in the laboratory

Conventional sterilization procedures such as steam autoclaving, dry heat, ethylene oxide gas and hydrogen peroxide gas plasma can be relied upon to effectively inactivate all hepatitis viruses. This is also true for liquid chemical germicides used as sterilants (sporicides). Such procedures are used primarily for medical instruments that are reprocessed for use on patients in health-care facilities. It is emphasized that this class of potent chemical germicide is designed and intended for exclusive use in 'total immersion' reprocessing of certain heat-sensitive medical instruments and is not appropriate for use on environmental surfaces.

In the context of laboratory settings where liquid chemical germicides may be used to disinfect laboratory worktops or laboratory instruments directly exposed to cultured or concentrated hepatitis viruses or human or animal source specimens containing these agents, it is recommended that chemical disinfectants in their appropriate concentrations and contact times capable of producing an intermediate level of disinfection activity should be used (e.g. oxidative or phenolic chemicals: see Table 53.4).

For general housekeeping purposes such as cleaning floors, walls and other similar environmental surfaces in the laboratory area, any disinfectant-detergent product can be used according to the manufacturer's instructions. In some high-risk areas such as laboratories, haemodialysis units and other spill- or splash-prone health care environments, one is confronted with the problem of decontaminating large and small blood spills, patient care equipment that becomes contaminated with blood and frequently touched instrument surfaces such as control knobs, which may play a role in environmentally mediated transmission of hepatitis B. The strategies for applying the principles of HBV inactivation vary according to the item or surface being considered, its potential role in the risk of hepatitis virus transmission and, to a certain extent, the thermal and chemical sensitivities of the surface or instrument. For example, if a significant spill of blood occurred on the floor or a countertop in a laboratory, the objective of the procedure to inactivate HBV or other blood-borne hepatitis viruses would be one of decontamination or disinfection and not sterilization. Consequently, in such a situation we would recommend that gloves be worn and the blood spill be absorbed with disposable towels. The spill site should be cleaned of all visible blood, and then the area should be wiped down with clean towels soaked in an appropriate intermediate-level disinfectant such as a freshly made 1/100 dilution of commercially available household bleach (approximate 5–6% sodium hypochlorite depending on brand, intended minimum of 0.05% at final dilution). All soiled towels should be put in a plastic bag or other leak-proof container for disposal.

The concentration of disinfectant used depends primarily on the type of surface that is involved. For example, in the case of a direct spill on a porous surface that cannot be physically cleaned before disinfection, 0.5% sodium hypochlorite (5000 mg/L available chlorine) should be used. On the other hand, if the surface is hard and smooth and has been cleaned appropriately, then 0.05% sodium hypochlorite (500 mg/L available chlorine) is sufficient. For commercially available chemical disinfectants, the use concentrations and instructions specified by the manufacturer should be closely followed.

Other types of environmental surfaces of concern include surfaces that are touched frequently, such as control knobs or panels on laboratory instruments. Ideally, gloves should be worn and manipulated in a manner

appropriate not only to avoid skin contact with patient materials but to avoid 'finger painting' of this contamination to a variety of other frequently touched surfaces. As this ideal is seldom fully realized in a busy laboratory setting, laboratory instrument and equipment surfaces (including fixtures such as light switches and door pulls or push plates) should be routinely cleaned and disinfected. The objective here would be to reduce the level of possible contamination to such an extent that the likelihood of disease transmission is remote. In a practical sense, this could mean that a cloth soaked in either 0.05% sodium hypochlorite or a suitable proprietary disinfectant or disinfectant/detergent could be used. In this context, the element of physical cleaning is as important, if not more important, than the choice of the disinfectant. It is not necessary, cost-effective or in many cases even feasible to attempt more powerful germicidal procedures with these types of items or surfaces.

As a rule, routine daily cleaning procedures used for general microbiological laboratories can be used for laboratories in which blood specimens are processed. Obviously, special attention should be given to areas or items visibly contaminated with blood or faeces. Furthermore, cleaning personnel must be alerted to the potential hazards associated with blood, serum and faecal contamination. Floors and other housekeeping surfaces contaminated in this manner should be thoroughly cleaned of gross material and then treated with a detergent-disinfectant. Gloves should be worn by cleaning personnel doing these duties. However, in the case of large blood spills as mentioned above, this type of procedure may have to be augmented by specific site decontamination using a more potent chemical agent such as an intermediate-level disinfectant (see Table 53.4).

## Conclusions

Strategies for disinfection and sterilization used in hospitals and other health-care institutions are based on relatively conservative criteria and do not need to be changed because of concern regarding the presence of hepatitis viruses. These viruses are inactivated by a wide variety of common physical and chemical sterilization and disinfection procedures. The resistance of individual species of hepatitis viruses to heat and chemical germicides varies, but none exceeds the resistance levels of bacterial spores or *M. tuberculosis*. Consequently, conventional sterilization, disinfection or decontamination procedures can be used for processing medical devices used on patients known to have viral hepatitis infection. Extraordinary procedures or formulations are not needed, nor is there an indication for the preferential use of products with specific label claims of efficacy against specific hepatitis viruses.

# Chapter 54
# Mechanisms of interferon resistance

Darius Moradpour, Markus H Heim, Hubert E Blum

## Introduction

Infections with the hepatitis B virus (HBV) and hepatitis C virus (HCV) are leading causes of chronic hepatitis, liver cirrhosis and hepatocellular carcinoma (HCC) worldwide. Interferon-α (IFN-α) or pegylated IFN-α (PEG-IFN-α), combined with ribavirin in the case of chronic hepatitis C, are currently used to treat both forms of chronic viral hepatitis. Sustained virological response rates, however, are limited to 30-40% in chronic hepatitis B and 50-60% in chronic hepatitis C. Thus, both viruses may have evolved mechanisms to counteract the antiviral effects of IFN-α, rendering therapy ineffective in many patients. More importantly, the IFN-induced cellular antiviral response is the first line of innate defence against viral infections. Therefore, viruses must first overcome the IFN-induced mechanisms blocking viral replication in order to establish a productive infection.[1–3] Hence, mechanisms of IFN resistance may not only contribute to the resistance to IFN-α therapy observed in many patients, but may represent general escape strategies of HBV and HCV contributing to viral persistence and pathogenesis.

The mechanisms by which IFN-α inhibits replication of HBV and HCV are incompletely understood and may involve both direct antiviral and immunomodulatory effects. Investigation of these mechanisms has been hampered by the lack of efficient cell culture systems and small animal models permissive for HBV and HCV infection and replication. Only recently, model systems have been developed that make it possible to study selected aspects of the interplay between HBV and HCV and the IFN system. These include, among others, transgenic mice that replicate HBV in their livers[4] and the replicon system for HCV.[5,6] These systems have allowed investigation of the effect of IFN-α and other cytokines on HBV and HCV replication. In addition, data obtained in these and other experimental model systems indicate that both viruses have evolved strategies to counteract the antiviral effects of IFN-α.

## The interferon system

IFNs are classified into type I IFNs, which comprise IFN-α and -β, and type II IFN, or IFN-γ. Type I IFNs are produced by leukocytes, fibroblasts, epithelial cells and other cell types and type II IFN is produced by T lymphocytes and natural killer cells. In the blood, the principal IFN-α producing cells are plasmacytoid[7,8] and non-plasmacytoid dendritic cells.[9] During HBV infection IFN-α is produced in the liver by infiltrating mononuclear cells, sinusoidal cells, Kupffer cells and, to a lesser extent, by hepatocytes.[10–12]

Over the past several years, the complete signal transduction pathway from the IFN receptors to the nucleus has been identified (reviewed in Heim[13]), and viral interference with IFN-induced signalling can now be studied in detail (Fig. 54.1). Type I IFNs bind to heterodimeric type I IFN receptors consisting of IFN-α receptor I and II (IFNARI and IFNARII). Ligand binding results in activation of two cytoplasmic protein tyrosine kinases associated with IFNARI and IFNARII, Tyk2 and Jak1. The activated kinases then phosphorylate tyrosine residues of the receptors. These phosphotyrosines are consecutively bound by the SH2 domains of signal transducer and activator of transcription 1 (Stat1), Stat2 and Stat3. The STATs are then tyrosine phosphorylated and form hetero- or homodimers through mutual SH2 domain–phosphotyrosine interactions. Stat3 and Stat1 form homodimers, designated serum inducible factor A (SIF-A) and SIF-C, respectively, and a Stat1-Stat3 heterodimer, SIF-B. Stat1 can also dimerize with Stat2, and this Stat1-Stat2 heterodimer associates with a third DNA-binding protein, ISGF3γ-p48, to form ISGF3. Binding of these STAT factors to their cognate sequences in the promoter regions of target genes results in enhanced transcription of a set of genes collectively termed IFN-stimulated genes (ISGs). A number of regulatory mechanisms of the Jak-STAT signal transduction pathway have been identified. The activity of the Jak kinases is controlled by phosphatases such as SHP1, SHP2, CD45, PTP1B and TCPTP

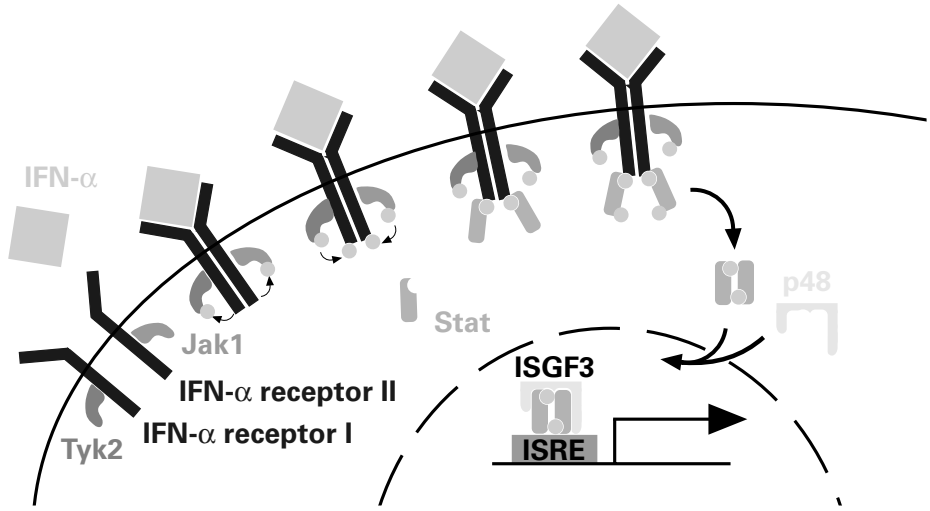

**Figure 54.1** The Jak-STAT pathway. IFN-α binds to heterodimeric type I IFN receptors consisting of IFNARI and IFNARII. Ligand binding results in activation of the cytoplasmic receptor-associated protein tyrosine kinases Tyk2 and Jak1. The activated kinases then phosphorylate tyrosine residues of the receptors. These phosphotyrosines are consecutively bound by the SH2 domains of STATs. The STATs are then tyrosine phosphorylated and form hetero- or homodimers through mutual SH2 domain–phosphotyrosine interactions. Stat1-Stat2 heterodimers associate with a third DNA-binding protein, ISGF3γ-p48, to form ISGF3. Binding of STAT factors to their cognate sequences in the promoter regions of target genes results in enhanced gene transcription.

and by suppressors of cytokine signalling (SOCS).[14] STAT proteins can be inactivated by dephosphorylation in the cytoplasm or the nucleus.[14] Furthermore, binding of Stat1 or Stat3 dimers to the response elements in the promoters of target genes can be inhibited by PIAS1 (protein inhibitor of activated Stat1) or PIAS3, respectively.[14] At any of the steps outlined above, viral proteins could interfere with the Jak-STAT pathway and inhibit induction of antiviral effector proteins.

In general, the direct intracellular antiviral effects of IFNs are mediated by several effector proteins, including double-stranded RNA-activated protein kinase (PKR), MxA GTPase, 2′-5′ oligoadenylate synthetase (2′-5′ OAS) and RNaseL.[15] In the case of HBV and HCV infection, the relevant antiviral effector systems have not yet been identified. As mentioned above, IFNs also have immunomodulatory effects. For example, they upregulate MHC class I and II expression, which leads to enhanced antigen presentation and stimulation of acquired immunity. The relative contribution of direct intracellular antiviral effects and indirect immunostimulatory effects in the elimination of HBV and HCV infections is unknown.

Interestingly, studies performed in HBV transgenic mice suggested that inflammatory cytokines released in the context of a cellular immune response, namely tumour necrosis factor (TNF)-α and IFN-γ, can block HBV replication by a non-cytolytic mechanism.[16] HBV clearance without destruction of infected hepatocytes has been documented in acutely infected chimpanzees as well, further supporting this concept.[17] The molecular mechanisms responsible for cytokine-mediated viral clearance are currently being investigated (reviewed in Guidotti and Chisari.[18]). Studies performed with the duck hepatitis B virus (DHBV), a virus closely related to HBV, have shown that recombinant duck IFN-α inhibits DHBV replication *in vitro* and *in vivo*.[19,20] This model may allow further investigation of the IFN-sensitive steps of the viral life-cycle.[21]

IFN-α inhibits HCV replication in primary human hepatocyte cultures,[22] demonstrating a direct antiviral effect *in vitro*. In addition, studies recently performed using Huh-7 cells harbouring HCV replicons demonstrated that IFN-α can efficiently inhibit viral RNA replication[5,23–27] (Fig. 54.2). These studies showed surprisingly low 50% inhibitory concentrations ($IC_{50}$) of 0.5–3 IU IFN-α/mL. However, it is presently unknown how closely the replicon system reflects the IFN sensitivity of a naturally infected hepatocyte. Interestingly, in the replicon system IFN-γ has a profound inhibitory effect as well.[28] Therefore, the replicon system is a powerful tool to analyze the antiviral activity of cytokines and to systematically dissect their mechanism of action as well as the cellular effector functions involved. In this context, it was shown that MxA is not involved in the inhibition of HCV RNA replication by IFN-α.[24] In addition, PKR does not seem to be a critical effector protein.[26] Studies investigating other IFN-α effector pathways are currently ongoing in several laboratories. The availability of additional cell lines harbouring

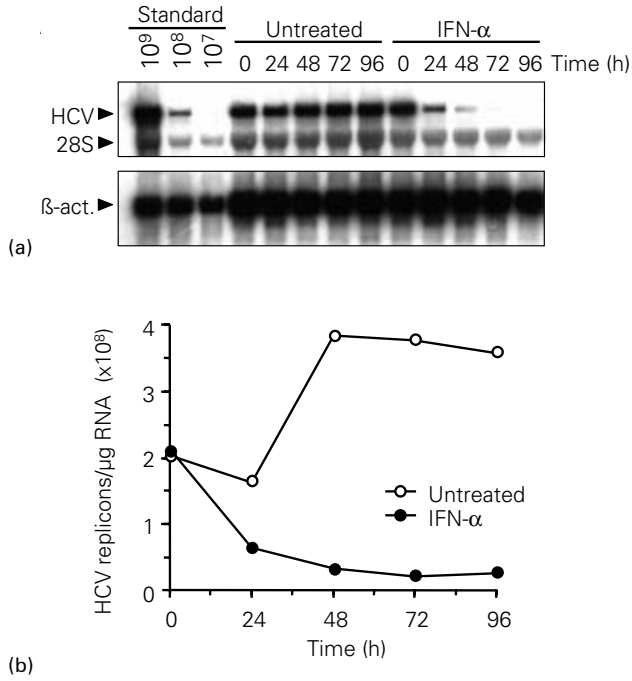

**Figure 54.2** IFN-α inhibits HCV subgenomic RNA replication. (a) Northern blot analysis of a Huh-7 cell line harbouring a subgenomic HCV replicon. Cells were incubated for the indicated times in the absence or presence of 1000 U/mL IFN-α. Total RNA was hybridized with HCV- and β-actin-specific radioactive probes. (b) Quantitative analysis of the data shown in (a). (Adapted from Frese *et al.*,[24] with permission.)

HCV replicons[29] and of replicons derived from different genotypes[30] will allow further investigation of these issues.

## Interaction of HBV with the IFN system

Only a limited number of studies have addressed a possible interference of HBV with the IFN system. In this context, expression of the HBV polymerase terminal protein has been reported to result in impaired activation of ISGF3.[31,32] Studies performed more recently in stably transfected Huh-7 human hepatoma cells suggested a selective inhibition of IFN-induced MxA protein expression by the HBV core protein.[33]

## Interaction of HCV with the IFN system

Perhaps the strongest evidence for the role of specific viral factors in determining the IFN sensitivity of HCV comes from the clinical use of IFN-α. Sustained virological response rates to PEG-IFN-α plus ribavirin combination therapy differ significantly between patients infected with HCV genotype 1 (40–50%) and genotypes 2 or 3 (~80%).[34–36] Indeed, among the viral and patient-related factors involved in determining response rates, the HCV genotype is a major factor (reviewed in Pawlotsky[37] and Zeuzem[38]). However, the biological basis for this difference is thus far unknown.

Among Flaviviridae family members, bovine viral diarrhoea virus (BVDV), a prototypical member of the pestivirus genus, was found to interfere with the IFN system to establish persistent infection.[39,40] Recent evidence suggests that the N-terminal autoprotease $N^{pro}$ of classical swine fever virus (CSFV), another pestivirus, inhibits innate immune responses.[41] With respect to members of the flavivirus genus, dengue virus non-structural protein 4B (NS4B) was recently found to inhibit IFN signalling.[42] Thus, pestiviruses and flaviviruses use different mechanisms to counteract innate immune responses, including the IFN system, and to establish productive infection.

Different mechanisms potentially underlying IFN resistance of HCV have been described. In principle, viral gene products could interfere with IFN-induced intracellular signal transduction, thereby inhibiting induction of a number of antiviral effector proteins. Alternatively, the virus could have developed defence strategies against these cellular effector mechanisms.

### Interference of HCV with IFN signalling

Numerous examples of viral interference with IFN signal transduction have been reported. Vaccinia virus, for example, encodes a soluble type I IFN receptor which neutralizes IFN before it can bind to the cellular receptor.[43] Human cytomegalovirus was reported to inhibit IFN-γ-induced Jak-STAT signalling, probably by enhancing Jak1 protein degradation.[44]

The effect of HCV on IFN-α-induced signalling through the Jak-STAT pathway was investigated using continuous human cell lines inducibly expressing HCV structural and non-structural proteins.[45] In these cells, the expression of HCV proteins can be regulated by the concentration of tetracycline in the culture medium.[46,47] As shown in Figure 54.3,[45] IFN-α-induced STAT activation, as examined by electrophoretic mobility shift assay (EMSA), was readily detectable only in cells cultured in the presence of tetracycline, i.e. in cells where viral protein expression has been repressed by tetracycline. If these cells were cultured in the absence of tetracycline, i.e. when they expressed HCV proteins, IFN-α-induced STAT activation was inhibited. Further experiments demonstrated that inhibition of Jak-STAT signalling occurred downstream of STAT tyrosine phosphorylation and resulted in reduced upregulation of IFN-α target genes,[45] as well as in an inhibition of antiviral IFN effector functions.[48] Interestingly, PKR activity was not influenced by the expression of HCV proteins in these cell lines (see below).

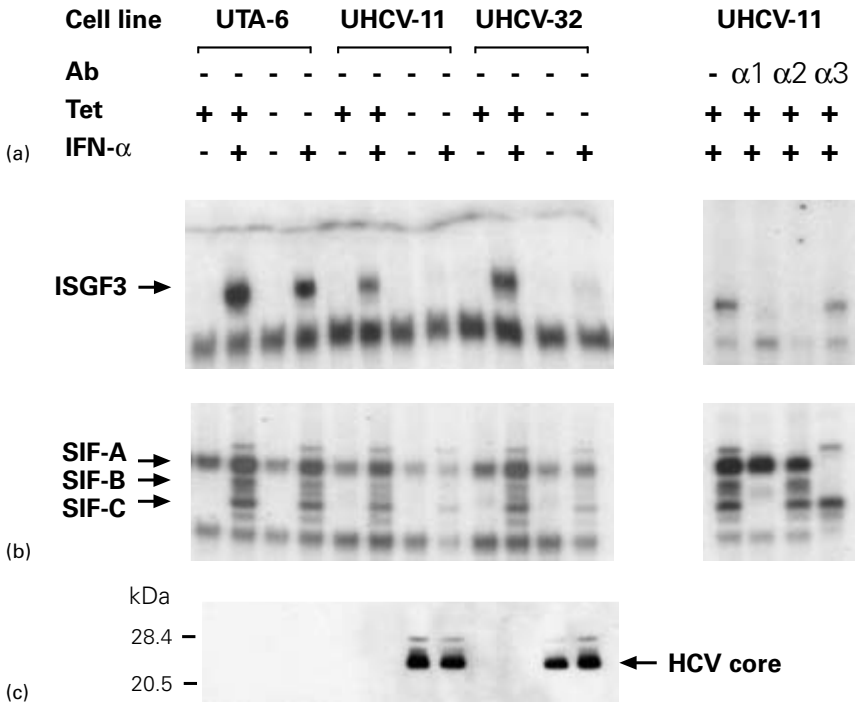

**Figure 54.3** Inhibition of IFN signalling through the Jak-STAT pathway in cells expressing HCV proteins. UTA-6, UHCV-11 and UHCV-32 cells were cultured in the presence or absence of tetracycline and then either left untreated or stimulated for 30 minutes with 500 U/mL IFN-α, as indicated. (a) Electrophoretic mobility shift assay (EMSA) with the ISRE oligonucleotide probe. The position of ISGF3 is indicated by an arrow. Supershift experiments shown in (a) on the right confirmed the identity of the induced shift as ISGF3. (b) The same nuclear extracts were tested with an m67 oligonucleotide probe. The positions of SIF-A, SIF-B and SIF-C are indicated. (c) Western blot with the monoclonal antibody C7-50 against the HCV core protein with the corresponding cytoplasmic extracts. Molecular weight markers in kDa are indicated on the left. (Adapted from Heim *et al*.,[45] with permission.)

It was recently found that transgenic mice expressing the HCV polyprotein under the transcriptional control of an α1-antitrypsin promotor had a strong inhibition of IFN-α-induced Jak-STAT signalling in their liver cells.[49] As previously observed in the inducible cell lines, inhibition occurred downstream of STAT phosphorylation. This resulted in an enhanced susceptibility of the transgenic mice to infection with a hepatotropic strain of lymphocytic choriomeningitis virus, impressively demonstrating the biological consequences of the observed inhibition of IFN signalling.

These findings were based on experiments performed in heterologous expression systems which may not appropriately reflect natural HCV infection. However, an inhibition of IFN-α-induced Jak-STAT signalling was found also in liver biopsies from patients with chronic hepatitis C.[50] As observed in the cell lines and in the transgenic mice, inhibition occurred downstream of STAT phosphorylation. In addition, it was found that protein phosphatase 2A (PP2A) is upregulated in liver extracts from HCV transgenic mice and in liver biopsies from patients with chronic hepatitis C. Upregulation of PP2A resulted in hypomethylation of Stat1, a consecutively increased association of Stat1 with its inhibitor PIAS1, and a reduced transcriptional activation of IFN-α target genes. Taken together, these results indicate that HCV may interfere with IFN-α-induced Jak-STAT signalling by a complex mechanism involving the upregulation of PP2A, a cellular phosphatase, and the increased binding of activated STAT1 by its negative regulator PIAS1.

Recently, Foy *et al*. have provided evidence for interference of HCV with a key component of the signalling pathways that activate the IFN system, namely IFN regulatory factor 3 (IRF-3).[51] IRFs are a family of transcription factors that share homology in their DNA binding domain and bind to similar DNA motifs. There are nine mammalian members of the family, termed IRF-1 to IRF-9.[52] Among them, IRF-3 and IRF-7 have been identified recently as key regulators of the induction of type I IFNs. IRF-3 is expressed constitutively in all cell types, and in uninfected cells resides in the cytoplasm. Upon virus infection, IRF-3 is activated by phosphorylation by a virus-activated kinase (VAK). Interestingly, the IκB kinase (IKK)-related kinases IKKε and TANK-binding kinase 1 (TBK1) have been identified as components of VAK.[53] This modification permits IRF-3 dimerization, nuclear translocation, and activation of the IFN-β and IFN-α1 genes (Fig. 54.4).[54] IFN-β and IFN-α1 are secreted and bind to IFN-α/β receptors in an autocrine or paracrine way. As a consequence, the Jak-STAT pathway is activated, and STAT-containing transcription factors such as ISGF3 transcriptionally activate a number of target genes, collectively called IFN-stimulated genes (ISGs). Among these ISGs is IRF-7. In the presence of a viral infection, *de novo* produced IRF-7 is again phosphorylated by VAK, translocates to the nucleus, forms a dimer with IRF-3, and transcriptionally stimulates additional members of the large family of IFN-α genes (Fig. 54.4). This feedback loop results in an enormous amplification of the signal, and leads to massive production of type I

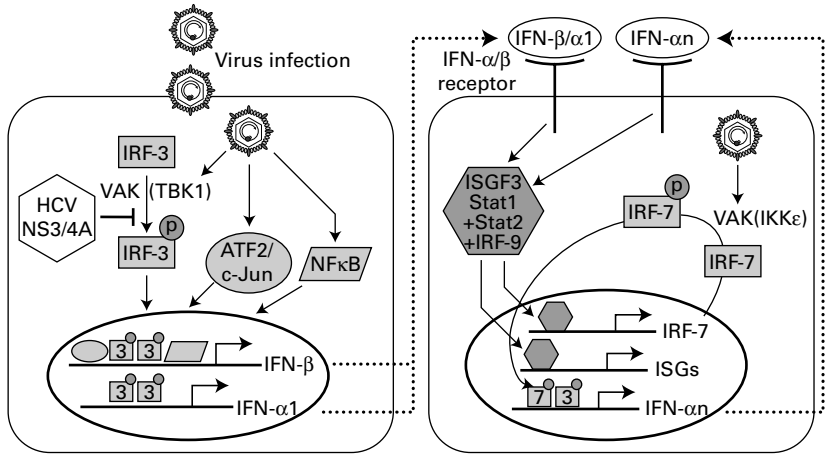

**Figure 54.4** Activation of the IFN system by viral infections. Infection of cells by viruses results in the activation of three transcription factors that are crucial for transcriptional activation of the IFN-β gene: nuclear factor κB (NFκB), ATF2/c-Jun and IRF-3. IRF-3 is activated through serine/threonine phosphorylation by virus-activated kinase (VAK). Secretion of IFN-β (and IFN-α1) and binding to IFN-α/β receptors starts an amplification mechanism through the STAT and IRF-7 dependent activation of additional IFN genes. This positive feedback system is controlled because ongoing production of IFNs requires the phosphorylation of IRF-7, and IRF-7 phosphorylation requires the activation VAK by viruses. (From Heim[54] with permission.)

IFNs. The system is controlled by three crucial features of IFR-7: expression of the IRF-7 gene is totally dependent on IFN-α/β-induced ISGF3 signalling, the IRF-7 protein has a short half-life, and IRF-7 (as well as IRF-3) must be activated by virus-induced phosphorylation.[55] These features guarantee that the activation of the IFN-induced antiviral defence system is terminated when cells are cleared from the viral infection.

Using Huh-7 cells harbouring HCV replicons and a panel of tetracycline-regulated cell lines inducibly expressing HCV proteins, Foy *et al*. mapped the inhibitory effect of HCV to the serine protease activity of the NS3-4A complex.[51] This raises the interesting possibility that novel antiviral agents targeting the HCV serine protease[56] may also restore responsiveness of the IRF-3 pathway. It will be interesting to investigate which component of the IRF-3 pathway is targeted by the HCV serine protease.

## Interference of HCV with PKR

As discussed above, HCV could also interfere with IFN effector functions. PKR has been most extensively studied in this regard. The HCV non-structural protein 5A (NS5A) and the envelope glycoprotein E2 have been reported to interfere with PKR activity. NS5A is a membrane-bound serine phosphoprotein of unknown structure and function.[57–59] A role for NS5A in modulating the IFN response was first suggested by studies performed in Japan by Enomoto *et al*. These investigators found a correlation between mutations within a discrete region of NS5A (HCV amino acid positions 2209–2248), termed IFN sensitivity determining region (ISDR), and a favourable response to IFN-α therapy[60,61] (Fig. 54.5). These studies demonstrated that strains closely matching the prototype HCV genotype 1b (HCV-J) ISDR sequence correlated with IFN resistance. These findings were largely confirmed in Japan, but not in Europe and North America (reviewed in Bréchot[62] and Herion and Hoofnagle[63]). The reasons for this discrepancy are not understood, but may involve both differences in doses and regimens of IFN treatment and the low prevalence of 'mutant type' HCV genotype 1b isolates in Western countries.[64] Even if a recent meta-analysis of published data seems to confirm an association of specific ISDR sequences with the IFN response,[65] this remains a controversial issue that has not translated into clinically applicable predictors. The same is true for other regions of NS5A that have been associated with the response to IFN therapy, such as a variable region in the C-terminal domain of NS5A termed V3[66–68] (Fig. 54.6).[5,57,60,61,69–71]

Interestingly, however, an interaction with and repression of the catalytic activity of PKR by NS5A has been found by biochemical, transfection and yeast functional analyses.[72] Mutations within the ISDR that were observed in clinically IFN-sensitive genotype 1b strains disrupted the ability of NS5A to interact with and repress PKR activity, supporting the notion that NS5A mediates HCV resistance to IFN through downregulation of PKR.[69] In addition, disruption of PKR-dependent translational control and apoptotic programmes by NS5A have been suggested to confer oncogenic potential to HCV.[73] Also, evidence has been provided for an src homology 3 (SH3) domain-dependent interaction of NS5A with growth factor receptor-bound protein 2 (Grb2) adaptor protein, which could interfere with mitogenic signal transduction pathways.[74] As growth factor signalling may be linked to IFN signalling pathways,[75] one could speculate that NS5A binding to Grb2 represents another mechanism by which HCV induces IFN resistance. Of note, this mechanism appears to be non-essential for viral replication *in vitro*, because replicons

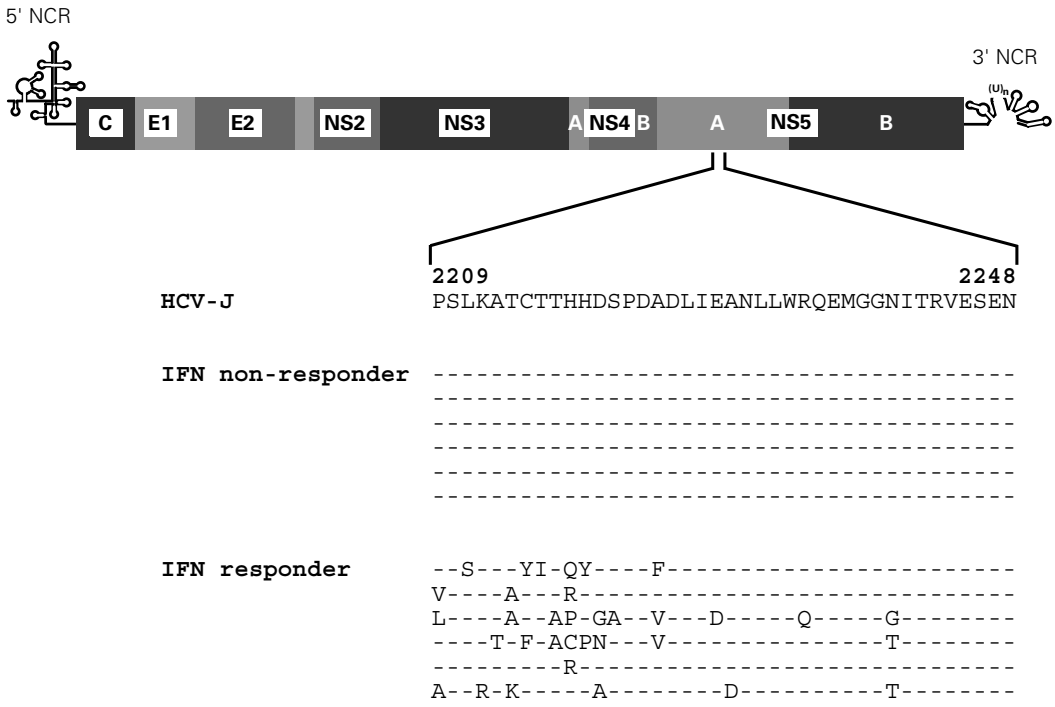

**Figure 54.5** The HCV ISDR. Examples of sequences of HCV amino acid residues 2209–2248 within the NS5A protein in genotype 1b-infected IFN-α non-responders and responders. Amino acid residues are indicated by the standard single-letter code. Dashes indicate residues identical to those in the HCV-J prototype genotype 1b sequence. Patients with 'mutant type' ISDR sequences (≥4 amino acid substitutions compared with the prototype sequence) showed a favourable response to IFN-α therapy, whereas patients with wild-type ISDR sequences did not respond.[60,61]

with a deletion of the ISDR and part of the PKR-binding domain replicate efficiently in cell culture.[5]

Expression of the NS5A protein in cultured cells resulted in a partial resistance to the antiviral effects of IFN-α against IFN-sensitive viruses, such as vesicular stomatitis virus (VSV) or encephalomyocarditis virus (EMCV).[73,76–80] This correlated with a partial attenuation of IFN-α- and -β-induced gene expression in cell lines expressing NS5A.[81] However, this effect was found to be independent of the ISDR sequence in three studies.[77–79] Similarly, NS5A sequences examined in the replicon system thus far do not correlate with the susceptibility to the inhibitory effect of IFN-α.[5,25] In addition, in line with observations made earlier in the context of the entire HCV polyprotein,[48] Podevin *et al.* found no effect of NS5A expression on PKR activity in Huh-7 cells consti-

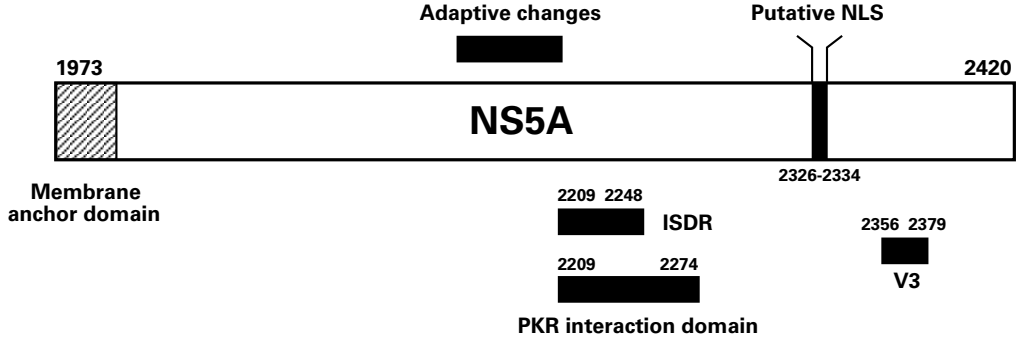

**Figure 54.6** Overview of the HCV NS5A protein. Amino acid positions are given relative to the HCV polyprotein. The N-terminal amphipathic α-helix which mediates membrane association of NS5A,[57] the region where cell culture-adaptive changes have been found to cluster in the replicon system,[5,70] the so-called IFN sensitivity-determining region (ISDR),[60,61] the double-stranded RNA-activated protein kinase (PKR) interaction domain,[69] the putative nuclear localization signal (NLS),[71] and variable region 3 (V3)[66] are highlighted.

tutively expressing different NS5A sequences.[78] Therefore, the inhibitory effect of NS5A may be mediated by PKR-independent mechanisms.

In this context, Polyak *et al*. recently reported an upregulation of the proinflammatory chemokine interleukin (IL)-8 in HeLa cells inducibly expressing NS5A.[82] These findings were subsequently confirmed by microarray studies.[83] IL-8 has earlier been shown to inhibit the antiviral actions of IFN-α *in vitro*, thus suggesting a novel mechanism to counteract the IFN system. Interestingly, pretreatment serum IL-8 levels were found to correlate with the response to IFN-α therapy in patients with chronic hepatitis C.[84]

The HCV envelope glycoprotein E2 contains a sequence identical to phosphorylation sites of PKR and the PKR target eIF2α. Starting from this observation, Taylor *et al*. described an interaction between E2 and PKR that resulted in an inhibition of the kinase activity of PKR and interference with its inhibitory effect on protein synthesis and cell growth.[85] The relevance of these observations for the natural history of HCV infection is not yet clear, but viral defence strategies targeting the effector mechanisms of IFN-induced antiviral activities could play an important role in viral pathogenesis.

## Conclusions

IFN-α is a major component of the innate immune response against viral infections including HBV and HCV. In clinical practice it is widely used for the treatment of both chronic hepatitis B and C. The mechanism of action and the IFN-α effector functions involved are only partially understood. There is evidence that HBV and HCV protect themselves against IFNs through interference with IFN production, signalling and antiviral effector systems. These and other as yet unknown mechanisms could contribute to the resistance to IFN-α therapy observed in many patients and may represent a general escape strategy of HBV and HCV contributing to viral persistence and pathogenesis of chronic liver disease. A better understanding of the interactions between these viruses and the IFN system may ultimately result in more effective therapies against HBV and HCV, which are leading causes of chronic hepatitis, liver cirrhosis and HCC worldwide.

# Chapter 55
# New *in vitro* testing systems for hepatitis B and C viruses

David Durantel, Olivier Hantz, Christian Trepo, Fabien Zoulim

In recent years, considerable efforts have been made to develop *in vitro* testing systems for the study of hepatitis B virus (HBV) and hepatitis C virus (HCV). These *in vitro* systems are meant to contribute to the better understanding of the biology of both viruses in order to identify and utilize new molecular targets for antiviral therapy. But these systems are also meant to study and understand the viral variability and its role in pathogenesis, as well as the causes and mechanisms of viral resistance. In this chapter, some of these testing systems will be described. Molecular assays designed to quantitatively measure the viral load, determine the genotypes, or detect mutations within clinical HBV or HCV strains will not be described as they are described elsewhere in this book.

## HBV

The *in vitro* study of HBV replication has become of critical importance for the elucidation of specific steps of the viral life-cycle, including the discovery of the cellular receptors for viral entry and cellular determinants involved in covalently closed circular DNA (cccDNA) formation, as well as the determination of the yet unknown role of the HBV X-protein. Furthermore, these *in vitro* studies have become of clinical importance, with the development of new nucleoside analogues and the subsequent selection of drug-resistant mutants, to determine the replication capacity and drug susceptibility of clinical isolates.

### Infection assays

#### *Human primary hepatocytes*

Human primary hepatocytes represent a unique system that allows the study of the full HBV replication cycle, including the early steps of virus–cell interaction, viral entry, or cccDNA formation. The demonstration of a full HBV replication cycle in human primary hepatocytes of adult or fetal origin was demonstrated by several groups in the late 1980s and early 1990s.[1–4] This study system allowed the study of specific antiviral targets such as virus–cell interaction and its neutralization by anti-envelope monoclonal antibodies.[5,6] As human primary hepatocytes are more closely related to normal hepatocytes than hepatoma cell lines, this system presents some interest for the analysis of the metabolism of nucleoside analogues and the study of their anti-HBV activity.

As an example, we have evaluated the anti-HBV activity of β-L-Fd4C, an L-nucleoside analogue of deoxycytidine, in human primary hepatocytes.[7] First, we showed that this compound did not increase lactic acid production by comparison with control culture and lamivudine-treated hepatocytes, suggesting that it did not significantly affect mitochondrial metabolism, at least in our experimental conditions. This was in agreement with observations made *in vitro* in human hepatoma cell lines, primary duck hepatocytes, and in infected ducks and woodchucks, showing a good therapeutic index.[8,9] In a 'curative' protocol, where drugs were administered for 7 days starting from day 8 after virus inoculation to day 15, the analysis of intracellular viral DNA at the end of treatment showed a dose-dependent inhibition of the synthesis of viral DNA replicative intermediates by the two compounds (Fig. 55.1). In this experimental protocol, at 0.1 and 1 μM, β-L-Fd4C inhibited viral replication more significantly than lamivudine (Fig. 55.1). However, even at the highest concentration of β-L-Fd4C, viral DNA was not cleared from infected cells. These observations are consistent with the greater effect of β-L-Fd4C d4C compared with lamivudine on the hepadnavirus reverse transcriptase hepadnavirus genome replication in duck primary hepatocytes, human hepatoma cell lines and *in vivo* in animals.[8,9] The lack of viral clearance, even with long-term administration of a potent reverse transcriptase inhibitor, has been observed previously in primary duck and woodchuck hepatocytes. It emphasizes that long-term antiviral treatment is required to control

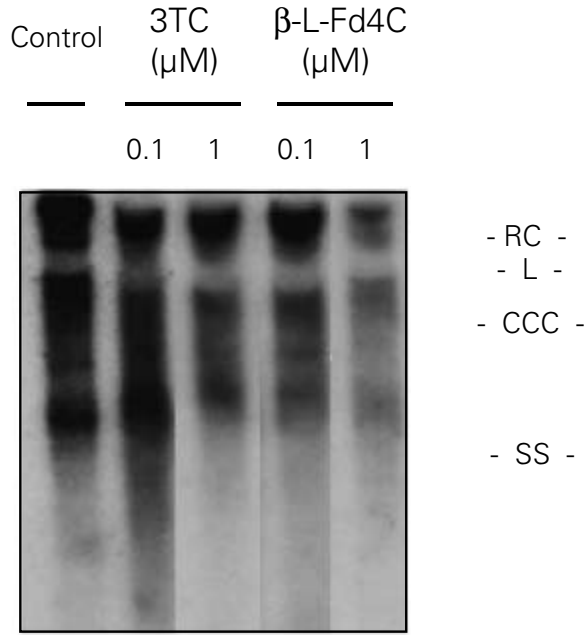

**Figure 55.1** HBV DNA synthesis in human primary hepatocytes and its inhibition by nucleoside analogues. Human primary hepatocytes were inoculated with an inoculum derived from the supernatant of the 2.2.1.5 cell line. Cells were then treated with lamivudine or elvucitabine from day 4 post-inoculation to day 12. Viral DNA replicative intermediates were analyzed after gel electrophoresis and Southern blot analysis. Results were compared with untreated control cells.

viral replication in the absence of a significant immune response directed against the residual infected cells and/or in the absence of hepatocyte turnover allowing the renewal of the infected liver with non-infected hepatocytes. The study of HBV replication when β-L-Fd4C or lamivudine were administered prior to virus inoculation until day 4, showed that β-L-Fd4C and lamivudine inhibited viral replication in a dose-dependent manner and delayed the time of detection of viral replicative intermediates by comparison with the control cultures. Interestingly, β-L-Fd4C at 1 μM inhibited viral replication more profoundly than lamivudine and its suppressive effect was maintained 12 days after cessation of treatment (until day 16 post-inoculation). Moreover, these results were confirmed by the study of hepatitis B surface antigen (HBsAg) expression and secretion in cell supernatants, which was lower in β-L-Fd4C-treated cells than in lamivudine-treated cultures. These results, in agreement with those obtained in primary duck hepatocyte cultures and in experimentally infected ducklings, suggest that neither lamivudine nor β-L-Fd4C could prevent the initial formation of cccDNA, but that the inhibition of viral replication by β-L-Fd4C resulted in a delay in viral cccDNA formation and in a decrease in viral protein expression. This suggests that although β-L-Fd4C and lamivudine would not prevent the infection of hepatocytes by the residual circulating virions during therapy, the kinetics of viral clearance may be accelerated by β-L-Fd4C treatment.

Unfortunately, there are major limitations in the use of human primary hepatocytes. These include ethical regulation of access to human liver samples for research, as well as the accessibility of liver samples of sufficient quality to perform hepatocyte cultures. The development of easier systems to cultivate human primary hepatocytes or to immortalize HBV-susceptible hepatocytes may hasten the discovery of new anti-HBV agents and their evaluation prior to clinical trials.

### *Duck, woodchuck and tupaia primary hepatocytes*

Owing to readier availability, the use of animal primary hepatocyte cultures has been and still is of great importance for the better understanding of some biological features of HBV homologue viruses, including duck (DHBV) and woodchuck (WHV) hepatitis viruses, as well as the study of antiviral agents. The demonstration of a full DHBV and WHV replication cycle in primary hepatocytes was achieved by several groups in the late 1980s.[10–12] These systems subsequently enabled: (1) the identification of the DHBV receptor[13–16] and domains of the pre-S protein involved in the interaction with this receptor,[17–19] (2) study of the entry route,[20] and (3) study of early events of the DHBV cycle.[21] Notably, duck and woodchuck primary hepatocytes have made it possible to study different antivirals, including cytokines,[22–25] antisense molecules,[26] and analogues of nucleosides/nucleotides – 3TC (lamivudine), FTC (emtricitabine), L-FMAU (clevudine), PMEA (adefovir), PMPA (tenofovir), FLG and b-L-FD4C.[7,27–36] More precisely, they have allowed the measurement of the impact of antivirals on the formation of cccDNA, synthesis of intermediate DNA, or elimination of the intranucleus pool of cccDNA. For instance, it was shown that analogues of nucleosides/nucleotides were neither able to prevent cccDNA formation nor able to clear cccDNA from infected cells, even when used in combination.[29,33]

Beside duck and woodchuck primary hepatocyte cultures, primary hepatocytes (PTH) from the asian tree shrew *Tupaia belangeri* have gained increasing interest in recent years because of their susceptibility to HBV infection itself.[37,38] This *in vitro* model offers the possibility to study the cellular and viral determinants involved in binding, uptake, upcoating, nuclear transport and cccDNA formation. It was used to confirm that the current nucleoside analogues, lamivudine and adefovir, cannot completely prevent the initial formation of human HBV cccDNA upon infection of cells,[39] thus confirming the results obtained with other animal and human primary hepatocyte systems.

Moreover, it was shown that the woolly monkey hepatitis B virus, although less infectious for human primary hepatocytes, has a higher replication competence in PTH. This may pave the way to obtain adapted mutants with enhanced replication capacity in PTH as well as *in vivo* in animals to facilitate the study of the early steps of HBV replication.

### *HepaRG cells*

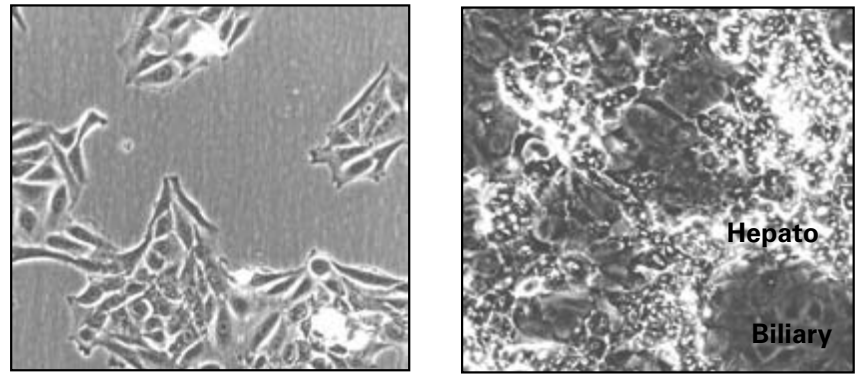
Among the numerous established human hepatoma cell lines, none were shown to be susceptible to HBV infection. Recently, a new cell line derived from a human hepatocellular carcinoma, called HepaRG, was generated.[40] This bipotent cell line is able to differentiate into two cell types after dimethyl sulphoxide-(DMSO) induced differentiation: hepatocytes and biliary-like cells (Fig. 55.2). After differentiation, the cell line exhibits liver-like organization, expresses specific hepatocyte enzymes and functions, and supports HBV infection as normal human primary hepatocyte cultures. Differentiation and infectability are maintained only when these cells are cultured in the presence of corticoids and 2% DMSO. It is worth noting that the HBV infectivity is enhanced by addition of polyethylene glycol (PEG) in the virus inoculum. All HBV replicative intermediates can be detected in infected cells, including viral cccDNA. The specificity of this HBV infection model was ascertained by both the neutralization capacity of HBV envelope protein-specific antibodies and the competition with an envelope-derived peptide. HepaRG cells therefore represent an interesting tool for analyzing further the mechanism of HBV entry, as well as the cellular and viral determinants involved in cccDNA formation and persistence during antiviral therapy. Moreover this cell line can be used to study the fitness of naturally occurring or drug-induced HBV mutants by performing competitive infection.

## Transfection and transduction assays

Although hepatoma cells, such as HepG2 and Huh7, cannot be efficiently infected by HBV, they are able to replicate and secrete the virus provided that the HBV genome is transfected or transduced into cells. Various vectors, including plasmidic and viral vectors, have been used to infect transiently or stably transformed hepatoma cells. These approaches are particularly important because the modification of HBV genome can be done by conventional molecular biology techniques. Thus, specific mutations associated with a particular phenotype *in vivo* (e.g. resistance to drug) can be transposed into these vectors and analyzed *in vitro*.

### *Classic transient transfection assays*

Until recently, the analysis of the phenotype of naturally occurring or drug-induced HBV mutants has relied either on PCR-mediated transfer of HBV genome cassettes or on site-directed mutagenesis within plasmids carrying 1.1 to 2 genome units of a well established replication-competent laboratory strain (Fig. 55.3). These plasmids contain the HBV genetic information necessary and sufficient to initiate the HBV intracellular replication cycle after transfection into cells. The synthesis of HBV pregenomic RNA can be driven either by the HBV promoter (i.e. 1.3 to 2 genome units) or a strong mammalian promoter (i.e. 1.1 genome unit). For example, the use of those genetically engineered plasmids allowed confirmation that the M204V/I ± L180M mutants selected in patients during antiviral therapy were indeed conferring resistance to lamivudine.[34,41–43] Despite its obvious utility to quickly characterize new mutations *in vitro*, the methods based on the exchange of a cassette or site-directed mutagenesis do not take into account the HBV genome variability existing in other parts of the genome. Moreover, the exchange of a cassette can cre-



(a) Undifferentiated HepaRG (b) Differentiated HepaRG

**Figure 55.2** HepaRG cell line. (a) HepaRG cells one day after seeding. (b) HepaRG cells 50 days after seeding and 30 days after the beginning of DMSO treatment. Hepatocyte-like and biliary-like cells are indicated

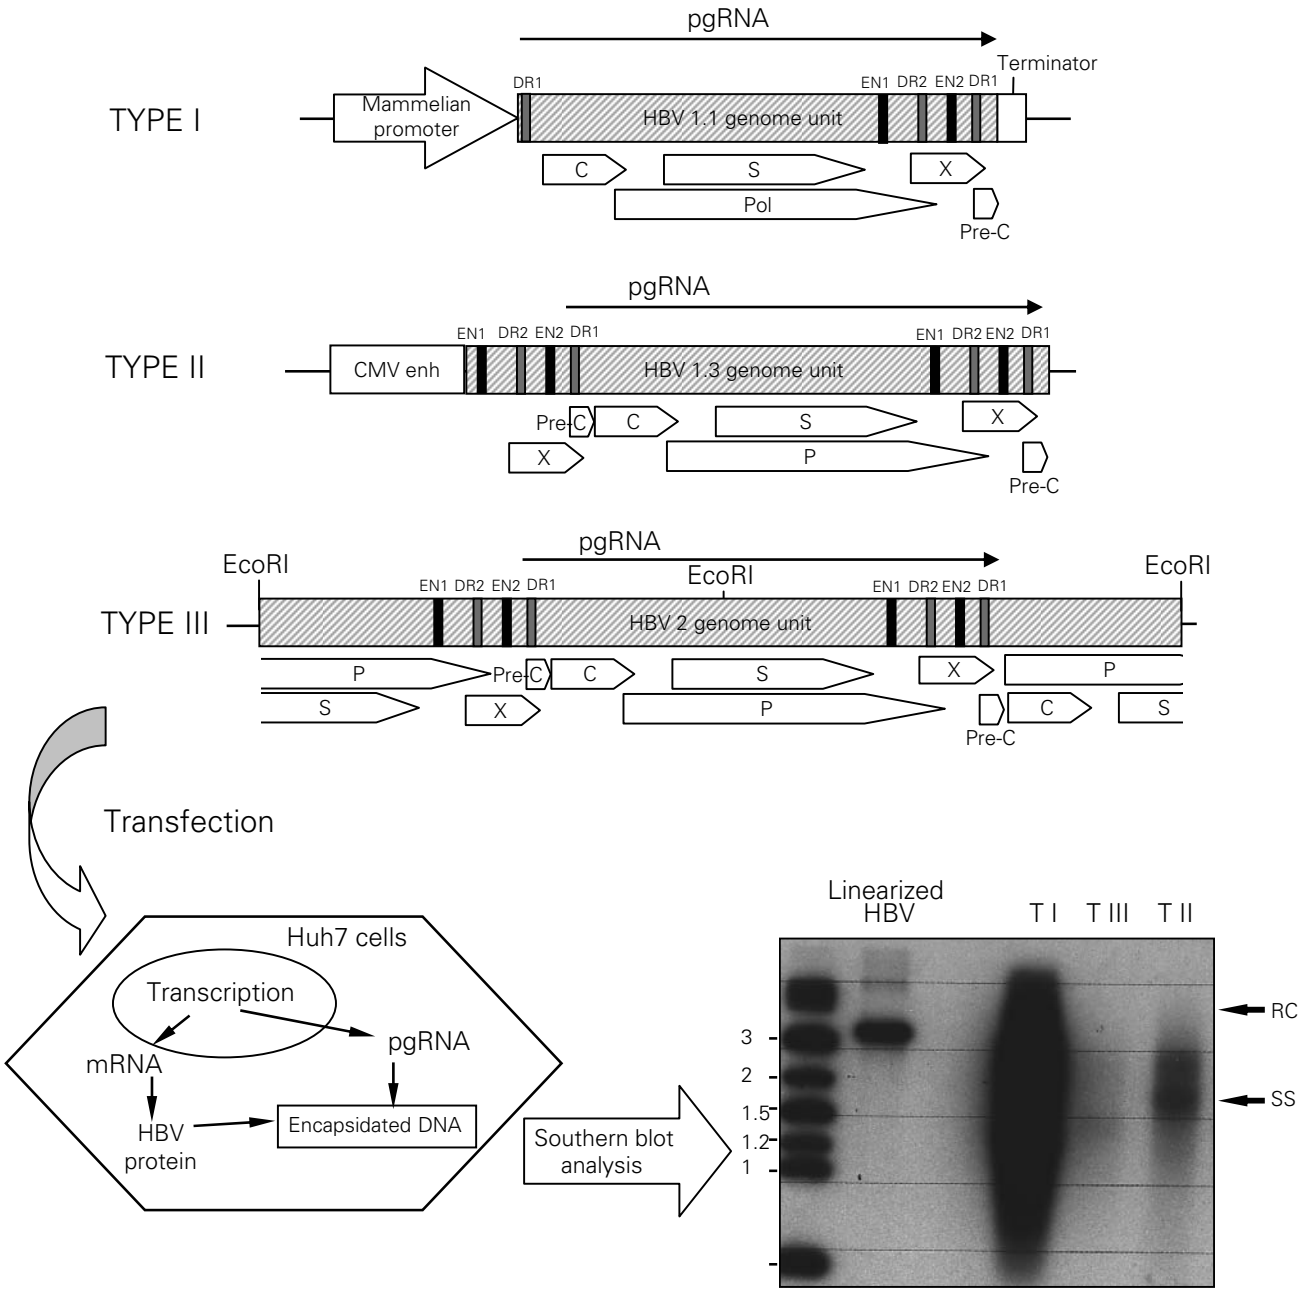


**Figure 55.3** Structure of plasmid loaded with HBV sequences and overall approach for a phenotypic study of HBV clinical isolates. Top: three types of plasmids containing 1.1, 1.3 or 2 HBV genome units are represented. Type I contains the minimal HBV length required for pgRNA synthesis. The synthesis of pgRNA is controlled by a strong mammalian promoter. Type II contains the sequence required for the synthesis of pgRNA plus the promoter of HBV. Thus, the synthesis of pgRNA is controlled by the homologous HBV promoter. Type III contains two head to tail genomes cloned using *Eco*RI restriction enzyme. Bottom: comparison of the amount of intracellular replicative HBV DNA intermediates produced after the transfection of Huh7 cells with the three type of vectors. An autoradiographic image resulting from Southern blot analysis of intracellular HBV DNA performed 4 days post-transfection is shown. A molecular marker was run on the right-hand side of the gel and radiolabelled for visualization after X-ray exposure.

ate non-natural chimeric genomes, especially when the genotype of the HBV to be studied is different from that installed in the receiver plasmid.

A vector-free method, meant to facilitate the analysis of naturally occurring HBV variants, was developed by Gunther *et al*.[44] This method relies on an original and efficient polymerase chain reaction (PCR) amplification of full-length HBV genomes isolated from patients. The amplicon obtained is then cut by a restriction enzyme that renders the extremities competent for the circular

closing of the molecules by ligation. The linear amplicon is tranfected into cells, and serves as a ccc-like DNA template for the initiation of the intracellular HBV replication after its repair and circularization by host enzyme. Depending on the nature of the HBV genome analyzed (e.g. particular mutants or genotypes), the level of replication obtained can be rather low. Therefore, this method remains interesting for fundamental research, but does not seem appropriate for clinical use as a standardized and transposable phenotypic assay, which requires solid replication levels.

### *Stably transfected cell line*

The absence of a productive HBV infection in most hepatoma cell lines is due to an inefficient entry process. Transfection of the HBV genetic information, as seen above, has made it possible to overcome this problem. However liposome-based transfection does not allow transfection of 100% of cells. To circumvent this problem, researchers have developed cell lines carrying HBV transgene in their genome that constitutively produces replicative viral DNA intermediates, mature Dane particles and high levels of viral antigens.[45,46] The first cell line obtained, called Hep G2 2.2.15, was widely used to study the effect of various antivirals, including cytokines,[47–50] analogues of nucleosides/nucleotides,[8,30,51–55] or inhibitors of morphogenesis.[56] Another cell line carrying lamivudine-resistant HBV genome was developed to study drugs potentially active against this mutant and more generally a cross-resistance phenomenon.[57] One could expect that for each new HBV mutant conferring a resistance to an antiviral, a cell line will be developed. However, the generation of such stably transfected cell lines is laborious and cannot be obtained for all cell types, as it implies most of the time the integration of the transgene into the host genome and this can be deleterious for the phenotype of the cells (e.g. HepaRG).

### *Baculovirus- and adenovirus-based assays*

Baculovirus and adenovirus vectors, which are able to penetrate very efficiently into mammalian cells including primary hepatocytes or hepatoma cells, have been used to improve the delivery of the HBV genetic material.

The antiviral properties of nucleoside analogues have been investigated *in vitro* in HepG2 cells infected with recombinant HBV baculovirus.[58] Different types of information can be obtained with the HBV baculovirus transduced HepG2 cells, as the levels of HBV replication can be significantly higher than those obtained from conventional HBV-expressing cell lines. Furthermore, the cultures can be manipulated and/or treated before or during the initiation of HBV genome replication. Interestingly, the high levels of HBV replication generated using this approach allow the rapid detection of HBV products including cccDNA from low numbers of HepG2 cells. The treatment of HBV baculovirus-infected HepG2 cells with 3TC resulted in an inhibition of HBV replication. The effect of 3TC on HBV replication was both dose- and time-dependent. As expected, levels of HBV transcripts and extracellular HBV antigens were not affected by 3TC. Importantly, the HBV baculovirus-HepG2 system made it possible to observe that HBV cccDNA levels are lower in cells treated with 3TC than in control cells. Delaney and colleagues[59] observed that the treatment of HepG2 cells prior to HBV baculovirus infection resulted in a slight increase in the efficacy of 3TC compared with treatments starting 24 hours post-infection. In this system, a detailed analysis confirmed that non-protein-associated relaxed circular HBV DNA, and particularly HBV cccDNA, are considerably more resistant to 3TC treatment than other forms of HBV DNA, including replicative intermediates and extracellular DNA. This system was then adapted to determine the cross-resistance profiles of drug-resistant HBV strains.[59] For these studies, novel recombinant HBV baculoviruses which encoded the L180M, M204I and L180M M204V drug resistance mutations were generated and used to examine the effects of these substitutions on viral sensitivity to lamivudine, penciclovir and adefovir. It was shown that (1) the L180M mutation confers resistance to penciclovir and partial resistance to lamivudine, (2) the M204I and L180M M204V confer high levels of resistance to lamivudine and penciclovir, and (3) adefovir is active against each of these mutants. The HBV baculovirus-infected HepG2 cells therefore represent an interesting study model for selected mutants. This model may be more tedious when considering the study of a large number of HBV mutants.

Adenovirus vectors have also been used to bypass the limiting receptor-mediated entry process and deliver HBV genome into hepatoma cell lines or primary hepatocyte cultures.[60] It was elegantly shown that adenovirus HBV vectors are able to transduce primary *Tupaia* hepatocytes (PTH) and lead to an infectious cycle including the formation of cccDNA.[60,61] This model may prove useful to gain insight in the cellular mechanism involved in cccDNA formation.

### *Rapid phenotypic assay*

In the case of HIV therapy, drug resistance testing is now recommended to guide the choice of new drug regimens after the first or multiple treatment failures.[62,63] In addition to genotypic assays, several phenotypic assays have been developed for HIV and are currently used in clinical practice to monitor drug resistance. Until recently, no standardized phenotypic drug susceptibility assays were available for HBV.

We have recently developed a new method for the cloning of HBV genomes isolated from patients into plasmidic vectors and defined the basis of one of the first phenotypic assays capable of assessing HBV drug susceptibility *in vitro* and evaluating new antivirals against clinical HBV strains (Durantel *et al*., submitted). The novel cloning technique enables the assembly of molecular clones, containing a 1.1 HBV genome unit, which allows the study of viral replication upon transfection of one clone or a mixture of clones into eukaryotic cells (Fig. 55.4). When transfected into Huh7 cells, these clones trigger the expression of pregenomic HBV RNA (pgRNA) under the control of heterologous promoters and therefore initiate the viral replication cycle including synthesis of intracellular viral DNA replicative intermediates. Thus, the initial synthesis of pgRNA is determined by the mammalian promoter of the vector and is identical from one vector to another irrespective of the HBV genome cloned. It ensures high levels of pgRNA synthesis and consequently a high level of viral DNA synthesis. This is particularly important in the context of a phenotypic assay which requires high levels of HBV DNA synthesis to facilitate the determination of drug susceptibility by standard procedures. This method enables the cloning of the whole HBV genome isolated from a given sample, and appears theoretically more appropriate to study complex situations, e.g. multiple mutations dispatched all over the genome or genotypically undefined phenotypes. Moreover, a multiclonal analysis (a mixture of at least 20 clones) enables the determination of the sensitivity of the viral population (i.e. quasi-species) to antiviral agents. This phenotypic assay was successfully applied to study the novel adefovir resistance (mutation N236T) associated with a viral breakthrough in a liver transplant patient.[64]

Another phenotypic assay was developed by Yang and colleagues.[65] This assay is based on a new plasmid vector that facilitates the cloning and expression of full-length HBV genomes amplified from the sera of chronic hepatitis B patients and enables efficient phenotypic analysis, i.e. drug susceptibility analysis of naturally occurring variants.

With the development of new anti-HBV molecules, these phenotypic drug susceptibility assays could become an important tool for the management of patients infected with resistant HBV isolates and for the evalua-

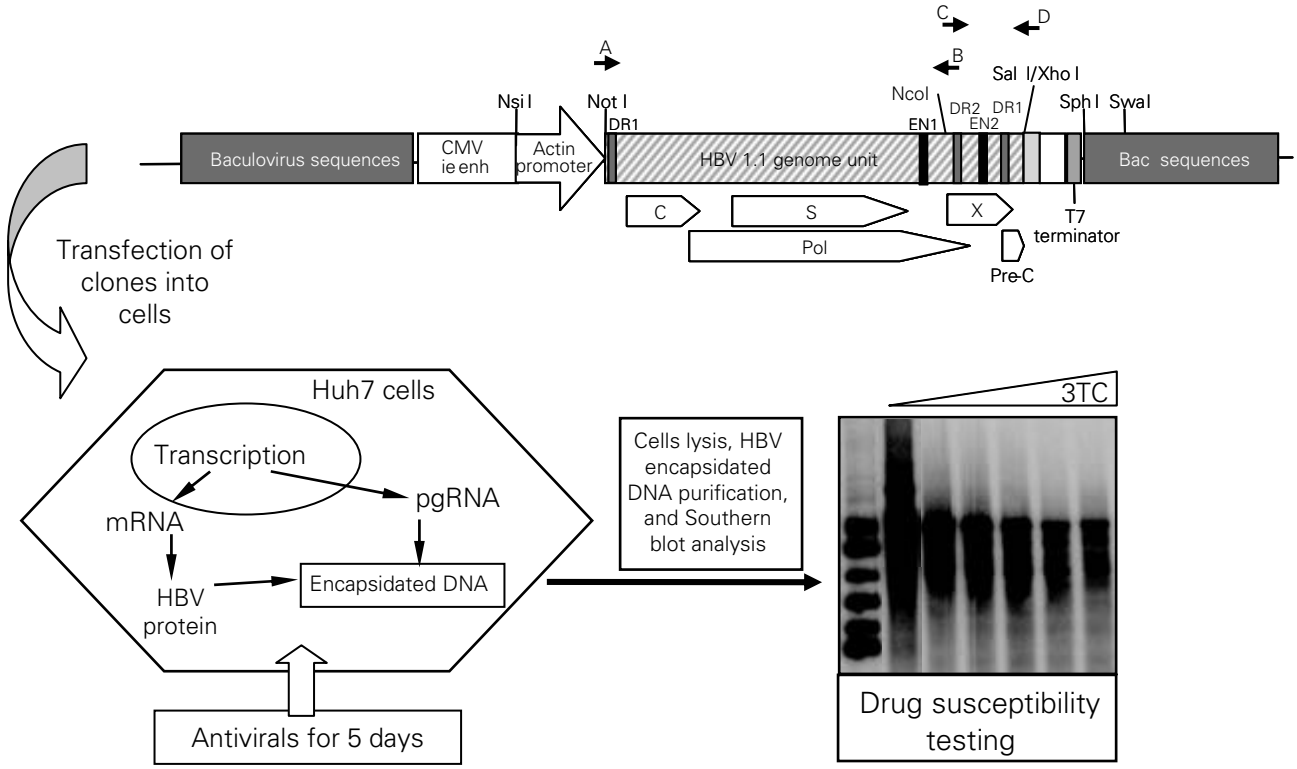

**Figure 55.4** Structure of plasmid used and overall approach for a phenotypic study (drug susceptibility testing) of HBV clinical isolates. A map of the vector pTriEX-HBV is presented at the top of the figure. The vector contains 1.1 HBV genome unit corresponding to the length of pgRNA. The primers A-B and C-D used to generate the two products which have been cloned to obtain the vector are also indicated. Vectors pTriEx-HBV were transfected into cells, in which they trigger HBV genome replication. Transfected cells were treated with drugs for 5 days before viral replicative intermediates were purified and subjected to Southern blot analysis. The $IC_{50s}$ and $IC_{90s}$ can be determined by phosphorimager analysis.

tion of new antivirals with clinical isolates circulating in the population.

### Polymerase assays

#### *DHBV polymerase assay*

The development of an *in vitro* acellular assay[66] that allowed the expression of an enzymatically active DHBV polymerase paved the way for the study of viral and cellular determinants required for reverse transcription, including (1) the formation of a complex between the 5′ epsilon structure on the pregenomic RNA, the viral polymerase and cellular chaperones, (2) the protein-primed initiation of reverse transcription, (3) the strand transfer and elongation of viral minus-strand DNA.[67–77] This system was useful to determine the mode of action of several nucleoside analogue triphosphates on the priming reaction or on the elongation of DNA synthesis.[8,34,78–80] Furthermore, the engineering of the drug-resistant mutants observed *in vivo* in HBV-infected patients in the DHBV polymerase system allowed further demonstration of their role in drug resistance and their susceptibility to new drugs.[34]

#### *HBV polymerase assay*

After the development of the DHBV reverse transcriptase assay, several attempts to develop such an assay for the human HBV polymerase were undertaken. Systems based on the expression of the enzyme in insect cells,[81,82] yeast,[83,84] bacteria,[85] or *in vitro*,[86] as well as a system based on the purification of nucleocapsid containing viral pregenomic RNA and polymerase,[87] were developed. However, these systems are not as robust as the *in vitro* system used to express DHBV polymerase, and further work is yet to be done to improve the expression of active HBV polymerase Nevertheless, the systems developed were critical to show that lamivudine-resistant polymerase mutants were indeed sensitive to adefovir diphosphate, and to determine that entecavir inhibits viral DNA synthesis through the inhibition of priming and by terminating the elongation of the DNA chain by the viral polymerase.[88]

Altogether, polymerase assays have been and still are of great use for the study of viral and cellular determinants required for reverse transcription, and the study of properties of mutant polymerases, including reverse transcription activity or drug susceptibility.

Table 55.1 summarizes the most relevant *in vitro* systems developed to study HBV.

## HCV

Since the molecular cloning of its genome in 1989,[89,90] research on HCV biology has been slowed down by the lack of an efficient cellular system able to efficiently replicate the virus. To circumvent this problem, numerous *in vitro* and *in cellulo* testing systems have been developed to enable the study of both fundamental and clinical aspects of HCV biology. The development of such systems aims at a better understanding of the replication of the virus to gain information on the hepatitis C disease, and also to study new molecular targets in order to identify new antiviral agents. With respect to clinical analysis, these assays are essentially meant to study and understand the viral variability in relation to pathogenesis, as well as the causes and mechanisms of viral resistance.

**Table 55.1** Summary of the most relevant testing systems for HBV

| System | Advantages | Limitations | Applications |
|---|---|---|---|
| Human primary hepatocyte | Full HBV replication cycle | Limited access | Receptor discovery<br>cccDNA formation |
| Tupaia hepatocytes | Full replication cycle | Low yield of replication<br>Non-human primate | Study of antiviral effects |
| HepaRG cells | Unlimited access<br>Full replication cycle | | Receptor discovery<br>cccDNA formation<br>Study of antiviral effects |
| Classic transient transfection | Post-transcriptional event | Absence of cccDNA | Role of single point mutations |
| Stably HBV transfected cell line | Post-transcriptional event | Absence of cccDNA | Study of antiviral effects |
| Baculovirus transduction | cccDNA formation | Construction of vectors | cccDNA studies<br>Study of antiviral effects<br>Drug resistance studies |
| Phenotypic assay | Rapid, polyclonal studies<br>Whole HBV genome | Absence of cccDNA | Drug resistance studies |
| Polymerase assay | Cell-free system | Difficulties of human HBV<br>Polymerase studies | Mechanism of action of inhibitors<br>Drug resistance studies |

## Infection assays

Despite considerable efforts made by all those involved in HCV research, no cellular systems capable of replicating HCV efficiently and reproducibly have been obtained to date. The development of such a system would be of great interest to better understand various aspects of the HCV life-cycle, including for instance viral entry and viral morphogenesis. An infection system would also be of great value to study biological differences between naturally occurring HCV strains in terms of infectivity, replication capacity or susceptibility to antivirals. The absence of a suitable cellular system for the replication of HCV is not due to the lack of research. Indeed, in the last decade several cell culture propagation systems, based on the infection of primary cell cultures or cell lines, have been described.

### *Primary hepatocytes*

The infection of primary hepatocytes from humans or chimpanzees has been tried extensively by several groups.[91–93] The infection is revealed by the presence of negative-stranded RNA intermediates and the production of neo-formed virions in the culture medium which were able to reinfect fresh cells. However, the level of replication is inconstant from one experiment to another and very low, as highly sensitive RT-PCR was needed for its detection. It is worth noting that such a system has nevertheless permitted the study of the antiviral effect of interferon (IFN)-α on the replication of HCV.[94] In addition to the lack of efficiency, the major drawback for the utilization of such infection systems resides in the difficulty of obtaining normal human or chimpanzee liver tissue. To overcome the latter, investigators have searched for new animal primary hepatocytes that are susceptible to HCV infection. In that respect, it was found that primary hepatocytes from the tree shrew *Tupaia belangeri* were susceptible to HCV.[95] As access to primary hepatocytes from *Tupaia* is facilitated by the rearing of this animal, this infection model may be of great interest to study HCV replication and other aspects of HCV biology.

### *Hepatoma cell lines*

Besides infection of primary hepatocytes, many attempts at infection have been undertaken with established cell lines of human origin. With respect to hepatoma cell lines, the most detailed results were obtained with the non-neoplastic cell line PH5CH.[96,97] In this cellular system, the replication of HCV is observed up to 100 days after the inoculation and is specifically inhibited by IFN-α. Moreover, a decrease in the complexity of the viral quasi-species used for the inoculation is noticed, suggesting that not all variants can replicate in these cells. Other hepatoma cell lines including WRL68, Huh7 and HepG2 were shown to be weakly susceptible to HCV infection.[98,99] Improvement of HepG2 infection was obtained by fusion of these cells to primary human hepatocytes prior to inoculation.[100] Altogether, infection of hepatoma cell lines remains inefficient and these systems are not yet really useful for many applications.

### *Other cell lines*

Although HCV is thought to be primarily a hepatotropic virus, an increasing body of evidence suggests that extrahepatic cells can be infected with the virus. Hence, it was found that several T-cell lines, including MT-2 and Molt-4, and the B-cell line Daudi, could be infected with HCV, although at a weak level.[101–105] The virus produced in these cells can reinfect fresh cells and can even be used to infect chimpanzee.[105] Another elegant attempt to replicate HCV is to cultivate *ex vivo* cells persistently infected by the virus. This has been done recently starting from non-Hodkin's B-cell lymphoma.[106] The cell line thus obtained is able to continuously produce infectious HCV virions in culture. This system may have some usefulness to produce analytical quantity of viral particles and therefore obtain information on virion structure.

All the systems described above are useful for performing some studies, such as infectivity experiments or analysis of the effect of some inhibitors/antivirals, but are not yet suitable for routine experiments and the elaboration of proper *in vitro* testing assays. To date, none of these systems has been used, for instance, to study the replication fitness or *in vitro* drug susceptibility of clinical strains of HCV, including treatment-escaping mutants. Further work has to be done to improve existing cellular systems or to identify new ones.

## Transfection and transduction assays

### *Transient transfection*

A permissive infection requires an efficient entry of the virus into cells. One could hypothesize that the lack of success with HCV infection may be due to a defect in entry. An option to circumvent entry is to transfect the viral genome into cells using liposomes or other transfectant reagents. The advantage of such a strategy is that the inoculum (e.g. cloned viral genome) is well defined and can be modified by molecular biology techniques, thus allowing genetic analysis. This strategy, which has been applied with success for many viruses including several plus-strand RNA viruses,[107] turned out to be very difficult with HCV. Nevertheless, the replication of transfected HCV genome and secretion of virions in the culture medium was obtained in the human hepatoma

cell lines Huh7 and HepG2.[108,109] Although the titre of HCV observed in the culture medium was very low, the infection could be passed to fresh cells. More recently, it was demonstrated that virions produced in this cellular system were able to infect chimpanzee.[110] Once again, the problem of this system is mainly quantitative. Indeed, the replication level is very low and can only be detected by highly sensitive RT-PCR. Then what would be a good cellular system? It should be a system where replication of the HCV genome could be detected, not by a highly sensitive RT-PCR, but by a conventional Northern blot. In fact, a higher replication level of the genome associated with a higher expression of viral protein would facilitate the study of their function during the life-cycle of HCV.

### *Baculovirus-mediated transduction*

Transfection of full-length HCV RNA into cells is not very efficient. The low level of HCV replication after transfection could be due to small numbers of transfected cells. To tackle this problem, some investigators have used other viruses to transfer the genetic information of HCV into cells. Hence, McCormick and colleagues have used baculovirus loaded with the whole HCV genome to transduce various cell lines and trigger HCV replication.[111] This transduction approach led to a higher level of RNA replication compared with transfection methods, as a Northern blot is sensitive enough to detect HCV RNA. This particular system of delivery is very interesting and deserves further attention.

### *Replicon systems*

The major breakthrough in the HCV research field has come from the development of genetically modified HCV minigenomes, called replicons, that self-amplify in cultured hepatoma cells to very high levels.[112,113] These replicons are bicistronic RNA genetic elements (Fig. 55.5a). The first traductional unit (or cistron) is composed of the 5′ UTR of HCV and the neomycin phosphotranferase gene. The *neo* gene that confers resistance to geneticyn (G418) is translated from the internal ribosomal entry site (IRES), which is included in the 5′ UTR. The second traductional unit is composed of the NS3-5B HCV coding sequence under the control of the EMCV IRES. Stably transfected cell lines resistant to G418 are obtained after transfection of replicon RNAs generated by *in vitro* transcription of the cloned replicon sequences and cell cloning by G418 selection (Fig. 55.5b).[114] Thus far, only replicons from genotype 1 have been successfully obtained. It is worth noting that replicons from genotype 1a have been obtained only with Huh7 cells that had been stably transformed first with a replicon from genotype 1b.[115] This result is somewhat surprising and so far no explanation has been proposed. The consequence of this genotypic restriction is that replicon technology cannot be applied to all HCV strains. Another limitation of this system comes from the fact that among human hepatoma cell lines only Huh7 cells have been successfully transformed with replicons. Recently, two other human cell lines, HeLa and 293, which are not of hepatic origin, have been reported to be susceptible to replicon transformation.[116,117] It was shown that cell lines maintaining subgenomic replicons express (1) high levels of negatively and positively stranded RNA easily, and (2) high levels of non-structural protein easily detectable by Northen and Western blots, respectively. More recently, adaptative mutations conferring even higher levels of RNA synthesis have been described by several groups (reviewed by Bartenschlager *et al*.[114]). These subgenomic replicon systems have become one of the most important tools to study several aspects of HCV RNA replication, pathogenesis and persistence. They will be very useful to identify host factors required for RNA translation and replication, and to study events responsible for the switch from translation to replication or vice versa. And perhaps most importantly in terms of drug development, these replicon systems have been, and still are, very useful to identify and/or study molecules interfering with the translation, the processing of the polyprotein, and the replication of the genome. Hence, various cytokines (e.g. IFN-α), inhibitors of protease, helicase and polymerase have been studied in these systems.[114,118,119] Moreover, this system has proven useful to investigate the mechanisms responsible for the IFN-induced inhibition of HCV replication.[120] Hence, it was shown that IFN-α could suppress the accumulation of viral RNA by a non-cytopathic pathway and could also induce apoptosis of virally infected cells in a concentration- and cell line-dependent fashion. In addition, it was found that functional proteasomes were required for establishment of the IFN-α response against HCV. Based on these results, a model for the mechanism by which IFN-α therapy suppresses HCV replication in chronic infections by both cytopathic and non-cytopathic means was established.[120]

After the generation of subgenomic replicons and using similar principles, full-length genomic replicons containing the whole HCV genetic information were obtained (Fig. 55.5a).[96,121] The knowledge accumulated while developing subgenomic replicons (e.g. role of adapting mutations) was useful to facilitate the establishment of these full-length replicons. A reasonable level of RNA replication was observed in a Huh7 clone stably transformed with HCV. These full-length replicons were initially devised, then developed in order to obtain production of infectious HCV particles in the cell culture medium. Unfortunately, the production of such particles was not observed, thus limiting the use of this

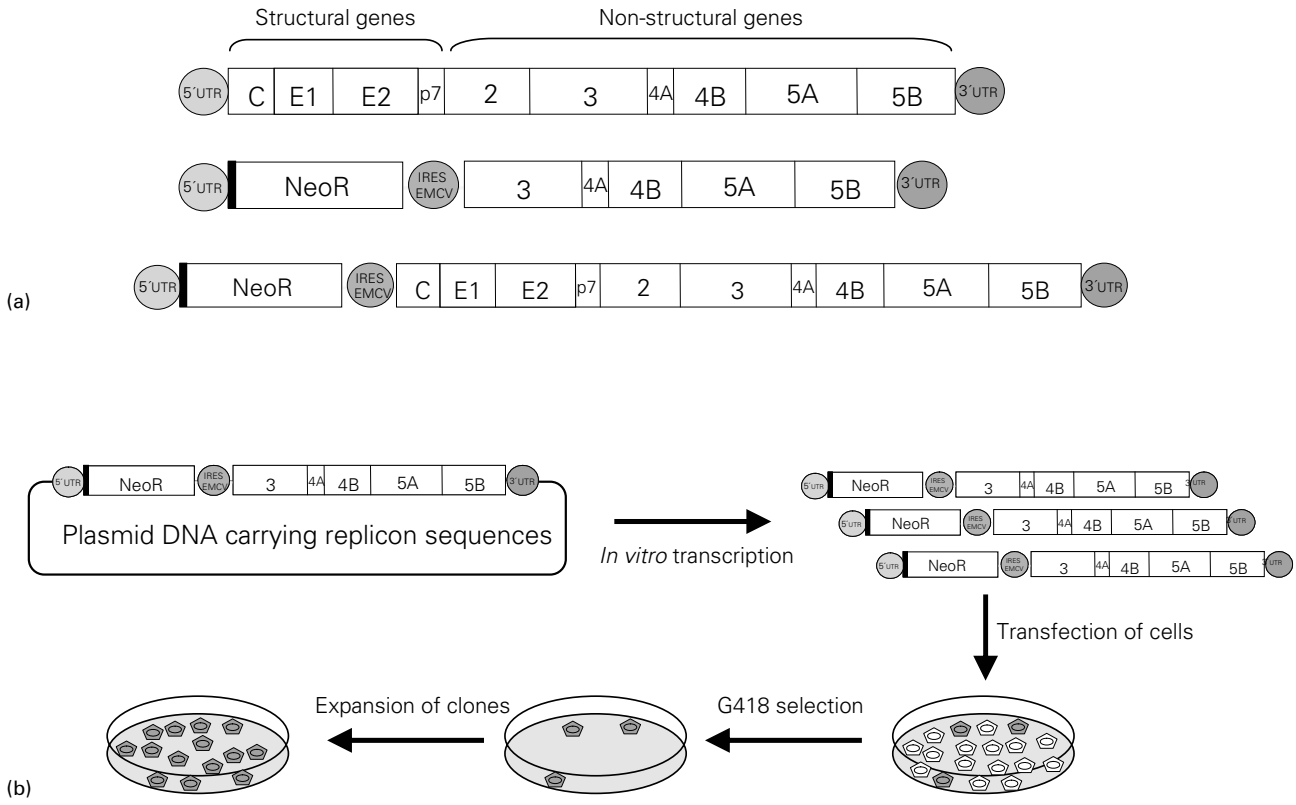

**Figure 55.5** Genetic organization of HCV and HCV replicons, and strategy of generation of cell lines carrying self-replicating HCV replicons. (a) The genetic organization of HCV genome, subgenomic and full-length replicons is presented. (b) Replicons RNA obtained by *in vitro* transcription are transfected into cells (transfected cells are in grey). If the replicon RNA self-amplifies in some cells, these cells can be selected by treatment with G418 (neomycin). The cell line is obtained by expansion of these cells under constant selection with G418. Once established, the cell line carrying self-replicating HCV replicons is cultivated with G418, but can be also be maintained without G418 for several months without loss of the replicon.

system to study, for instance, HCV morphogenesis. Further studies are required to understand why the morphogenesis is not possible in Huh7 cells.

Altogether, these replicon systems have led to tremendous progress in the knowledge of HCV biology.[114] Like *in cellulo* testing systems, they are very useful to identify, study and decipher the mechanism of action of some antivirals. One very important question remains open concerning these replicon systems. Are they going to be useful when phenotypic studies are required to analyze the drug susceptibility of HCV strains isolated from patients undergoing antiviral treatment and experiencing viral resistance? To date, only one report has described the use of replicons to analyze the drug susceptibility of an HCV mutant that appeared during ribavirin monotherapy. The sequence containing the mutation was inserted in a subgenomic replicon and a cell line was obtained. This mutant was found to be resistant to ribavirin *in vitro*, and the resistance is associated with a mutation in the polymerase gene (NS5B) at amino acid 415 (F415Y).[122] With the utilization of other antivirals targeting HCV enzymes, it is likely that other mutations will appear in the HCV genome. We have described in the HBV section how phenotypic studies could quite easily be done after the cloning of clinical strains into plasmids, subsequently used in transfection experiment. As cell lines harbouring replicons are tedious to obtain and moreover cannot be obtained for all genotypes, this replicon system does not seem appropriate for routine phenotypic assays. Further work is needed to develop other *in cellulo* systems based on either easy or non-cloning strategies that will enable phenotypic studies (e.g. replication capacity or drug susceptibility) of HCV quasispecies.

## Enzymatic assays

As infection assays and other *in cellulo* systems are not very well suited or are difficult to use, particularly to study viral resistance to antivirals, enzymatic assays have an important role to play. The HCV genome encodes a polyprotein that is proteolytically cleaved into

four structural proteins (C, gpE1, gpE2, p7) and six non-structural proteins (NS2, NS3, NS4A, NS4B, NS5A, NS5B) (Fig. 55.4a).[123–125] It is worth noting that an additional protein, called F, has recently been identified.[126] As its function is not clear, this protein has not yet been classified among the structural or non-structural sets of proteins. Some non-structural proteins carry one or two enzymatic activities.[123–125] There are two different proteases, including a metalloproteinase (NS2/3) and a serine protease (amino-terminal domain of NS3),[127–129] one ATPase/helicase (carboxy-terminal domain of NS3),[130–132] and one RNA-dependent RNA polymerase (NS5B).[133] Except for NS2, all non-structural proteins are thought to form a complex called replicase, which is involved in the replication of the genome. Because these enzymes are crucial for the replication of the virus, they represent an ideal target for an antiviral intervention.[119,134–137] In an attempt to first, better understand and characterize the function of each enzyme and second, identify and study molecules interfering with their activity, *in vitro* systems have been developed. They are based on the expression of enzyme in prokaryotic or eukaryotic cells, the subsequent purification of a biologically active form of the protein and the setting up of the *in vitro* assay.

### *NS3 protease*

Following its cloning and expression in different systems, the structure and biochemical properties of NS3 have been extensively studied in recent years.[119,138,139] Surprisingly, it was found that the HCV NS3 protease had structural and functional differences in comparison with other serine proteases described to date. These include (1) the heterodimerization of NS3 with a co-factor (NS4A) that enhances its stability and proteolytic activity,[140] and (2) the presence of a prominent zinc-binding site that stabilizes the complex.[141,142] However, the most important discovery, relevant to antiviral drug development, was that the catalytic site of HCV NS3, unlike other serine protease, is long, shallow and flat in conformation, rendering difficult the design of molecules able to bind and inhibit its activity.[143] Retrospectively, this explained why this protein was particularly refractory to inhibition by conventional serine protease inhibitors. Most of the data gained on NS3 have been obtained thanks to the development of *in vitro* assays based on the expression of the protein in *Escherichia coli*, insect, or mammalian cells, and its biochemical purification.[119,144–147] As new information was gained on NS3, much more sophisticated assays were developed. To date, several high throughput screening (HTS) assays have been developed[148,149] and used to identify new inhibitors of the NS3-4A serine protease among chemical libraries.[119] These assays, often called cleavage assays, utilize purified NS3 protein and artificial substrate containing the cleavage sequence of NS3. The cleavage is quantitatively measured by either radiometry or fluorometry.[148,149] In principle, the NS3 protein used in these assays can be either wild-type or mutant. Thus, these assays can be used to identify new inhibitors, but also to study mutant NS3 protein (obtained by mutagenesis or cloned from patients) and determine their susceptibility to inhibitors.

### *NS3 helicase*

The carboxy-terminal 450 amino acids of NS3 have an ATPase/Rnase helicase activity.[130–132,150] The expression of this protein in bacteria followed by purification using conventional biochemical procedures has allowed the characterization of HCV helicase at molecular level. Hence, it was demonstrated that NS3 helicase is able to unwind duplex RNA (as well as duplex DNA and DNA/RNA) structures only in a 3′ to 5′ direction, by disrupting hydrogen bonds that keep the two strands together, and that this unwinding activity is associated with hydrolysis of nucleoside triphosphate (NTP). Once again from simple *in vitro* assays, more sophisticated assays have been designed and set up to screen and identify inhibitors of the enzyme. These assays utilize purified NS3 protein and artificial substrates, which can be DNA duplex. The strand displacement is measured by radiometry or fluorometry. A good example of such an assay is the Flashplate helicase assay developed by BioChem Pharma.[151]

### *NS5B RNA polymerase*

NS5B bears the RNA-dependent RNA polymerase (RdRP) activity of HCV, and is therefore responsible for the synthesis of both the negative- (i.e. RNA intermediate) and positive- (i.e. viral genome) stranded RNA. Due to its specificity and crucial role in the viral cycle, this enzyme is an excellent target for antiviral therapy. Therefore, considerable efforts have been made to express it in heterologous systems and to purify a biologically active form of the enzyme so as to establish *in vitro* testing assays. First full-length enzyme was purified and used for biochemical studies.[133,152] However, the full-length enzyme displayed a rather poor activity.[152,153] A deletion of 21 amino acids at the carboxy-terminal domain enabled researchers to obtain a soluble form of the enzyme with improved activity.[153,154] The protein was expressed in a wide range of cellular systems, including bacteria[153,154] and mammalian[155] cells. While developing these assays, major enzymologic and structural[156] data were obtained about NS5B. They have been extensively reviewed in the literature.[119] Besides their use in the study of the enzymology and the structure of NS5B, *in vitro* biochemical assays are potentially of great interest to identify new inhibitors. Thus far, no HTS assay has

**Table 55.2** Summary of the most relevant testing systems for HCV

| System | Advantages | Limitations | Applications |
|---|---|---|---|
| Human primary hepatocyte | Full HCV replication cycle | Limited access<br>Low yield of replication | Receptor discovery<br>Study of antiviral effects |
| Tupaia hepatocytes | Full HCV replication cycle | Low yield of replication<br>Non-human primate | Receptor discovery<br>Study of antiviral effects |
| Subgenomic replicons | Replication of HCV genome | Absence of morphogenesis | Study of the replication complex<br>Study of antiviral effects<br>Drug resistance studies |
| Full-length replicons | Replication of HCV genome | Absence of viral secretion | Study of the replication complex<br>Study of virus/host cell interaction |

| Enzyme assays | Cell-free system | | Discovery of new antivirals<br>Mechanism of action of inhibitors |

been set up due to the complexity of the *in vitro* systems developed. However, existing systems allow the screening of rationally selected molecules.[157]

### *Concluding remarks on enzymatic assays*

All the *in vitro* enzymatic assays described above have been of great use to better understand enzymologic and structural aspects of HCV enzymes, as well as to identify and study inhibitors of these enzymes which could be developed as antivirals. In the near future, this *in vitro* assay could also be very useful to study enzymes encoded by resistant HCV strains. Indeed, with the probable introduction of new antivirals, including anti-protease, anti-helicase, or anti-polymerase agents, it is likely that new patterns of resistance will appear.

Table 55.2 summarizes the most relevant *in vitro* systems developed to study HCV.

## Conclusions

In this chapter, we have summarized the different *in vitro* testing systems that have been developed recently to better understand HVB and HVC biology and identify new targets to develop novel antiviral therapy based on drug combinations, as well as to study clinical aspects of HBV and HCV infection, including viral resistance to antivirals and pathobiology of natural and drug-induced mutants. In the near future, the further development of *in vitro/in cellulo* testing systems, in particular for HCV, will be important to (1) discover new drugs to better combat HBV and HCV infection, (2) monitor and prevent the appearance of mutants, and (3) better understand liver disease induced by these viruses.

# Chapter 56
# New vaccine technologies and the control of viral hepatitis

Colin R Howard

It is universally accepted that the development of vaccines against hepatitis A and B represent major milestones in the control of viral hepatitis, but the contributions these developments have made in advancing the design of products against other infectious diseases is perhaps less widely recognized. In particular, experience gained over two decades with recombinant hepatitis B vaccines, whether produced in yeast or mammalian cells, has confirmed that such recombinant products are safe and effective. Hepatitis A vaccines were quickly found to be exquisitely immunogenic in humans and deemed so promising in early clinical trials that one hepatitis A vaccine was licensed prior to efficacy trials having been completed. A vaccine against hepatitis E is now on the horizon, and again this will represent a first for vaccine research given the difficulties there have been in developing vaccines against related agents. It is not surprising, therefore, that vaccine researchers investigating new adjuvants, delivery vehicles and vectors turn to viral hepatitis as paradigms where much is known, both at the level of immunological properties but equally importantly how new vaccines can best be assessed and monitored in humans. Increasingly, much of this work is being done by smaller biotechnology companies, pushing back the boundaries and challenging previously cherished concepts in vaccine design. The paradox is the extreme difficulties experienced hitherto in developing a vaccine against hepatitis C virus (HCV), a member of the Flaviviridae family of viruses containing agents such as yellow fever and tick-borne encephalitis, against which effective vaccines have been available for many years. The way forward is most certainly cross-utilization of technology platforms informed by a better understanding of what constitutes immune protection in hepatitis C. This knowledge can be extended to improving the antiviral treatment of patients with chronic infections.

Therapeutic vaccination to complement antiviral treatment of those patients with chronic hepatitis B has become a major goal in vaccine research. Some attempts to modify and adapt existing products designed for prophylaxis have largely been unsuccessful. The considered opinion is that such products need to stimulate a different type of immune response that is focused on class I major histocompatibility complex (MHC)-mediated presentation of peptides derived from the hepatitis B virus (HBV) core antigen, as well as enhancing the level of co-stimulatory cytokines that may directly aid virus clearance from hepatocytes. However, it is likely that – once developed – their availability will facilitate the design of better preventative vaccines, especially for administration to those carriers of either HBV or HVC during the years before the development of clinical disease.

New vaccine technologies are being developed as our understanding grows of the inflammatory events leading to both innate and adaptive immune responses. In particular, vaccine design has begun to focus on the role of dendritic cells (DCs) and the need to bring these into close proximity to the antigen. For example, the oligonucleotide CpG sequences present within DNA plasmids are thought to mediate their effect in part by binding to a Toll-like receptor (TLR-9) on dendritic cells.[1] Other adjuvants may play a similar role in dendritic cell recruitment by recognizing Toll-like receptors on dendritic cell surfaces.[2] Newer adjuvants for peptides and recombinant proteins capable of providing signals for both DC maturation and cytotoxic T-lymphocyte (CTL) stimulation are likely to prove particularly effective. There are considerable hurdles, however, in bringing such technologies to the marketplace, not least of which is the lack of a suitable small animal model for either hepatitis B or hepatitis C. Although chimpanzees have proved invaluable in the past for unravelling the pathogenesis accompanying infection and for demonstrating proof of principle for vaccine candidates, their high cost, limited availability and ethical issues preclude their practical use for screening large numbers of candidate formulations and adjuvants in any meaningful way. The woodchuck and duck hepadnavirus models fill this shortcoming to some degree but are hampered, respec-

tively, by the lack of immunological marker reagents for the woodchuck and the limited nature of the immunopathology in ducks. Mice transgenic for part of or the whole HBV genome have done much to identify possible strategies for therapeutic vaccination, but as with DNA vaccination, encouraging results in rodents are not necessarily mirrored in humans.

This chapter focuses primarily on new vaccine technologies within the context of the prevention and treatment of hepatitis B and C. Hepatitis A vaccines based on more traditional technologies, with recent developments focused on delivering these vaccines in combination with other vaccines, are advances discussed elsewhere in this book. A plethora of alternative vaccine technologies have been proposed as 'third-generation' hepatitis B vaccines and these are reviewed first. Immunization against hepatitis C virus has proved exceedingly difficult, and areas where newer technologies might prove useful are touched upon where appropriate. The last section deals with the increasing interest in applying new vaccine technologies for post-exposure therapy (so-called therapeutic vaccines).

## Can existing hepatitis B vaccines be improved upon?

Despite the clear success of HBV vaccination programmes, there remains much that can be done to improve the vaccines currently in use. For example, one need is increasing the potency of licensed products for those individuals with acquired or natural immunodeficiencies who respond poorly to existing HBV vaccines. The length of time required together with the necessity of utilizing at least three doses is also a major drawback, particularly in poorer regions of the world where access to vaccine is difficult, as well as in the developed world where non-compliance, especially among younger people, is increasingly of concern. It is also possible that vaccines may require modification if HBV variants are found to become more prevalent in the face of developing herd immunity in vaccinated populations, particularly in areas such as Asia where HBV carriage is so high. In addition, the large number of doses that are required annually could cause supply difficulties, as can the need for trained personnel to deliver the vaccine. A final point is that presently licensed products do not contain the complete antigenic repertoire present on the virus particle itself. The inclusion of pre-S epitopes, for example, may enhance vaccine potency and efficacy. For these reasons, there are considerable resources devoted towards improved, 'third-generation' HBV vaccines (the first and second generations are regarded as products obtained from plasma and recombinant DNA technology, respectively).

There has recently been an upsurge in activity directed at new vaccines generally. These novel vaccine concepts offer several opportunities to develop improved HBV vaccines. These include the use of new adjuvants, additional (pre-S) components, synthetic peptides and DNA immunogens. To this list must be added non-viral vectors and mixed immunization regimes, for example, the 'prime-boost' approach,[3] although this work tends to be more focused on the development of post-exposure vaccines, particularly for the immunotherapy of chronic infections.

One concern is meeting the global demand for hepatitis B vaccines, and achieving this at a price that is affordable for less well off countries. In this context, much publicity has been given to the use of plants for the production of virus vaccines, and hepatitis B surface antigen (HBsAg) has been expressed successfully in tobacco and potatoes.[4,5] The utility of plants as alternative sources of antigen is restricted, however, by the low yields in wet weight and the resultant difficulties in purification. The concept of antigen expression in edible vegetables and fruits is driven by the theoretical possibility that such transgenic plants would open up fresh opportunities for the development of oral vaccines, but in practice control of dose, proteolytic sensitivity following digestion and the frequent lack of immunogenicity when many antigens, e.g. HBsAg, are delivered across the mucosal surface of the gut, are all major challenges. The development of systemic immunity by oral immunization requires a detailed understanding of how viral antigens can stimulate specialized lymphoid structures and the eventual expression of Th1- or Th2-dependent immune responses.[6] Unfortunately, this basic information is largely lacking for all hepatitis virus infections, and thus an oral vaccine against HBV or HBC appears unlikely in the foreseeable future.

### Inclusion of pre-S

There is a view that current hepatitis B vaccines could be improved by the inclusion of pre-S domains, the N-terminal extension to the major S proteins found predominantly on the envelope of complete HBV particles. The rationale is that the pre-S region bears the ligand essential for HBV binding to the hepatocyte receptor, and thus antibody to this ligand would induce more potent neutralizing antibodies. In the absence of an *in vitro* assay for neutralizing antibodies, this is difficult to confirm in the manner possible for other viruses, but it is a paradox that the major *a* determinant responsible for inducing a protective antibody is highly conserved across HBV genotypes yet is not thought to play a predominant role in the attachment of virus to host cells. The difficulty has been in expressing HBsAg particles

with stable pre-S sequences, partly due to its sensitivity to proteases. Whereas the complete pre-S region may be required for hepatocyte recognition, there is evidence from animal work that the pre-S2 region alone may have some benefit. For example, Schirmbeck *et al*.[7] showed enhanced clearance of HBsAg from transgenic mice injected with DNA expressing both pre-S2 and S proteins. A substantial improvement in immunogencity for mice is obtained if particles express both S and the complete pre-S sequence,[8] but attempts to mirror such an improvement in humans have proved disappointing. No significant difference in antibody or cellular responses has been found in volunteers found previously to be non-responsive to vaccine containing only S protein.[9] An important observation from the latter study was the finding that many non-responders eventually seroconverted if given one or more additional doses of an existing licensed product. Similar results have been obtained using a vaccine with an additional pre-S component.[10]

## The potential of short peptides

The use of synthetic peptides as potential vaccines is often dismissed, yet recent advances in peptide chemistry coupled to developments in delivery systems for small molecules makes the reality of a peptide vaccine that much nearer. Synthetic peptide vaccines and killed virus vaccines share the problems of poor immunogenicity and the requirement for booster doses. The use of peptides as immunogens has been achieved for some viruses, however. For example, Sarin and colleagues[11] showed that a synthetic peptide immunogen consisting of 30 amino acids from the p17 protein of HIV-1 coupled to keyhole limpet haemocyanin (KLH) and adsorbed onto alum can be delivered to humans without undue toxicity. This peptide immunogen induced a protective cell-mediated immune response as demonstrated by the transfer of vaccinated human peripheral blood mononuclear cells to severe combined immunodeficiency (SCID) mice, followed by protection against challenge with a different strain of virus. The critical issue is protection against challenge in the target species, however. This has been achieved by Langeveld *et al*.[12] who successfully protected dogs against challenge with canine parvovirus using a vaccine containing two synthetic peptides mimicking the N-terminal region of the major capsid protein VP2.

Moynihan *et al*.[13] designed and synthesized a 48-mer amino acid peptide, representing the entire *a* determinant of the HBsAg sequence (*adw2* subtype). The S121/48 peptide sequence was designed to resemble the native *a* determinant as much as possible. In the case of the S121/48 peptide, a T-helper cell epitope is known to be located between amino acids 164 and 167 and so a promiscuous epitope was not added. This sequence is thus worth considering for inclusion in a synthetic peptide vaccine candidate. The design of the S121/48 peptide is supported by previous work by Manivel *et al*.[14] and Mishra *et al*.[15] using a synthetic peptide representing amino acids 124–147 of the HBsAg sequence (*adw*) showing that the peptide contained HBsAg-related antigenic determinants, specifically the *a* determinant. This antigenicity was mostly destroyed in disulphide-reduced analogues. The peptide induced antisera recognizing different HBsAg subtypes in rabbits, and the B-cell epitopes contained within the peptide sequence were found to be dominant in humans. The region of amino acids 148–174 of the pre-S2 sequence is recognized by T cells of seven MHC haplotypes tested and is thought to contain multiple T-cell epitopes that are recognized uniquely by the different MHC haplotypes.[14] Work by the same group on a model polyepitope immunogen, a recombinant polypeptide containing pre-S1, pre-S2 and S sequences, demonstrated the immunogenicity of the polyepitope in different strains of mice and also confirmed the presence of B-cell and T-cell epitopes in HBsAg between amino acids 124 and 147.[16] The S121/48 peptide elicited a sustained anti-peptide antibody response both in BALB/c (H-$2^d$) mice and guinea pigs, when immunized with FCA. Cross-reactive, anti-HBs antibodies were induced. These antibodies were directed against a significant proportion of the conformationally restrained epitope repertoire on the native HBsAg particles. Collectively, these data demonstrate that a long synthetic peptide mimicking conformational and linear epitopes can be produced by chemical synthesis and can be used to induce significant titres of anti-HBs antibodies after a single injection.[13] Peptides are able to induce both immunity and tolerance, however. A single subcutaneous injection of a peptide in incomplete Freund's adjuvant protected mice against challenge with lymphochoriomeningitis (LCM) virus, but repeated injections of the same peptide intraperitoneally resulted in tolerance.[17]

In order to formulate a synthetic peptide immunogen, some form of adjuvant effect is normally required to compensate for the inherent low immunogenicity of small peptides. Adjuvants may also act as delivery vehicles for antigens, resulting in the targeting of antigens to immunocompetent cells. Examples include liposomes,[18–21] virosomes,[22,23] oil adjuvants, small (<10 μm) PLG microspheres and immune stimulating complexes (ISCOMs).[24,25] Compounds such as muramyl dipeptide,[26] cholera toxin,[27] MF59 (an oil-based adjuvant),[29] lipopolysaccharide and certain CpG oligonucleotides[30] act as immunostimulators. Such delivery systems can direct the immune response to synthetic peptides towards either Th1 or Th2 phenotype, dependent upon which is required. In addition, modification of an antigen, for example, coupling of synthetic peptides to KLH, tetanus toxoid[31] or palmitoylation of peptide antigens[32] may improve immunogenicity.

Biodegradable lactide polymers, such as poly(lactide co-glycolide) (PLG) microparticles, have been used extensively as vehicles for targeting antigens to antigen-

presenting cells on mucosal surfaces or after parenteral injection. The microparticles undergo degradation principally by non-enzymatic hydrolysis to lactic and glycolic acid, thus releasing encapsulated antigen. The integrity of the entrapped antigen may play a role in the induction of different IgG subclasses, as may the microparticle shape, the hydrophobicity of the microparticles and the amount of intact antigen.[33] Controlled release, single-dose vaccines can theoretically be made using PLG microparticles of differing lactide contents and injecting them together. Different lactide concentrations affect the rate of hydrolysis of the microparticles, and thus the judicious use of particles in a single injection could be used to induce a sustained immune response from a few days to as long as a year. Moynihan *et al*.[13] have shown that such preparations containing the 48-mer peptide described above (Fig. 56.1) can induce a high titre antibody response in mice directed against the major a determinants. Oligosaccharide ester derivatives of trehalose, a disaccharide, are alternatives to PLG, overcoming some of the stability problems associated with the use of PLG.[34]

## Nucleic acid vaccines

There has been much excitement over the past decade as to the potential of nucleic acid immunogens to circumvent at least some of the shortcomings associated with protein subunit and inactivated whole virus vaccines – most notably, the limited capacity of vaccines other than attenuated products to induce class I MHC responses. CTLs play a particular role in the pathogenesis of HBV and HCV, and thus there is a dogma that vaccines against these infections could be enhanced by the capacity to stimulate both antibody- and cell-mediated immune responses. This is particularly the case for the development of post-exposure therapeutic vaccines, as discussed below. In contrast to protein subunit or inactivated vaccines, the relevant epitopes are expressed intracellularly after the DNA is taken up into antigen-presenting cells. Thus, both MHC class I (CTL-inducing) and MHC class II (antibody-inducing) pathways are stimulated. But DNA immunization offers additional advantages. The response is often longer in duration and the relative titre of the immune response components can be fine-tuned by varying the route of delivery and by including co-stimulatory molecules. Other advantages include use in neonates where immunization results in a response despite the presence of maternal antibody,[35] and such vaccines also have the potential for use in immunocompromised individuals.

DNA vaccines have been found to be effective against a growing number of viral diseases, including HIV, rabies and rotaviruses.[36,37] A number of studies have looked at the potential of this approach for the development of candidate hepatitis C vaccines. Encke *et al*.[38] showed that the injection of mice with a plasmid encoding for the NS3 and NS5 proteins of hepatitis C virus elicited a good class I MHC response.

Safety continues to be a major concern, particularly with regard to the potential for plasmid DNA integration into the host chromosome and the risks associated with endotoxin contamination during the growth of plasmids in gram-negative bacteria such as *Escherichia coli*. There is the additional, albeit theoretical, risk that autoantibodies to host DNA could arise, predisposing recipients to

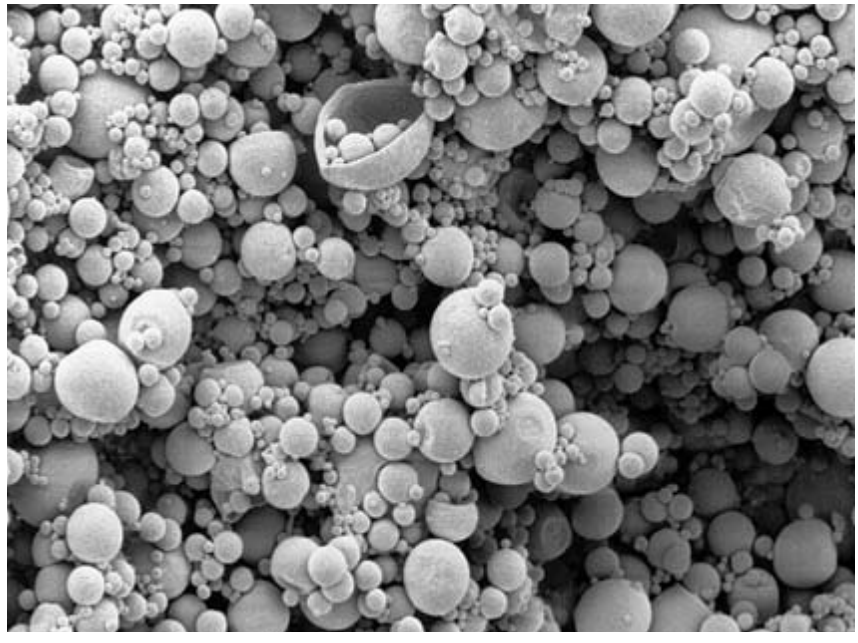

**Figure 56.1** Polylactide-polyglycolide (PLG) microparticles containing a 48-mer peptide of hepatitis B surface antigen. Immunization of mice stimulates high titre anti-HBs antibodies reactive with the major *a* determinant.[13]

autoimmune diseases such as systemic lupus erythematosus (SLE). Very small quantities of DNA can act as an adjuvant, principally due to the presence of CpG motifs, stimulating B-cell responses as well as secretion of interleukin (IL)-6, IL-12, IL-18 and interferon (IFN)-γ.[39]

Muscle cells are particularly efficient in taking up extracellular DNA, with intramuscular injection inducing predominantly a class I-type response leading to activation of virus-specific CTLs.[40] In contrast, epidermal inoculation using DNA bound to gold beads induces a predominantly class II-type response, preferentially inducing specific antibodies.[41] This difficulty can be partially overcome by inducing muscle degeneration in animals, but this is clearly not an option in humans.

Brazolot Millan *et al*.[42] demonstrated the different responses seen in young and adult mice. Mice immunized below 3 days of age with an HBsAg/alum/CpG formulation produced a mainly Th2-type response, whereas older mice produced a mixed Th1/Th2-type response. The experiments also showed the difference between different vaccine types in that immunization of young mice (<7 days) with a DNA vaccine for HBsAg produced Th0-type responses, whereas older mice stimulated the Th1 phenotype. The researchers also noted that the HBsAg/alum/CpG immunizations led to faster and higher antibody responses and stronger CTL responses than DNA immunization. Prange and Werr[43] analyzed the humoral immune response to HBV DNA injected intramuscularly and demonstrated that high levels of antibodies were induced following immunization with the S protein, or S plus pre-S1 and pre-S2 epitopes (with secretion), but not with the L protein or S plus pre-S1 and pre-S2 (without secretion). A note of caution, however, is that the nature of the immune response may differ compared with conventional vaccination as was shown by Mor and colleagues who found that a DNA immunogen coding for the malarial circumsporozoite antigen induced tolerance in neonatal mice.[44]

Immunization with an HBsAg-encoding plasmid with aluminium or calcium phosphate adjuvants has been shown to induce enhanced Th1-type responses over naked DNA.[45] DNA vaccination of woodchucks with constructs expressing the WHV core and surface antigen proteins (WHcAg and WHsAg, respectively) has been shown to partially protect woodchucks against WHV challenge.[46] Cationic polymers are a class of non-viral transfection agents which condense plasmid DNA by ionic interaction. Results generally have been disappointing, although recent studies using poly (2[dimethylamino] ethyl methacrylate, pDMAEMA) derivatives show significant promise for DNA delivery. High levels of anti-HBs antibodies were induced in mice, predominantly of the IgG2a isotype, suggestive of a Th1 type of immune response (Fig. 55.2).[47]

The greatest hurdle to developing a DNA vaccine for human use is the lack of a suitable delivery system. Over 90% of DNA injected either in saline or bound to microparticles is degraded before cellular uptake. Most work that has focused on this issue has involved the use of lipid-based liposomes to protect the DNA from extracellular nucleases.[48] By incorporating specific ligands targeted to specific cells and tissues, it is thought possible to target such DNA–liposome complexes to specific cell types, thereby increasing the efficiency of uptake. For example, the inclusion of epidermal growth factor[49] and the reovirus σ1 protein that interacts with intestinal M cells.[50] There is no reason why such liposome-based delivery systems could not be tailored to the delivery of hepatitis B or hepatitis C genes to antigen-presenting cells and/or hepatocytes.

## The use of viral vectors

The use of viral vectors for delivering immunogenic proteins confers a number of advantages, particularly for stimulating CTL responses. After injection, limited replication occurs, allowing the expression of the gene

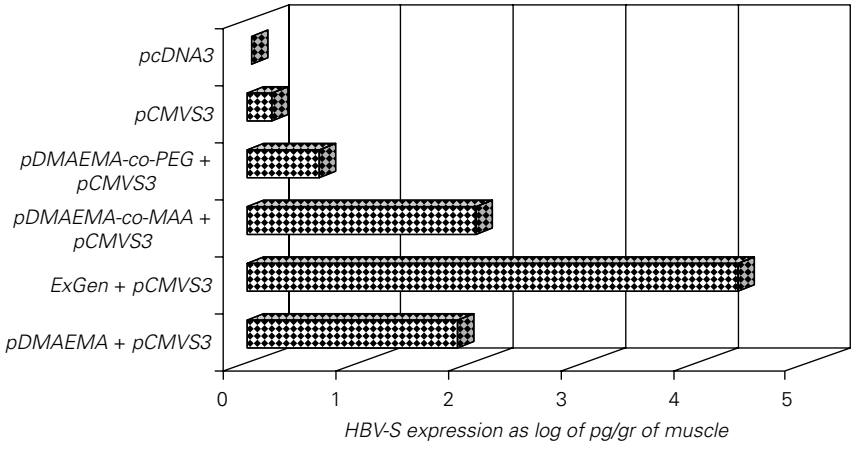

**Figure 56.2** Immune response in mice injected with a DNA construct expressing HBsAg delivered together with polymers of poly-(2-dimethylamino) ethyl methacrylate (pDMAEMA). From Bos *et al*.[47]

product to a level sufficient for the induction of both antibody and cellular responses.[51] Progress has been made with the development of a vaccinia-based recombinant HBV vaccine whereby the HBV S gene is incorporated into the genome of vaccinia virus used previously for the eradication of smallpox. Although adenovirus vectors are an alternative, these are not derived from attenuated parent viruses and thus generate safety concerns. The use of vaccinia recombinants has a number of advantages, e.g. it need be delivered only once, is easy and cheap to produce and offers the opportunity to induce both antibody- and cell-mediated immune responses. However, there are a number of disadvantages, not least of which is the risk of adverse reactions in a significant number of recipients, particularly young infants. Heightened concern as to bioterrorism has revised the perception that vaccinia constructs could be used increasingly as the level of herd immunity to vaccinia declines in the human population.

## Prospects for hepatitis C vaccines

Despite the success of yellow fever and Japanese encephalitis vaccines, hepatitis C vaccine development has proved problematical, largely due to the circumstantial evidence that immunity needs to take account of the variability between isolates, particularly in the so-called 'hypervariability 1' (HVR1) region towards the N-terminus of E2, one of two viral envelope proteins. There is evidence that CTLs can limit infection in humans[52,53] and a multi-specific response has been noted in chimpanzees with resolving disease.[54] Thus, the perception is that a successful hepatitis C vaccine should include a cross-reactive antibody response against a wide number of prevailing subtypes as well as eliciting a strong CTL response to limit the spread of virus that is not neutralized by vaccine antibody.

In contrast to hepatitis B, there appears to be little or no immunity to hepatitis C after exposure,[55] and chimpanzee studies using recombinant E1/E2 heterodimer preparation produced immunity lasting only for a few weeks.[56] Importantly, this study showed that immunity is limited even against challenge to homologous virus. Current thinking is that HCV-specific memory exists and may be at a sufficient level to impart a degree of protection, particularly if the challenging virus dose is of low titre. However, once infected, the virus rapidly disseminates and runs ahead of the host's capacity to mount an effective CTL response. Because of the heavy antigen burden, HCV-specific CTLs become functionally impaired and thus have a restricted capacity to limit or resolve the infection. It is this functional impairment that presents the greatest hurdle to overcome in the design of any therapeutic or preventative vaccine if antibody alone is insufficient to confer protection.[57] There has been very limited progress towards this end, however. DNA immunogens show most promise: Rollier *et al*. have shown that immunization of chimpanzees with a construct expressing all three major structural proteins together with NS3 altered the course of disease on challenge.[58] This study also revealed just how important the quality of the response is to individual conserved epitopes if the correct T-helper response is to be stimulated. This complexity is confounded more by the requirement to ensure the DNA coding for epitopes is of the correct length and construction for optimum expression.[59]

## Therapeutic vaccines

There remains the treatment of those individuals already persistently infected with HBV or HCV. Can the immune system of these persons be stimulated to clear virus before the onset of chronic liver disease? Recent studies in transgenic mice and patients with chronic hepatitis indeed suggest that a therapeutic vaccine delivered many years after first exposure may be effective in reducing, if not eliminating, the virus.[60] Combined antiviral and immunotherapeutic treatments – delivered simultaneously or sequentially – may yet offer an alternative strategy to controlling these diseases which represent a major drain on public health resources in many countries.

Individuals persistently infected with HBV (or HCV) have lost their ability to mount an effective immune response at the time of the acute infection, and the specificity of the missing component plays a pivotal role in recovery. The big question is: what is the relevant antigen to stimulate a class I MHC-mediated response? There is ample evidence of the importance of HBcAg specificities being expressed on the surface of infected hepatocytes, and Hilleman has argued strongly that any strategy must take into account the role of tolerance to HBeAg in maintaining the persistent state, and that progression from mild to severe clinical disease is frequently accompanied by its absence.[61] Put another way, a marker of a successful therapeutic product would be seroconversion to e antigen. Notwithstanding, there remains a view among many investigators that modifying existing prophylactic vaccines may be beneficial.

Perhaps one of the simplest approaches is to combine HBsAg particles with anti-HBs antibodies to form immune complexes, as it is well known that such complexes stimulate both arms of the immune response. HBsAg complexed with anti-HBs antibodies and immunized intranasally in BALB/c mice was found to induce IgG1 antibodies (Th2-type systemic and mucosal responses) when immunized alone or IgG2a antibodies (Th1-type response) when given with cholera toxin or CpG motifs. These results were in contrast to HBsAg delivered intranasally (without adjuvant), where no anti-HBs response

was seen.[62] Antigen–antibody complexes have been shown to be immunogenic in hepadnavirus-infected ducks,[63] and there is some evidence of benefit to patients with chronic hepatitis B.[64] Larger-scale studies are currently underway in China.

The strategy of prime-boosting involves priming the immune system with one vector and then selectively boosting the response to the target antigen by use of a second vector. Particularly powerful levels of synergy can be obtained by first using DNA followed by a vector such as vaccinia or adenovirus.[3] A strategy that exploits the priming capacity of DNA followed by a boost with a vector expressing the homologous antigen is increasingly becoming a focus of attention. There are a number of studies in mice that show priming the response using DNA targeted to hepatitis C antigens followed by peripheral injection of a recombinant vector produces sustained and high titre systemic responses to the immunizing antigen.[65,66] An indication of the utility of the prime-boost approach is the work of Pancholi and colleagues who showed in chimpanzees chronically infected with hepatitis B a >400-fold decline in the levels of HBV DNA with coincident increase in the level of IFN-γ.[67] Several human trials are currently underway focusing on the use of prime-boost strategy for malaria and HIV.[68,69]

A number of adjuvants have been shown to enhance CTL responses to injected proteins, but the magnitude of class I responses obtained in humans generally is disappointing. A number of cytokines, particularly IL-2, IL-12 and granulocyte macrophage colony-stimulating factor (GM-CSF), have been tested in patients as part of trials to evaluate anti-tumour vaccines, but such approaches are limited owing to the relatively short half-life of cytokines when given as recombinant proteins. The effects are more prolonged when the relevant gene is given together with the gene coding for the target antigen in the same plasmid construct, as was shown by Barouch and colleagues[70] who found long-lasting CD4+ and CD8+ CTL responses to SIV-gag protein in rhesus monkeys injected with a DNA construct that included the sequence for IL-2.

The best small animal models for hepatitis B are mice transgenic for the HBV genome, although the discovery that chimpanzees can recognize HLA-A2- and HLA-B7-restricted HBV epitopes gives hope for the eventual testing of potentially therapeutic vaccines for HBV in higher primates.[71] Several groups have exploited the use of transgenic mice for evaluating DNA immunogens. Both class I and class II MHC responses can be induced, but antibody alone is insufficient to achieve long-term clearance of the antigen and IFN-γ-secreting T cells are required.[72,73] Chisari and colleagues have shown that passive transfer of CTLs or their cytokines TNF-α, IFN-γ and IL-2 clear HBV DNA from the nuclei of murine hepatocytes, with a concomitant cessation of nucleocapsid formation and a reduction in viral RNA transcription.[74,75] These findings inform the process of developing therapeutic vaccines, and it seems as a result that any successful immunotherapeutic for chronic hepatitis B will need to include one or more of these cytokines, or at least the genes coding for these modulators.

Hui *et al*.[76] have demonstrated the induction of humoral and cytotoxic immune responses in 57/BL6 mice, and clearance of circulating HBsAg in transgenic mice, following immunization with a plasmid which coded for a pre-S1-derived peptide, fused to the C-terminus of HBsAg.[76] Efficient processing of an antigenic sequence for presentation by CD8+ MHC class I molecules depends upon the neighbouring residues in the protein, and the degree of protection against lethal viral disease is related directly to the amount of naturally processed antigen peptides.[77] As antibody is protective against HBV, induction of CD8+ T-cell responses is not essential for protection. However, the importance of CTL responses in clearing chronic HBV infection suggests that if a peptide were to be designed for therapeutic HBV vaccination, then inclusion of correct flanking sequences bordering the CTL epitope would be important. Data suggest that a synthetic CTL epitope can be made into a vaccine which is immunogenic and which promotes a protective Th1-type response. This has been achieved by coupling a 10-mer CTL epitope from herpes simplex virus (type 1) to a 15-mer region from β2 microglobulin through a GGG spacer. The construct is known as a ligand epitope antigen presentation system (LEAPS™) and is injected with a non-phospholipid surfactant liposomal adjuvant.[78] Two examples of the use of HBV peptides for therapeutic vaccination are the use of short, linear peptide PADRE (Pan DR helper T-cell epitopes) constructs to break CTL tolerance in a transgenic mouse model[79] and immunization with an HBV core epitope-containing lipopeptide to induce CTL responses in chronically infected humans with a variety of HLA-A2 types.[80] This construct, although stimulating a good CTL response in humans, proved to have little efficacy in patients with chronic hepatitis B.[81]

## Conclusion: the vision

The deployment of vaccines against infectious diseases is undoubtedly one of the major medical achievements of the last century. Despite the overwhelming success of hepatitis B vaccines, an extensive reservoir of infection will remain for at least the next 25 years owing to virus persistence in a small, but significant number of those infected, especially early in life. Although claims of near 100% efficiency are made for existing products, only a few per cent escaping immunization or being non-responsive is all that is required for the infection to persist within a community where HBV is endemic. Thus,

the ideal prophylactic vaccine is one that relies on fewer doses, gives rapid seroconversion against all the antigenic repertoire of the virus, and immunological memory that extends at least beyond the years where exposure is most likely to induce a chronic persistent infection. Vaccine technologies already exist that go some way to meeting these criteria, but increasingly severe regulatory hurdles are likely to prevent manufacturers from pursuing such developments, especially as the market for the products is in the main in the economically disadvantaged regions of the world. The newer technologies also rely on the bringing together of individual components or delivery vehicles each subject to separate patenting and licensing arrangements, adding further complexity to the development progress. However, the drive to use such technologies for the more economically attractive market of treating patients with chronic hepatitis is likely in the longer term to benefit the future development of preventative vaccines, especially for those individuals identified as carriers of the virus ahead of developing clinical disease. Therapeutic vaccination is an often-discussed concept but as yet has not produced significant advances in the clinic. This may be largely due to our lack of understanding of all the immunological process that triggers the disease state as much as a lack of the right technology platforms. A more realistic first goal is the reduction of the virus burden to the level where there is distinct patient benefit rather than the elimination of the virus completely. How this is achieved may depend on designing the right synergy of antiviral compound and immunotherapeutic agent. Quite apart from the scientific challenges, newer vaccines are likely to be more complex in terms of formulation, giving rise to additional regulatory hurdles, especially if different products are to be used at various times during the immunization process.

These issues are compounded by the issue of hypervariability in the instance of hepatitis C. Despite extensive efforts, progress towards hepatitis C vaccines is frustratingly slow. Among the other flaviviruses of humans, dengue shows a number of parallels in that vaccine development has been hampered by the presence of four distinct serotypes and the fear that immunity to one may exacerbate disease if a recipient is then exposed to another. Hepatitis C may well be the first infectious disease where therapeutic vaccination becomes a reality before the availability of a prophylactic vaccine: post-exposure treatment focuses on stimulating CTLs that have broader serotype reactivity than is the case for antibody responses. Advances in the design of delivery systems for drugs are likely to be increasingly relevant for combined antiviral and immunostimulatory molecules. Ultimately, the wish is for new products to be delivered orally but this dream is probably some way off as yet. Notwithstanding, the vaccine industry has undergone a dramatic revival in the last decade, with smaller companies being prepared to meet the challenges of vaccine design. It is the challenge for investors, public funding bodies and regulatory authorities to ensure that such effort is translated into the clinic.

# Chapter 57
# Safety of hepatitis B vaccines

Arie J Zuckerman

## Introduction

Concerns about vaccine safety have increased substantially as the incidence of vaccine-preventable diseases is reduced by the increasing use of effective vaccines and the success of immunization programmes. True adverse vaccine reactions and those associated with immunization only by coincidence are reported frequently and with enthusiasm on the Internet, by the media and by anti-vaccination groups. Indeed, some scientists approach the popular media before or simultaneously with publication. If the hypothesis relates to vaccine safety, whether or not there are valid supporting data, the issue frequently becomes a topic of public debate before scientific investigation could possibly generate data which support or reject the hypothesis, and important public health programmes can be damaged. Even if the hypothesis is disproved, the public has already seen images of damaged children supposedly linked to the vaccine and the issue may be exploited by anti-vaccination groups, liability lawyers and certain elements of the media who thrive on this type of reporting.[1] When scientific data become available, the 'news worthiness' of established facts is lost and they remain unreported by the media.

Review of the literature on clinical studies and trials of hepatitis B vaccines, and the results of post-marketing surveys indicate that serious clinical adverse events directly related to immunization were recorded very rarely. Most adverse reactions reported include minor symptoms at the site of injection, temporary malaise, fatigue, headache, nausea, rash, influenza-like symptoms, dizziness, arthralgia, myalgia, urticaria, paraesthesia and drowsiness.

Nevertheless, there are allegations of at least three serious disorders resulting from, or associated with, hepatitis B vaccination:

- sudden infant death syndrome,
- chronic fatigue syndrome, and
- multiple sclerosis.

There is no evidence (reviewed below) of a causal link between immunization against hepatitis B and these conditions. The features common to recent vaccine scares have been summarized extremely well by Professor Neil Halsey, Head of the Institute for Vaccine Safety at Johns Hopkins University, Baltimore as reported by Jefferson.[2]

- A causal link is usually claimed with a disease or condition of unknown or unclear aetiology.
- The association is claimed by one investigator or a group of investigators.
- The association is not confirmed by peers or by subsequent research.
- The claims are made with no apparent concern for potential harm from public loss of confidence and refusal to vaccinate children (and adults).

In addition, the findings of subsequent studies that fail to confirm the original claim never get the publicity given to the 'original finding', and thus the public never receives a balanced view.[3]

Note that over one billion doses of hepatitis B vaccine were used between 1981 and 1998 with an outstanding record of safety and efficacy.[4]

## Hepatitis B vaccine and sudden infant death syndrome

Although allegations have been made that hepatitis B immunization of infants causes sudden infant death syndrome (SIDS), these allegations did not gain any credibility, as outlined by Harold Margolis before the US House of Representatives on 18 May 1999 as follows:

> 'Allegations have been made that hepatitis B vaccination of infants causes Sudden Infant Death Syndrome (SIDS). Because almost 10 million doses of hepatitis B vaccine are administered to infants each year, some infants will die shortly after vaccination by coincidence alone. Available scientific data do not support any causal role of vaccination in the deaths. In fact, in 1992, the first full year after the hepatitis B vaccine was first recommended universally for infants, there were 4800 SIDS deaths and hepatitis B vaccination coverage was 8%. In contrast, by 1996, when coverage had risen to 82%,,

the number of SIDS deaths had actually decreased to 3000 deaths. These data are reassuring because if hepatitis B vaccines were a major cause of SIDS, we would have expected an increase in SIDS, not a decrease. SIDS deaths have continued to decrease as a result of the effort to change infant sleep position, despite a marked increase in hepatitis B vaccination coverage'.[5]

## Hepatitis B vaccine and chronic fatigue syndrome (post-viral fatigue syndrome or benign myalgic encephalomyelitis)

In 1991, the Canadian press reported on the possible association between immunization against hepatitis B and chronic fatigue syndrome. Chronic fatigue syndrome is a non-specific condition of unknown aetiology and there is no objective test to confirm the diagnosis, which is made, in part, by excluding other diseases.

The reviews by the Bureau of Communicable Disease Epidemiology and by the Working Groups of the Laboratory Centre for Disease Control, Canada are referred to frequently. The Working Groups met in September 1989 and in November 1992 to consider a suggested possible link between hepatitis B immunization and chronic fatigue syndrome. The Working Group which met in 1992 examined the data collected on 30 self-reported cases of chronic fatigue syndrome, meeting a standard case definition, and concluded that there was no evidence of causal association between hepatitis B vaccination and chronic fatigue syndrome.[6,7]

It is understood that from August 1987 to June 1995, some 7 million doses of the recombinant yeast-derived hepatitis B vaccine (Engerix B) were distributed in the UK and Ireland, and that 10 reports of chronic fatigue, post-viral fatigue syndrome or myalgic encephalomyelitis were made in temporal association with vaccination. A causal link between the vaccine and the symptoms was not established.

There are suggestions in the literature that immune complexes are responsible for neurological symptoms during viral hepatitis, and that a similar mechanism may pertain to immune complexes which may be formed between antigen present in the vaccine and antibodies elicited by immunization. There are no published laboratory data to support this hypothesis. However, it has been noted that although hepatitis B surface antigen–antibody complexes have been found in biopsies from several organs in patients with hepatitis B with neurological symptoms, these complexes have not been found in nerve tissues. Vasculitis has been shown in the epineurium of sural nerve biopsies from such patients.[1]

A DNA sequence homology between the encephalogenic site of myelin base protein and an 8 amino acid site of hepatitis B virus DNA polymerase has been demonstrated in experimental allergic encephalitis in rabbits. But this observation may not be relevant to the higher primates which are susceptible to hepatitis B virus. A search of the recombinant surface antigen gene of hepatitis B reveals no homology between human albumin, myelin basic protein and other central nervous system (CNS) proteins.

Indeed, it was concluded that among the millions of people worldwide who acquire acute hepatitis each year, few have neurological symptoms, which suggests that access of hepatitis B virus to the central nervous system must rely on host-dependent or environmental factors.[8]

## Hepatitis B vaccine, multiple sclerosis and other demyelinating diseases

In 1996–1997, articles in the French popular press and television programmes raised concerns that hepatitis B immunization may be linked to new cases or flare-ups of multiple sclerosis (MS) or other demyelinating diseases, following a report of primary demyelinating events within 8–10 weeks of immunization against hepatitis B using a recombinant vaccine at a hospital in Paris.[9,10] On 1 October 1998, the French Ministry of Health decided to suspend routine hepatitis B immunization of adolescents in French schools, while continuing the immunization of infants and high-risk adults.

However, CNS demyelinating diseases and MS are believed to have multifunctional pathogenesis with the contribution of both genetic and environmental factors. The age distribution of the onset of disease and migration studies suggests that exposure to an environmental agent in early childhood or adolescence contributes to the pathogenesis of MS with a 10–15-year interval to the onset of disease. The geographical incidence and prevalence of hepatitis B are the opposite of those for MS, with the highest rates of MS and the lowest rates of hepatitis B in Scandinavia and northern Europe, while sub-Saharan Africa and Asia have the lowest rates of MS and the highest rates of hepatitis B virus infection. If the virus does not cause MS, it is unlikely that the vaccine which is prepared from the surface protein of the virus could do so.

Post-marketing surveillance (reports of adverse events following vaccination) from the USA were examined in 1987 and 1996, and from Canada in 1992. No increased rates of MS or other neurological diseases were found compared to the background. Similar results were obtained in France and in other countries.

The results of an official pharmacovigilance study on the neurological tolerance of all hepatitis B vaccines available in France were presented to a National Commission in December 1994 and in December 1996. The data showed that over 60 million doses of hepatitis B

vaccine were distributed in France between January 1989 and December 1996, and a total of 106 case reports of CNS and peripheral nervous system demyelinating diseases were notified in vaccine recipients. The notification rate of demyelinating diseases in temporal association with hepatitis B immunization was approximately 0.6 cases per 100 000 vaccinated subjects. This rate is significantly lower than the expected incidence of demyelinating disease in the same population which, for MS alone, is 1–3 cases per 100 000. The epidemiological patterns of the notified cases were similar to those expected in a similar non-vaccinated population in terms of age distribution, gender ratio and the nature and severity of neurological symptoms. The time interval between vaccination and the occurrence of neurological symptoms was random.[11]

Observations in other countries (Australia, Belgium, Canada, Germany, India, the UK and the USA) show similar patterns to those observed in France of 0.1–0.8 cases of demyelinating disease per 100 000 vaccinees.[11]

The findings of two more recent large-scale studies have also shown no significant association between hepatitis B vaccination and the development of multiple sclerosis. A case-crossover study in patients included in the European Database for Multiple Sclerosis who had a relapse between 1993 and 1997 showed that there was no increase in the specific short-term risk of relapse associated with hepatitis B vaccine.[12] The second study in a large population of women studied in the USA for many years also provided solid evidence that there was no relation between receiving hepatitis B vaccine and the development of multiple sclerosis.[3]

## Conclusions

No vaccine is completely safe and no system of immunization is completely free of human error.[13] Nevertheless, hepatitis B immunization of the population has been introduced into National Immunization Programmes in over 150 countries and well over 1000 million doses of hepatitis B vaccine have been used. The evidence to date is that the licensed hepatitis B vaccines are the safest vaccines ever introduced for the protection of the public.

Anecdotal, provocative and unfounded stories stressing temporal associations with immunization continue, currently in relation to hepatitis B vaccines and diabetes mellitus, rheumatoid arthritis and other autoimmune diseases. However, only in a few rare cases has autoimmune pathology been firmly associated with particular vaccines;[14] for example, polyradiculoneuritis in the 1976–1977 vaccination campaign against swine influenza, and idiopathic thrombocytopenia after the administration of the measles-mumps-rubella vaccine (MMR). It is undoubtedly becoming increasingly difficult to persuade a sceptical public (and compensation lawyers) of the safety and enormous success of immunization programmes in reducing or eradicating infectious diseases. To that end, the establishment, as a priority, by the World Health Organization of the Immunization Safety Priority Project to introduce a comprehensive system to ensure the safety of all immunizations given in national immunization programmes, is a valuable strategic development – strengthening the position that protective immunization is one of the safest of health interventions.

# Chapter 58
# Before and since the discovery of Australia antigen: a chronological review of viral hepatitis

Philip P Mortimer, Arie J Zuckerman

## Introduction

Infectious jaundice was known to Hippocrates, and its clinical and pathological features had already been accurately described by the end of the 19th Century. However, its varied aetiology led to much confusion up to the end of the first half of the 20th Century, and full clarity has only emerged within the last 15 years with the discovery of the main agent of 'non-A, non-B' hepatitis. The turning point, though, was undoubtedly the discovery in 1965 of Australia antigen and its subsequent association with hepatitis B virus (HBV). This was an advance which, as John Enders observed, refreshed hepatitis studies 'like an unexpected shower on desert soil'. It ushered in a series of serological, virological and molecular findings that have since borne fruit in the form of effective vaccines and the first antiviral treatments against chronic hepatitis.

To understand how hard it was to investigate infectious hepatitis before Australia antigen was discovered requires an exercise of the imagination. No specific tests existed and the rapid virological advances in other fields from the 1930s to the 1960s, for example the culture of many mammalian viruses in fertile eggs and tissue culture, or on cell monolayers, all passed the human hepatitis viruses by. The very existence of hepatitis viruses was at that time inferential, and there was no evidence for there being more than two types, whereas five at least are now known. There was, nevertheless, a wealth of clinical and epidemiological data to draw on, as summarized by F.O. MacCallum in his opening address to the International Hepatitis Symposium that took place in Toronto in 1971.[1] It was MacCallum who, 25 years before, had proposed the A and B nomenclature for the two putative hepatitis viruses then recognized.

In briefly reviewing infectious hepatitis before the discovery of Australia antigen, we have taken four vantage points – 1900, 1920, 1940 and 1960 – and, using those milestones, have picked out the discoveries that show the way through that confused period. Then, in the latter part of this chapter, we describe the discovery of Australia antigen and the many developments that flowed from it. After that discovery, clinical and human volunteer experiments became less important as new opportunities, first serological and then molecular in nature, arose. These have brought about spectacular diagnostic and prophylactic successes, and they may soon lead to effective suppressive and even curative treatment for the chronic forms of viral hepatitis.

## A 1900 standpoint

In 1900, what is now understood to be viral hepatitis was seen as a single disease, 'catarrhal jaundice', said by the influential pathologist, Virchow, to be the result of inflammation at the biliary–duodenal junction. This was contrary to observations by, for instance, Richard Bright who had written as early as 1836 that jaundice could be due to 'inflammatory action of the liver [that] occurs in its substance … producing a gradual change in the texture of the liver'. Nevertheless, following the 'bacteria craze' of Koch and his followers in the 1880s,[2] jaundice was usually attributed to biliary obstruction secondary to a specific, even if not yet identified, bacterial infection. At first a salmonella was proposed as the cause, later (see below) a hepatotropic leptospira. The term 'catarrhal jaundice' reflected the idea of an obstructive process, and in the 19th Century the occurrence of catarrhal jaundice was generally regarded as sporadic. This was in spite of the large outbreaks observed during military conflicts, for instance in the American Civil War and the Franco-Prussian War. Recovery from catarrhal jaundice was usual, but acute yellow atrophy of the liver was a rare and usually fatal complication, first described by the Viennese pathologist Rokitansky, in 1842.

At the turn of the 19th Century, research in Cuba by the Reed Commission showed that yellow fever – a particular form of acute hepatitis in which other systems were also involved – had a distinct incubation period following exposure to an infected mosquito and was caused by a 'filterable agent' i.e. a virus.[3] At the time, however, no analogy seems to have been drawn between this and catarrhal jaundice, presumably because the clinical aspects of yellow fever were so acute and its mortality so much higher. The clue that catarrhal jaundice might also be caused by a filterable agent was therefore ignored. Instead, most researchers followed the Japanese-American researcher Noguchi in erroneously ascribing all forms of jaundice (including, it should be added, yellow fever) to leptospiral infection, and so accepted the rather implausible implication that leptosira could wriggle through filters that withheld other bacteria.

Other physicians, meanwhile, were reluctant to recognize that catarrhal jaundice, which they encountered mostly as a sporadic condition, was an infection at all. The idea that a proportion of most infections (not least infectious jaundice) occurred subclinically, making it hard to recognize chains of infection, had yet to develop.[4] And even when clusters of cases of jaundice were recognized, false conclusions were drawn about sources, incubation periods and routes of infection. With long incubation periods and so many non-icteric illnesses involved, successive cases of catarrhal jaundice that might point to its infectious nature were hard to recognize.

## A 1920 standpoint

In 1912, E.A. Cockayne published an article on catarrhal jaundice that reveals how what is now commonly known as infectious or viral hepatitis was conceived of at that time.[5] Cockayne was a young physician who subsequently became paediatrician to the Great Ormond Street Hospital for Children, London, and his review stemmed from work for his doctoral thesis. He was perhaps the first to use the term 'infectious hepatitis', one which did not gain general currency until the 1940s.

Cockayne distinguished between acute, generally benign, jaundice in the community and the more severe form of jaundice with nephritis first described by Weil in 1886. The causative leptospira of the latter disease were first observed microscopically by Japanese researchers in 1914, and this same group went on to culture *L. icterohaemorrhagica* in 1916.

Cockayne, in his review, drew an instructive analogy between infectious hepatitis and mumps. This shows that he had turned his back on Virchow's theory that catarrhal jaundice was, as its name would suggest, the consequence of biliary stasis. Instead, he believed that the jaundice was, as Bright and a few others had previously suggested, due to an inflammation of the liver itself. For Cockayne the analogy was clear. Just as mumps was an inflammation of the salivary glands, catarrhal jaundice was an inflammation of liver parenchyma. He commented: 'the great rarity of gastro-intestinal trouble with jaundice in epidemics and the early appearance of tenderness over the liver also suggest that the liver is attacked primarily'. Cockayne also mentioned approvingly several authorities who had speculated that catarrhal jaundice in its sporadic and epidemic form were both the same disease, and at that point made an insightful comparison with the sporadic and epidemic forms of poliomyelitis, another viral disease in which subclinical infections made clinical discovery of chains of infection difficult, if not impossible.

Plenty of room for error remained, though. Had Cockayne pursued his analogy with mumps he might have realized that the incubation period of infectious hepatitis in any of its forms is measured in weeks not days. Instead, he offered a clinical description of his own case of infectious hepatitis which he assumed that he had caught from his housemaid who had become ill two days previously. With hindsight we know that that imputation was unjust! Cockayne was also of the view, in common with most authorities up to the 1940s, that infectious hepatitis (in contrast to Weil's disease) was transmitted by the airborne route. On the other hand, he did perceive that for practical purposes patients became non-infectious once jaundice had appeared. Cockayne's peroration is worth quoting:

> 'I regard catarrhal jaundice as a specific disease due to an unknown organism endemic over a wide area and appearing not uncommonly in restricted and, very rarely, in widespread epidemics. If the view of its pathology which I have suggested is correct [i.e. the analogy with mumps] the name "infectious hepatitis" would more accurately express the condition than 'catarrhal jaundice'.

Cockayne's paper also includes a section on acute yellow atrophy of the liver which 'in nearly every instance I consider to be a sequel to [catarrhal jaundice] … Its great frequency in women is well known and it occurs in the proportion of two women to one man … due to its special incidence in pregnancy'. In addition, Cockayne refers to the association of jaundice with syphilis which was first being seen at about the time of his review. He correctly related this to intravenous anti-luetic treatment.

The First World War brought a resurgence of 'campaign' jaundice. Dr (Lt Col) C.J. Martin wrote:

> 'During Autumn 1915 troops at Gallipoli, and to a lesser extent in Egypt, suffered from a nearly non-fatal form of infectious jaundice, usually without complete obstruction of the bile passages, and not associated with any tendency to haemorrhages. [It] appeared to be markedly infectious; some units

had 25% of their strength affected and many cases occurred amongst patients in hospital for other complaints'.[6]

Martin's paper was valuable for several reasons. It disposed of the idea that infectious jaundice was due to '*Bacillus typhosus*'. It reported on the post-mortem examinations of three soldiers who died in the course of jaundice, and it challenged Willcox and Hurst's repetition of the concept of catarrhal jaundice. Martin wrote:

'it seems to me unfortunate that in the absence of definite knowledge of the aetiology of the disease these gentlemen should thus light-heartedly throw the weight of their authority in favour of one possible interpretation of its pathology and method of spread …, I submit … we are dealing with a hepatitis following a systemic infection'.

Among the reasons Martin gave for this were that: (1) jaundice is ushered in by a febrile attack like influenza; (2) jaundice does not occur for some days and is preceded by swelling and tenderness of the liver; (3) the spleen is often enlarged; (4) histologically, there is inflammation around the portal areas and necrosis of liver cells. Martin's paper also contains a lone reference to the idea that epidemic jaundice in its mild form (i.e. not Weil's disease) might be due to a pathogenic agent 'invisible like that of yellow fever', an insight offered to him in 1915 by an otherwise unidentified 'Professor Kartulis'.

## A 1940 standpoint

By 1940, many clues had been uncovered as to the diversity of infectious hepatitis, although orthodox medical opinion held fast to the view that catarrhal jaundice was a single disease. An old guard still remembered Noguchi's leptospiral theory, and not until 1939 did the technique of percutaneous liver biopsy provide proofs that catarrhal jaundice was an inflammation of the liver parenchyma and not of the biliary tract, and that it was not bacterial in nature.[7]

By 1940, also, two sets of epidemiological evidence had emerged that were in retrospect very significant. The first was due to clinical observations such as those by W.N. Pickles on catarrhal jaundice in Yorkshire, England. Pickles carefully documented incubation periods in a rural community outbreak of jaundice. During four cycles of infection in an extended family group between August and December 1929, the incubation of cases of jaundice was always close to 28 days (Table 58.1).[8] By his close observation of jaundice in the community, Pickles also confirmed Cockayne's opinion that during the latter part of the illness patients were non-infectious, adding: 'It is those who are mildly affected and able to carry on their usual avocations that are mainly responsible for spread'.

By contrast, there was a second quite different presentation of jaundice in clinics where patients were treated for syphilis by intravenous infusions or injections of arsphenamine ('salvarsan').[9] This drug was given weekly for 7, 10 or even more weeks, often with inadequately sterilized needles and syringes. The associated jaundice showed a longer and more chaotic incubation period than the 28 days observed by Pickles. The contrasting sets of observations on what were to prove different forms of viral hepatitis were later confirmed by experimental means in US Army volunteers in the mid-1940s (Fig. 58.1).

By 1940, it had also been noted that intravenous therapies and other medical interventions in which plasma or serum might be exchanged between humans carried the risk of what came to be called 'homologous serum jaundice'.[10] Measles prophylaxis with convalescent sera, vaccines against smallpox and yellow fever to which human serum had been added to stabilize them, and transfusions of blood and plasma (in particular pooled plasma), all carried the risk of jaundice. The associated wide range of incubation periods observed in homologous serum jaundice had a median of between 2 and 3 months in contrast to the regular 4-week intervals between cases of 'catarrhal' jaundice described by Pickles in a community setting.

The impact of viral hepatitis in debilitating the combatant armies during World War II is hard to exaggerate.

**Table 58.1** The incubation period of epidemic catarrhal jaundice: note the regular intervals of 4 weeks between cases reported by Pickles[8]

| Patient | Date of onset (1929) | Remarks | Interval (days) |
|---|---|---|---|
| N | 16 August | Young woman, source of infection not traced | 29 |
| O, P | 14 September | Brother and sister of N | 27 |
| Q | 11 October | Brother of N, O and P | |
| R | 12 October | Young woman, a great friend of the family | 27 |
| S | 7 November | Sister of N, O, P and Q | |
| T | 6 November | Little girl, inseparable from the family | 28 |
| U | 4 December | Fiancé of S (contact of N) | |
| V | 2 December | Two-year-old sister of T | 27 |
| W | 29 December | Father of T and V | |

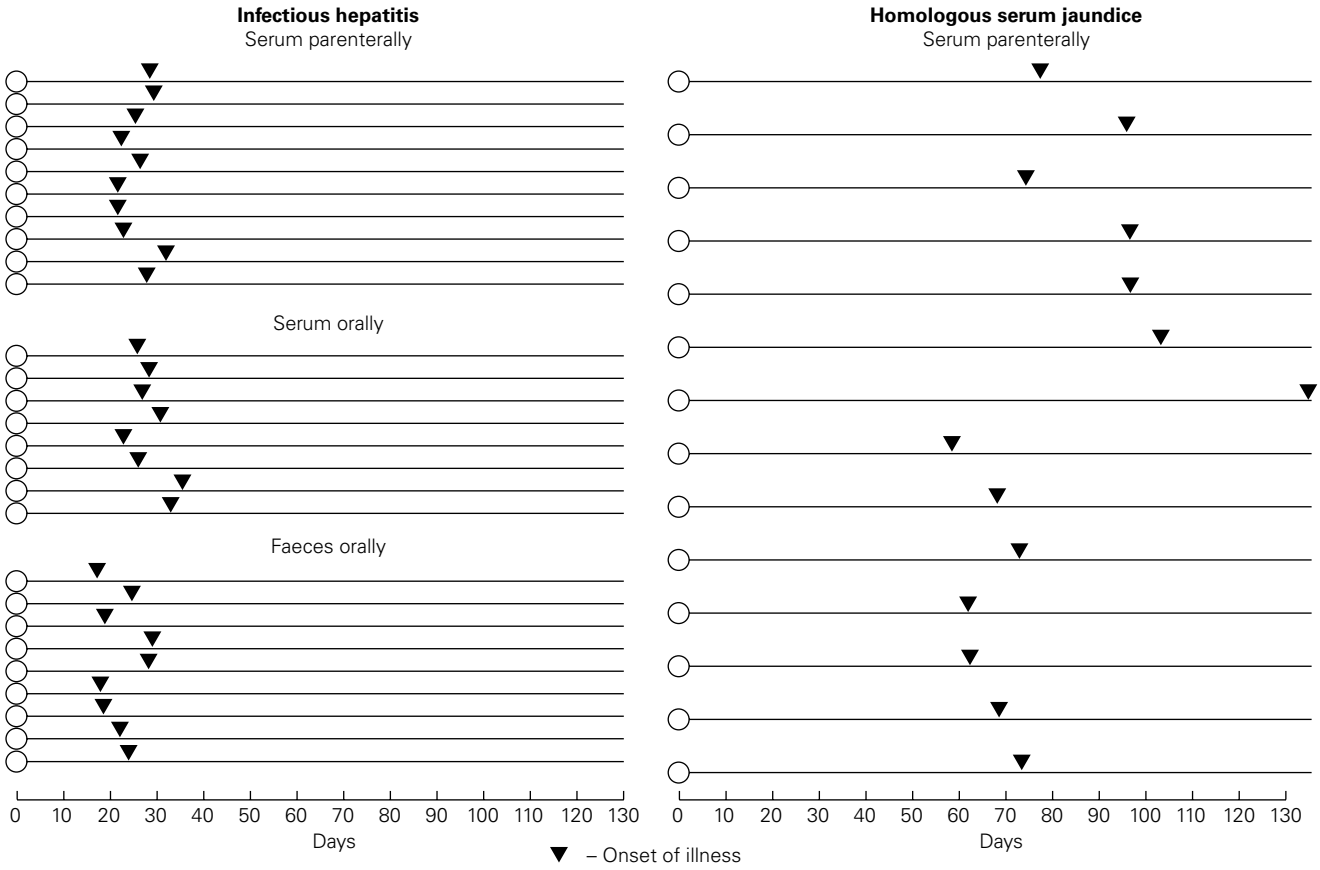

**Figure 58.1** A comparison of incubation periods to onset of hepatitis for US volunteers given either serum or faecal suspensions from cases of infectious hepatitis, or injected with serum from cases of 'homologous serum jaundice'.

Although 'campaign' jaundice had been described in successive wars since the 18th Century, and the tens of thousands of cases seen in World War I had greatly compromised battlefield effectiveness, the allied armies of World War II were ill-prepared when the same phenomenon recurred. This is what L.D. Heaton, US Surgeon General, wrote in his foreword to the official history of 'Preventive Medicine in WWII':

> 'Hepatitis furnished the most unexpected, and perhaps the most serious, problem of all the diseases discussed in this volume. Although this was an "old and ugly camp follower", neither its enormous incidence nor its serious potentialities had been foreseen by any medical authorities before the war. During 1943, in the midst of hard combat in the North African theater, medical officers were suddenly confronted with … hepatitis, the infectious variety, whose victims filled to overflowing the hospitals just to the rear of the combat area'. This came fast upon the "bombshell" of epidemic serum hepatitis, caused by the use of icterogenic human serum in certain lots of yellow fever vaccine'.[11]

It was a situation that both confirmed the existence of two main forms of viral hepatitis and greatly boosted research into them. The occurrence of nearly 50 000 cases of jaundice after the ill-conceived programme of yellow fever vaccination of US troops in early 1942,[12] plus the high incidence of jaundice in battlefield conditions, and the heavy toll of jaundice and acute yellow atrophy following pooled plasma transfusions for injuries to combat troops,[13] were the stimuli for important observational[14] and military volunteer[15,16] studies. These studies addressed various conflicting theories current at the time about the nature of infectious hepatitis:[11]

> '(1) That it was a contact disease spread by droplet infection and that measures conceivably useful in the control of respiratory disease should be considered; (2) that it was transmitted through the agency of human excrement and spread primarily through human carriers of the virus, as is typhoid fever; (3) that some unknown, extrahuman factor, such as rodents, insects, or pigs, was responsible for its spread; (4) that the disease was an example of bacterial warfare; and (5) that it was due to or made worse by malnutrition and inadequate diets'.

Together with British studies in conscientious objectors between 1943 and 1946, the studies on volunteers by the US Army medical teams finally established that

there were at least two forms of infectious hepatitis, A and B, that there was no cross-immunity between them, that the A virus was spread not by the respiratory route but by the faecal-oral route, that the B virus was present in icterogenic serum and was often carried indefinitely by individuals who were themselves usually healthy and not jaundiced, and, finally, that Cohn's recently described cold ethanol method for fractionating human plasma pools isolated an immunoglobulin fraction which, when given intramuscularly, protected fully against exposure to the A and partially against the B virus. This immunoglobulin fraction was, moreover, not itself icterogenic.

These volunteers had made an extraordinary contribution to the elucidation of hepatitis, as was graciously acknowledged: 'The contribution made by these volunteers to the welfare of humankind was great, and no discussion of their participation in human research should fail to take cognizance of their courage and generosity'.[11]

At the same time as humans were being exposed experimentally, laboratory investigations into hepatitis were intensified. Attempts to culture virus in embryonated eggs and tissue culture were renewed and (following the description in 1928 of the rhesus monkey model for yellow fever by Stokes, Bauer and Hudson[17]) transmission of putative hepatitis viruses to all manner of monkeys and other animals was attempted.[18] None of this work was successful, and it unfortunately led to the erroneous conclusion that human hepatitis viruses could not infect experimental animals, even primates. It was to be another 20 years before that potentially fruitful line of investigation was renewed through the work of Deinhardt, Purcell and others.

## A 1960 standpoint

In the years following World War II, hepatitis research again suffered from competition from those branches of virology where success was more easily won. The huge wartime epidemics of infectious hepatitis were over and the disease had mostly assumed again its sporadic character. It was a time when attempts to grow hepatitis viruses in monolayer cell cultures repeatedly failed and when the mistaken belief that these viruses could not be transmitted to primates was rarely challenged.[19]

However, a new incentive to continue the quest for hepatitis viruses emerged in the form of the growing range of medical interventions found inadvertently to transmit hepatitis (Table 58.2). Hepatitis proved to be a serious complication of multi-transfusion and of renal dialysis. Furthermore, from the late 1960s, the new blood products prepared from pooled plasma such as factor VIII concentrate almost universally transmitted hepatitis.[20] This was a phenomenon which in retrospect should have been anticipated from what had already been learnt in wartime and later of the dangers of plasma transfusion. For instance, Lahane[21] had shown that large-pool (at least 300 donations) plasma prepared before 1945 gave rise to jaundice in 11.9% of recipients, whereas plasma prepared from fewer than 10 donations gave rise to jaundice in only 1.3% of recipients. (From this study in the Liverpool region, it was possible to estimate that the hepatitis carrier rate in the donors was 0.35%.)

**Table 58.2** Medical procedures found to transmit hepatitis

| Procedure | First described |
|---|---|
| Arm to arm smallpox vaccination | 1885 |
| Syphilis therapy with arsphenamine | 1917 |
| Insulin therapy and associated glucose estimations | 1925 |
| Measles prophylaxis with convalescent serum | 1936 |
| Serum stabilization of yellow fever vaccine | 1937 |
| Mass yellow fever immunization of US servicemen | 1942 |
| Blood transfusion | 1943 |
| Mass therapy for schistosomiasis, yaws | 1950s |
| Renal dialysis | 1960s |
| Treatment with anti-haemophilic factor concentrate | 1975 |

Hepatitis was also endemic in institutional settings where faecal-oral contamination, scratching and biting might occur,[22] and any intervention seemed as difficult as the case post-transfusion jaundice. For want of specific virological tests, it was hard to study the efficacy of immunoglobulin prophylaxis in this institutional context and apparently impossible to develop vaccines. However, the empirical use of a heated MS2 serum as a vaccine by Krugman and Giles, first reported at Toronto in 1971,[23] was able to anticipate this advance. As Krugman foresaw, the first generation of hepatitis B vaccines would be in the form of a heat-inactivated clarified plasma collected from healthy carriers. Krugman's experiments were a bold initiative that was to bring great benefit, although their design and context have since become mired in ethical controversy.

Meanwhile, the wide range of epidemiological associations of HBV that is now taken for granted – sexual and mother-to-child transmission, the relationship to liver cancer – was still largely unsuspected. This was in spite of there having been in the 1940s occasional recorded instances of secondary spread, e.g. to sexual partners,[12] some evidence of hepatitis in infancy and reports of long-term risk of cirrhosis following acute hepatitis. Acute yellow atrophy of the liver or fulminant hepatitis also occurred as a feared and ill-understood phenomenon.

**Table 58.3** Early landmarks in the understanding of viral hepatitis

| |
|---|
| The Reed Commission of 1901–1902 (yellow fever due to a 'filterable agent', i.e. a virus) |
| Stokes, Bauer and Hudson's description of a model of clinical yellow fever in the rhesus monkey (1928) |
| Pickles defines the incubation period of community hepatitis (1942) |
| *In vivo* liver biopsy findings consistent with a viral aetiology for hepatitis (1943) |
| Ministry of Health memorandum describes 'homologous serum jaundice' (1943) |
| Fractionation and viral inactivation necessary for blood product safety (1940s) |
| Realization of the importance of needle and syringe hygiene (1950s) |

In summary, then, this 'dark age' of hepatitis leading up to the ground-breaking description of Australia antigen in 1965 contained unanswered questions but landmark discoveries, some of which are listed in Table 58.3. Some other observations and conclusions of that era were false and became obstacles to understanding that later had to be cleared away.

## Up to 1980 (the discovery of HBV and HAV)

That the last four decades of hepatitis research have proved so much more productive than the previous ones is ascribable to the discovery of Australia antigen, the subsequent rapid development of serological tests for hepatitis B, the use of immune electron microscopy, the many experimental transmission studies in non-human primates and, most recently, the application of molecular biology to the whole, disparate, group of human hepatitis viruses.

Before considering these advances, the immediate post-World War II period must be dealt with. It was the wartime studies in Germany, the British Mandate of Palestine, the UK and, most extensively, the US (reviewed by Zuckerman[24]) that first established the varied viral aetiology of hepatitis. The post-war studies at the Willowbrook State School in New York then greatly extended knowledge of its prophylaxis.

The number of children at the Willowbrook State School, an institution for children with learning disabilities, increased between 1949 and 1963 from 200 to over 6000, and from 1953 viral hepatitis was endemic among them. Many hundreds of cases of viral hepatitis with jaundice were observed to be transmitted in this institution by natural contact, and most of the newly admitted children contracted the infection within the first 12 months. The decision to artificially expose these children to the Willowbrook strains of hepatitis virus was reached after consideration of many factors.[25] For instance, it was almost inevitable that children would become infected with hepatitis in the institution, and induced viral hepatitis was observed to be mild in the 3–10-year age group. These studies were carried out with optimum isolation facilities to protect the inoculated children from other infectious diseases such as shigellosis and parasitic and respiratory infections that were also prevalent. Controlled exposure to hepatitis conferred immunity to infection and thus, over a period of 12 years, approximately 250 children participated in experimentally induced hepatitis with parental consent and in accordance with the contemporary ethical approval of local, state and federal agencies. The studies were also in compliance with the World Medical Association's Draft Code of Ethics on Human Experimentation.

The work at Willowbrook confirmed that there were at least two distinct epidemiological, clinical and immunological types of hepatitis circulating in the institution. One, induced by MS-1 serum, closely resembled hepatitis A, and a second, induced by MS-2 serum, resembled hepatitis B. There was no cross-immunity between MS-1 and MS-2. Persistence of infection, i.e. a carrier state, occurred in some cases. A most important observation was that the inoculation of diluted MS-2 serum heated at 98 °C for 1 minute was not infectious and provided immunity against challenge. This laid the foundation for the later production of a plasma-derived hepatitis B vaccine consisting of inactivated, highly purified, 22-nm hepatitis B surface antigen particles. The serum bank of >25 000 serum specimens obtained from both naturally acquired and experimental infections became a valuable source of material for the study of the natural history of both hepatitis A and hepatitis B.

Meanwhile, in the laboratory, hepatitis studies had reached a turning point as a result of a largely serendipitous discovery, that of hepatitis B surface antigen. It came about as follows. 'Polymorphism' is defined as the occurrence in the same habitat of two or more inherited forms of a species in such proportions that the rarest of them cannot be maintained merely by recurrent mutation. In polymorphic traits, two or more of the genotypes determining variation of the trait are common in the population. Polymorphisms arise as a result of selective differences between genotypes, and they provide convenient systems for the study of discontinuous inherited biochemical variations in man. Such systems include the red blood cell antigens (ABO, MNS, P, rhesus, etc.), sickle cell haemoglobin, haptoglobin, transferrin, glucose-6-phosphate dehydrogenase deficiency and gamma globulin groups.

On this basis, in 1961, Allison and Blumberg[26] argued that as donor blood was commonly only matched for the major red blood cell antigens before transfusion, patients would be likely to receive blood containing other proteins that they had not themselves inherited. Some of these would be antigenic and lead to the development of antibodies in the transfused patients. A systematic investigation of the serum of transfused patients was therefore begun, using the two-dimensional micro-Ouchterlony immunodiffusion technique to visualize lines of precipitation of immune complexes.

After examining 13 sera from frequently transfused patients in the centre well and a panel of sera from different geographical areas in peripheral wells, one transfused patient's serum was found often to react with a precipitin present in some of the sera in the panel. It was soon demonstrated that this patient's serum acted as an antiserum identifying a system of inherited antigenic specificities of low density beta-lipoproteins, designated the Ag system. A search for additional antisera was initiated and in 1963 two sera from multiply transfused American haemophilia patients were found to give an identical precipitin line with 1 of 24 sera in a test panel. The antigen in this one serum contained little or no lipid and clearly differed from the Ag precipitin, but it stained with azocarmine, indicating that protein was a major component. The reactive serum had been obtained from an Australian Aborigine and so the antigen was named 'Australia' antigen.[27]

Subsequent studies of the distribution of Australia antigen in normal populations in different geographical areas revealed that it was rare in North American and European communities, but occurred frequently in the serum of apparently healthy people living in the tropics and south-east Asia (6–25%). Because the antigen was found frequently in the serum of patients with acute leukaemia, it was suggested in 1965 that the presence of Australia antigen might be of value in the early diagnosis of leukaemia. It was further postulated that the antigen might be related to a virus causing leukaemia. Evidence was also presented that Australia antigen was inherited, probably as a simple autosomal recessive trait. A corollary of this hypothesis was that individuals at high risk of developing leukaemia might have an increased frequency of Australia antigen. As if to corroborate this theory, up to 30% of patients with Down's syndrome, who were known to have a high risk of leukaemia, were found to carry Australia antigen.

In 1966, Blumberg observed a patient with Down's syndrome who on initial examination did not have the Australia antigen, but in whose serum the antigen was found on a subsequent test. Liver function tests and a liver biopsy revealed that this patient had developed anicteric hepatitis concurrently with the appearance of Australia antigen in his blood. Then, in April 1967, a technician working on Australia antigen in Blumberg's laboratory developed malaise, loss of appetite and dark urine. Australia antigen was detected in her blood for a single day and she subsequently developed a mild icteric hepatitis.[28] Sera of other patients with viral hepatitis were examined for Australia antigen and it was present in 10.4%.

In 1968, a strong association was observed in Japan between Australia antigen and post-transfusion hepatitis,[29] and subsequent studies established that Australia antigen was actually the lipoprotein surface antigen of hepatitis B virus (HBsAg). Thus, by 1970 it had become possible to screen blood donations for HBsAg with an immediate impact on the incidence of post-transfusion hepatitis. Within 5 years of the description of Australia antigen, huge benefit had emerged from what had begun as an academic interest in the genetics of serum precipitins.

A second line of investigation involved electron microscopy (EM). Although viruses were among the first objects to be examined by EM in the 1930s, little information had been obtained on their fine structure except in the case of bacteriophages. Then, in 1959 a negative-contrast technique for high-resolution EM was introduced. In this method particles such as viruses are suspended in a rigid electron-dense material, e.g. a uranium salt. This offers good preservation of the biological material with minimum distortion of structure. In the technique of immune electron microscopy (IEM), to increase sensitivity and specificity, virus particles are concentrated within an immune complex by the addition of an antiserum.[30] Bayer and colleagues in 1968 were the first to examine serum specimens rich in Australia antigen by IEM.[31] These specimens were obtained from three patients, one with acute myelogenous leukaemia, one with chronic reticuloendotheliosis and one with Down's syndrome and chronic hepatitis. Negative-contrast staining revealed spherical particles with a diameter of 19–21 nm and surface knob-like subunits about 3 nm in diameter. Elongated particles varying in length from 50 to 230 nm were also observed. The particles had been aggregated by the addition of rabbit antibody raised against Australia antigen. Then, in 1970, the complete HBV virion (Dane particle), measuring about 42 nm in diameter with a 28-nm core, was visualized.[32]

In 1973, IEM was also used to identify hepatitis A virus (HAV) in faecal extracts obtained before illness or during the acute phase from adult volunteers who had been infected orally or parenterally with the MS-1 strain.[33] The availability of HAV antigen in faeces collected in the pre-icteric phase also allowed the development of specific serological tests for hepatitis A, and for immunity to it. Soon afterwards, it was shown by the same group that the virus could be propagated through long incubation in monolayer cell culture.

Meanwhile, following the lead given by the Willowbrook experiments, the first hepatitis B vaccines were prepared, derived from the plasma of healthy carriers of Australia antigen (by then designated HBsAg). These vaccines, consisting of highly purified and inactivated 22-nm surface antigen particles, were licensed for general use in 1981 and 1982. Yeast-derived hepatitis B vaccine produced by recombinant DNA technology followed and was licensed in 1992. This has since been introduced into national immunization programmes in over 150 countries.

As a result of the successful propagation of HAV, as a virtually non-cytopathic infection of various monkey and semi-continuous human cell lines, inactivated hepatitis A vaccine became available in Europe in 1991, and then in the USA and elsewhere in 1995. These vaccines are whole virus preparations from HAV grown in cell culture and then formaldehyde-inactivated. The first combined inactivated hepatitis A and B vaccine was licensed in 1997.

In 1977, another nuclear antigen had been detected, by immunofluorescence, in hepatocytes of patients with chronic hepatitis B infection. This antigen resembled the core antigen of hepatitis B in its cellular localization and was always associated with hepatitis B infection, but it rarely co-existed with the core antigen. The antigen was named delta, and patients with the antigen develop specific anti-delta antibodies.[34] In 1980, delta antigen was recognized as a component of a novel defective virus that requires HBV co-infection for its replication. The delta hepatitis virus (HDV) has HBsAg as its virus coat and, as its core, delta antigen and a circular single-stranded RNA genome. In its genome structure and its replication HDV resembles certain subviral agents of plants, especially viroids.

## Since 1980

As the specific diagnosis of types of viral hepatitis increasingly became possible, it was apparent that there must be at least one other important form, unrelated to hepatitis A, B or D, that was transmitted by the parenteral route. This was referred to as non-A, non-B or NANB hepatitis. During the 1980s, this became the object of intense research efforts, both epidemiological and experimental.

Results from several carefully conducted epidemiological surveys of post-transfusion hepatitis in the United States and elsewhere provided strong evidence of the transmission of NANB hepatitis, and it was found to be universally present in a proportion of blood donors. Indeed, in the many countries where all blood donations were already by 1980 being screened for HBsAg by sensitive techniques, NANB hepatitis accounted for some 90% of cases of post-transfusion hepatitis. Outbreaks of NANB hepatitis, often subclinical, were also associated with treatment with batches of blood clotting factor VIII and IX concentrates. NANB hepatitis occurred in haemodialysis and other specialist units, among intravenous drug users, and after accidental inoculation with contaminated needles. (Mother-to-infant transmission of NANB hepatitis has only occasionally been reported.)

Some NANB cases were apparently not associated with transfusion or drug use, and these sporadic cases of NANB hepatitis accounted for up to 25% of all adult patients with clinical viral hepatitis. Thus, in many cases of NANB hepatitis the mode of transmission of this type of hepatitis could not be identified. The illness was in general mild, anicteric or even subclinical, but severe hepatitis with jaundice did also occur and NANB hepatitis accounted for some fulminant hepatitis. In many patients, the infection was followed by prolonged viraemia and a persistent carrier state.

Transmission studies in chimpanzees established that the main agent of parenterally acquired NANB hepatitis was likely to be an enveloped virus, 30–60 nm in diameter. These studies also made available a pool of plasma which contained a high titre of the main NANB agent which was cloned in 1989 and thereafter referred to as hepatitis C virus (HCV).[35] The genome of HCV resembled those of the pestiviruses. Hepatitis C virus has six closely related but distinct genotypes with differing geographical distribution. The degree of divergence apparent within the viral envelope proteins implies the absence of a broad cross-neutralizing antibody response to infection by different HCV isolates, and these may co-exist in the same patient. There is no evidence for non-pathogenic HCV variants.

The successful cloning and expression of portions of the HCV genome permitted the development of diagnostic tests.[36] The 5-1-1 antigen was the first to be detected, by antibodies in the serum of an infected patient, and it was an obvious candidate as the basis of an ELISA to detect the presence of HCV antibodies. Then a larger clone, C100, was assembled from a number of smaller overlapping clones and expressed as a fusion protein in yeasts, facilitated by the use of human superoxide dismutase sequences. The C100 fusion protein was widely used as the antigen for first-generation tests for anti-HCV. However, this first-generation ELISA was associated with a rather high rate of false-positive reactions when applied to low incidence populations, and also in the retrospective studies done on stored sera. Second- and third-generation ELISAs, which included antigens from the nucleocapsid and further non-structural regions of the HCV genome, proved more specific and sensitive, and immunoblot tests served further to assure specificity. Polymerase chain reaction (PCR) amplification confirmed the presence of HCV viraemia and quan-

tified it as a means of monitoring the success of antiviral treatment.

Epidemics of enterically transmitted non-A, non-B hepatitis have often occurred in countries in Asia and Africa where sanitation is suboptimal. Transmission is by the faecal-oral route, commonly via contaminated water supplies. A virus, hepatitis E, was first identified in 1983 in a volunteer study[37] and was subsequently cloned in 1989. The virus genome resembles most closely in sequence those of rubella virus and beet necrotic yellow vein virus. While man is the natural host of hepatitis E virus (HEV), swine strains have been identified and are able to cross the species barrier and infect humans. In endemic areas, antibodies to HEV have been found in 42–67% of domestic farm animals, and there is some evidence of infection in rodents, suggesting that HEV may be a zoonotic infection.

## Epilogue

In 2005, viral hepatitis remains a major public health problem throughout the world. Effective vaccines are available against hepatitis A and hepatitis B, and trials of a vaccine against hepatitis E are in progress. However, only modest progress is being made in developing a vaccine against hepatitis C. In all cases, antiviral therapy is proving difficult, although progress is being made, especially against hepatitis C. Meanwhile, infant vaccination against hepatitis B is having a huge impact on carrier rates of HBV in adolescents and young adults, mitigating the anticipated burden of chronic disease in the countries of south and south-east Asia and elsewhere. This is an achievement in international public health that rivals the global eradication of smallpox in 1978.

Other blood-borne viruses have recently been identified, including the GB viruses (in particular GBV-C), the Torque Teno viruses (TTV) and SEN virus and TTMV, but they are not specifically associated with hepatitis. There may be still other non-A, non-B, non-C, non-D, non-E hepatitis viruses awaiting discovery, but it appears that their pathogenicity is minor. Therefore, by a combination of vaccination and antiviral treatment, the long-term prospect of bringing viral hepatitis under control worldwide is now realizable. This goal should not be lost sight of through lack of imagination and/or parsimonious funding, as historically the clinical consequences and economic costs of viral hepatitis have made it one of the most important of all infectious diseases.

Note: Page numbers followed by 'f' refer to figures and those followed by 't' indicate tables.

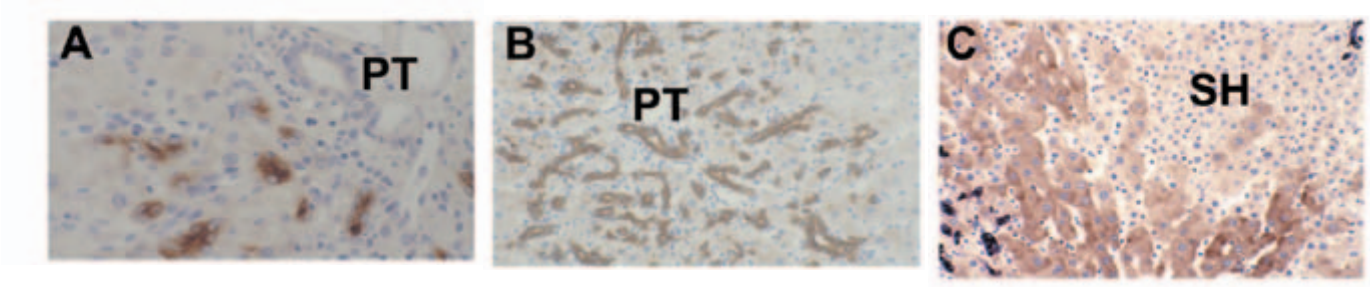

**Plate 1.1** Oval cell behaviour in the rat liver treated by the AAF/PH protocol. (A) AFP expression (IHC staining) is typically observed in the migrating oval cells; note the absence of staining in the interlobular duct in the portal tract (PT). (B) The oval cell response can be visualized by CK8 immunostaining, with cords of cells emanating from the portal tract (PT). (C) At later times, the cords of oval cells differentiate into small hepatocytes (SH) but with a notable lack of CYP immuno-expression (brown staining). Note the occasional residual oval cell ductules expressing CK19 (purple staining).

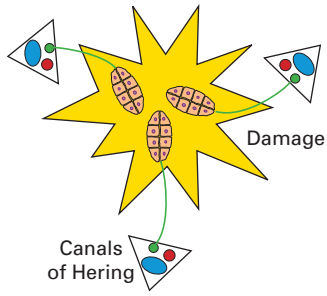

**Plate 1.2** The canals of Hering (green) extend from the portal areas into the proximate third of the hepatic lobule in the human liver (see Theise *et al*[33]), and major hepatocyte damage activates the lining cells to divide and probably differentiate into hepatocytes.

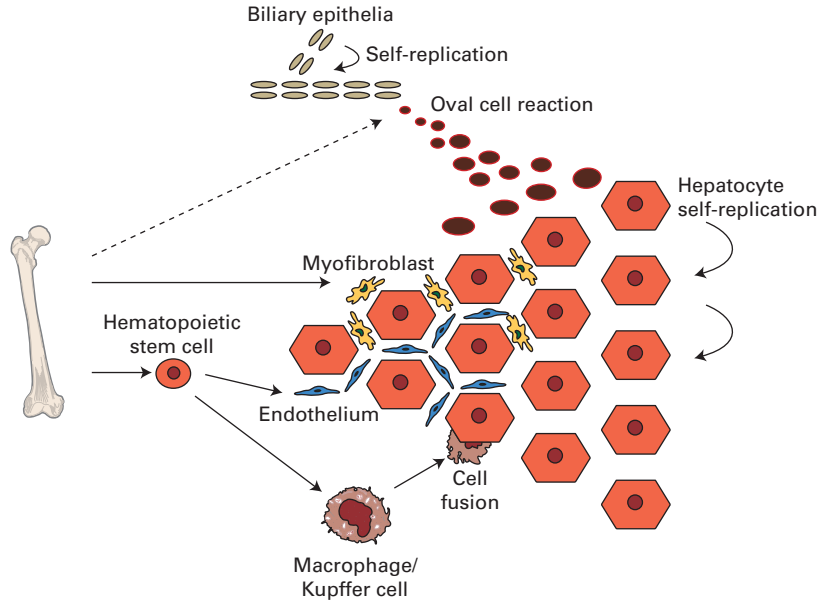

**Plate 1.3** Most hepatocyte regeneration comes from self-replication. This pathway is efficient and can replace the great majority of hepatocytes under most circumstances. Under conditions of regenerative stress such as fulminant hepatic failure or later stage chronic hepatitis, a second axis of hepatic regeneration comes into effect. The so-called oval cells or hepatic progenitor cells develop from the terminal branches of the intrahepatic biliary tree. They probably differentiate into hepatocytes by passing through an intermediate hepatocyte stage. There is currently controversy as to whether oval cells can be supplied from the bone marrow. Previous reports of bone marrow cells transdifferentiating into hepatocytes may in fact represent fusion of bone marrow-derived macrophage lineages with mature hepatocytes. The bone marrow does supply non-parenchymal cells to the liver; inflammatory cells and Kupffer cells traffic from the bone marrow to the liver. The bone marrow is also able to supply the hepatic endothelium and a proportion of the hepatic myofibroblasts.

(b)

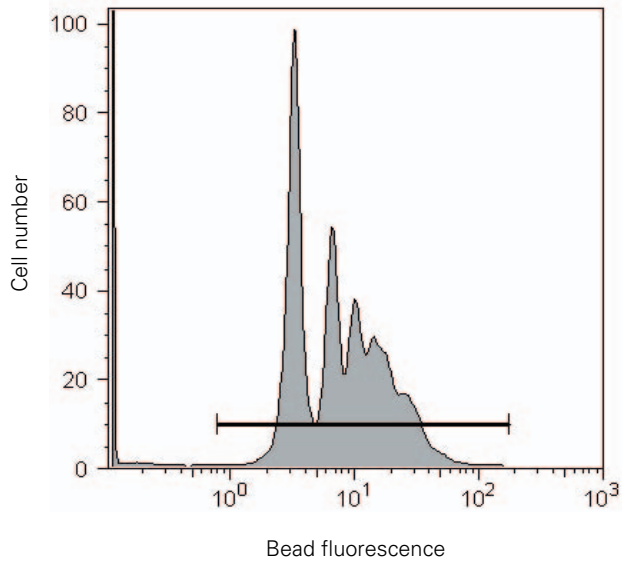

**Plate 2.4** (a) Mouse liver status/post injection of fluorescent beads (red, fluorescent nanospheres; blue, F4/80; sytox green nuclear stain). (b) Flow grapgh showing cells with phagocytosed beads.

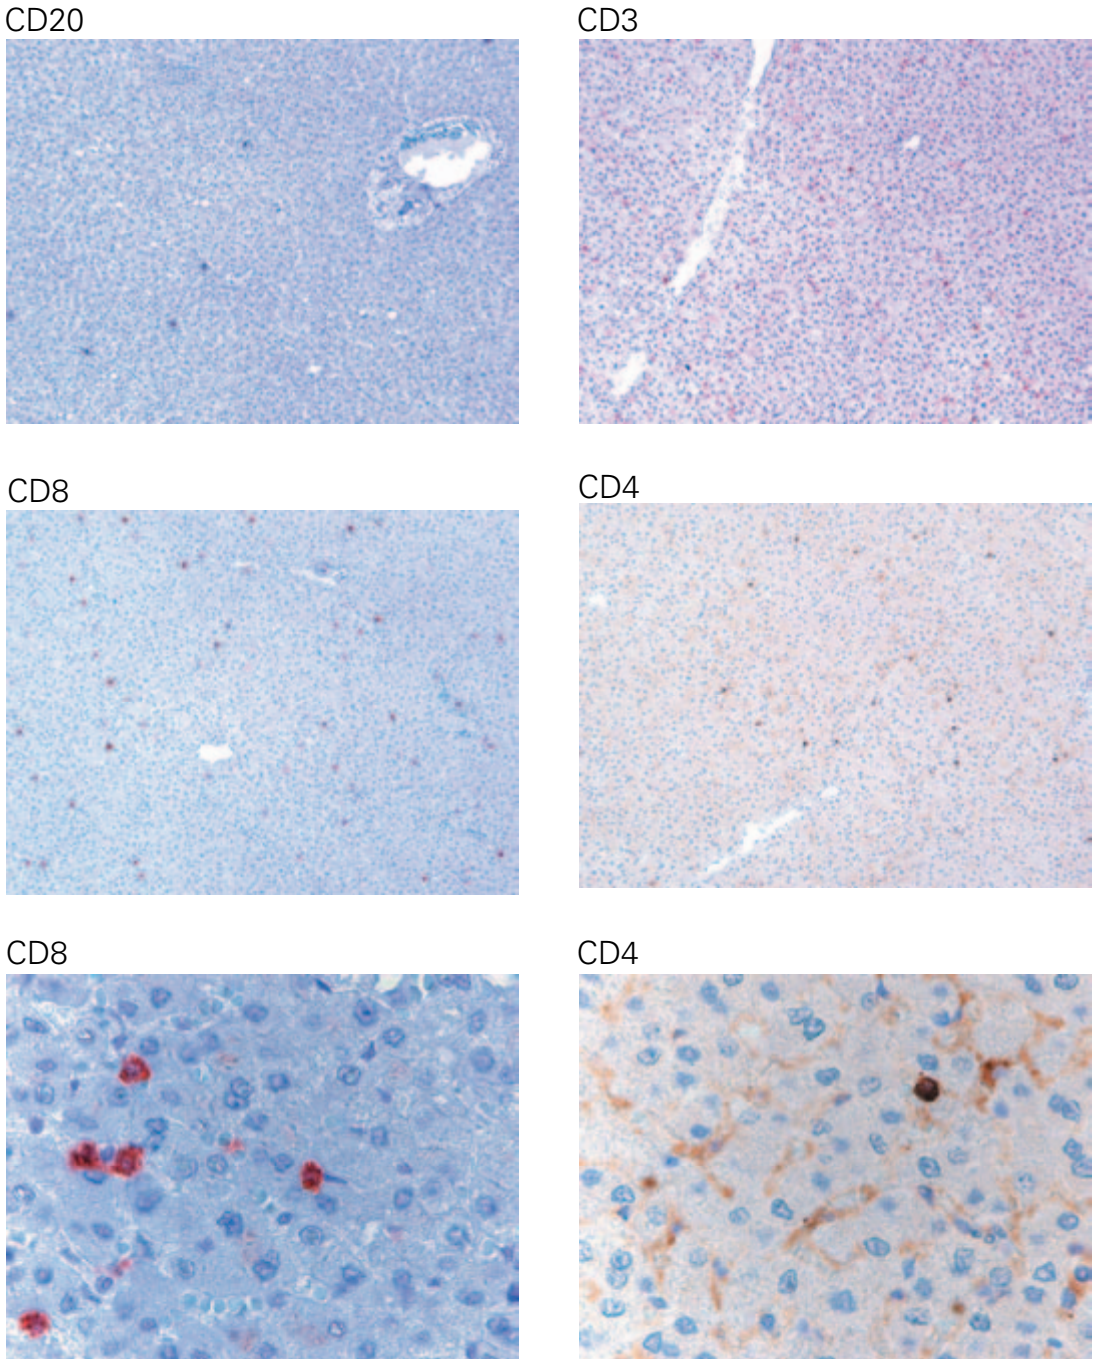

**Plate 2.5** Normal human liver immunohistochemistry. CD20, CD3, CD8 and CD4 at 100x magnification; CD8 and CD4 at 600x magnification.

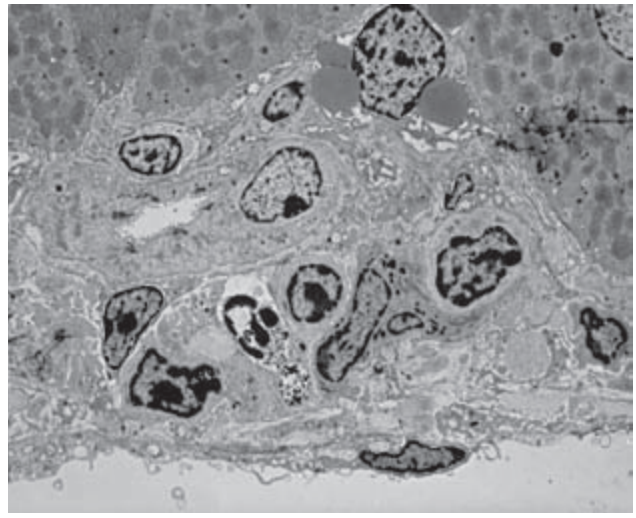

**Plate 2.6** Transmission Em of inflammatory focus (OT-1 model) in subendothelial space of Disse.

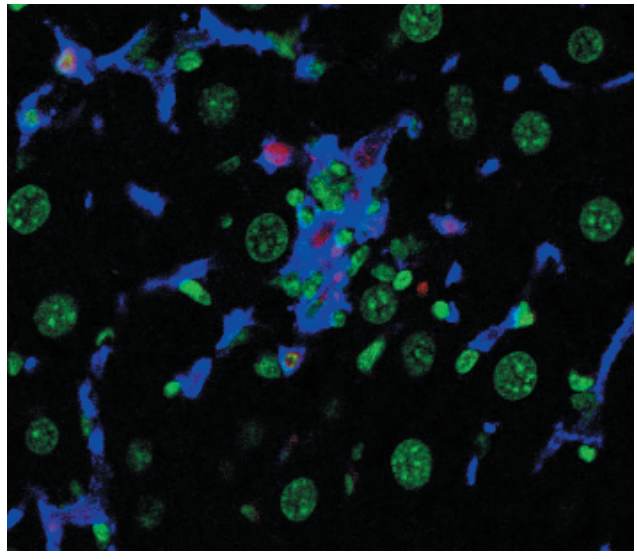

**Plate 2.7** Chronic hepatitis in association with AAV: TUNEL, F4/80, sytox green.

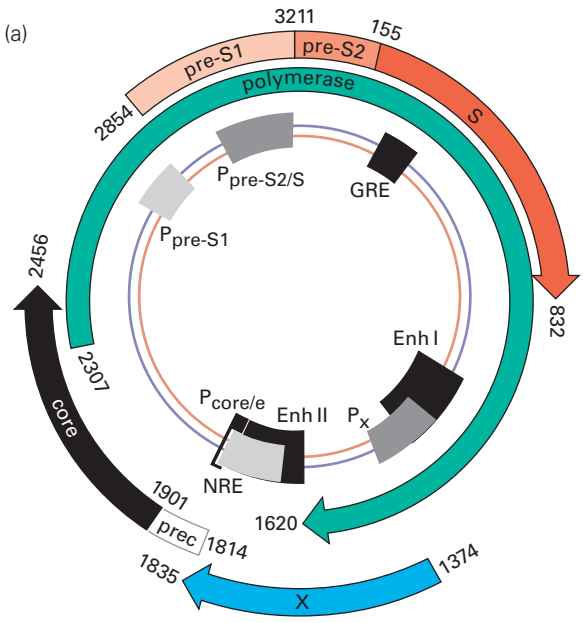
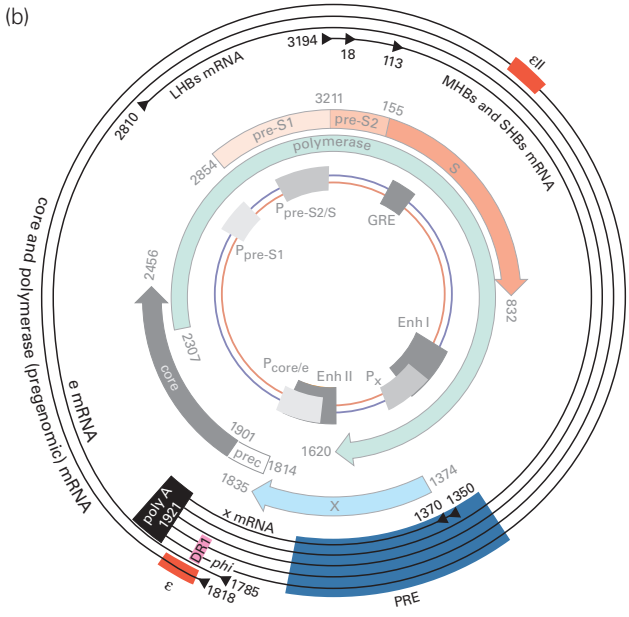
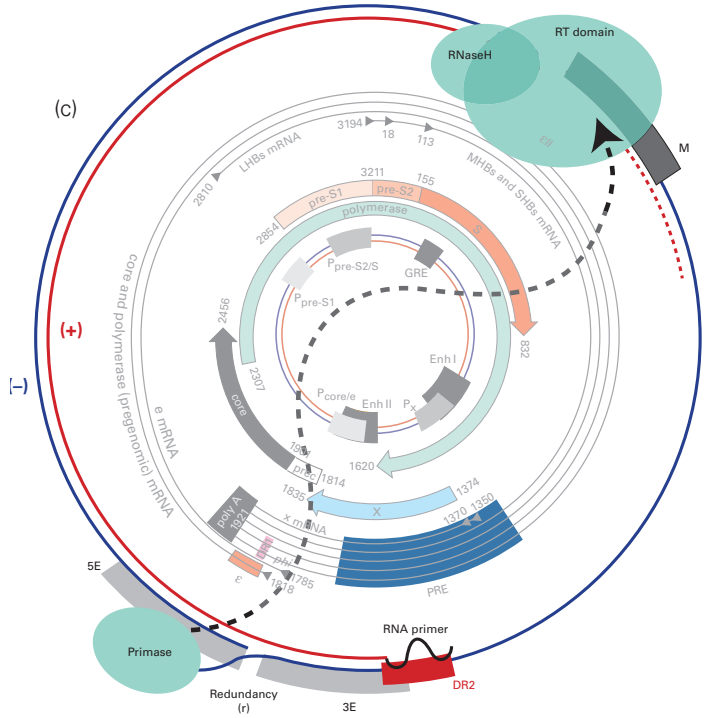
**Plate 10.1** (a) Genome organization and regulatory elements on HBV cccDNA. The numbering is according to the HBV isolate 991 (HBs subtype adw2, genotype A) starting at the unique EcoRI site. All known complete HBV genomes are circular and between 3181 and 3221 bases long. The negative strand is depicted as a blue line, the positive DNA strand as a red line in the centre. The ORFs shown here are defined by the first start codon of protein synthesis and the first stop codon. Some in-frame internal start codons are also shown. The longest ORF, with its four contiguous domains, encodes the polymerase polyprotein of HBV. Nonconserved ORFs or ORFs of uncertain function are not shown. The promoters are shown as grey boxes, the enhancers: the negative regulatory element (NRE), and the glucocorticoid responsive element (GRE) as black boxes. The CCAAT element overlapping the S promoter is not depicted. Liver-specific promoters are drawn in light grey; obligatorily used promoters are depicted as mid-grey boxes. Transcription of the cccHBV DNA is governed by enhancers I and II, the glucocorticoid response elements (GRE) and the promoters upstream of the mRNA start sites. The common termination signal for all mRNAs is the TATAAA box at base 1921.
(b) HBV mRNAs and their signal elements. The initiation sites of mRNA synthesis for the various HBV proteins are shown as triangles. All HBV mRNAs are polyadenylated and comprise the post-transcriptional regulatory element (PRE) that prevents splicing. Other elements, such as ε I, ε II, phi and the DR1, are only functional on the pregenomic mRNA and are required for packaging and subsequent minus-strand DNA synthesis. Plate 10.1a is included in the centre of this figure.
(c) HBV DNA as it is found in the virion. The DNA strand that encodes the viral proteins (i.e., the minus-strand) is of full length but is not covalently closed (blue line). It has a small redundancy (r) of 9 to 10 bases at the ends and the domains 5E, 3E and M required for circularisation of the genome during plus-strand DNA synthesis. The minus-strand (red line) carries at its 5′ terminus a covalently bound part of the viral polymerase, known as terminal protein or primase because it is necessary for priming of the minus-strand synthesis. As indicated by the dashed line the primase domain is only one part of the polymerase that comprises the RT domain and the RNase H domain (all domains in green), catalysing DNA synthesis of both strands and degradation of the RNA in the intermediate hybrid of minus DNA strand and RNA. The plus-strand keeps the minus-strand in a circular conformation because it bridges the discontinuity of the minus-strand. The 3′ end of the plus-strand is not at a fixed position and is still connected with the HBV DNA polymerase. Most virion-bound genomes contain a single-stranded gap of 300 to 2000 bases long. Plates 10.1a and 10.1b are included in the centre.







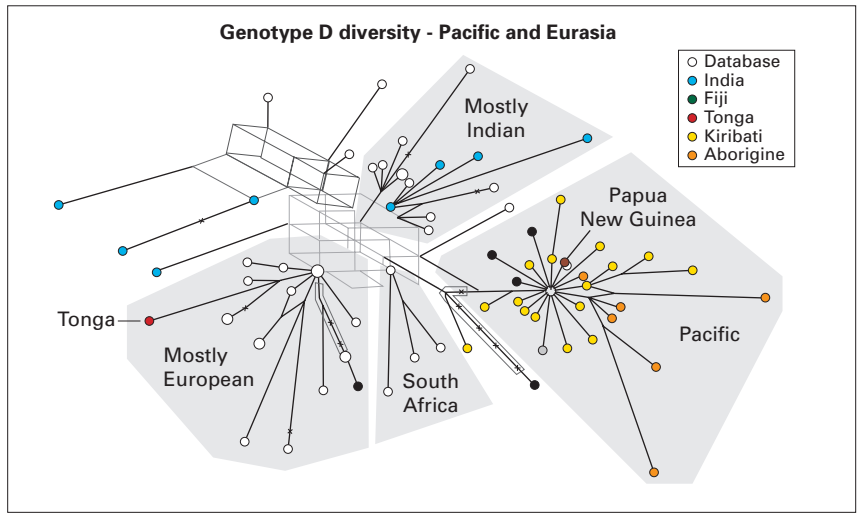


**Plate 14.1** Network analysis of D genotype S genes from a number of regions of the world, with particular emphasis on the Pacific. Note how most examples in the Pacific were found in Kiribati and that isolated examples only were found in other Pacific islands, perhaps due to subsequent movement between islands. This network is unresolved in the centre (see boxes) because of the large number of strains; the links between geographical areas are therefore unclear.

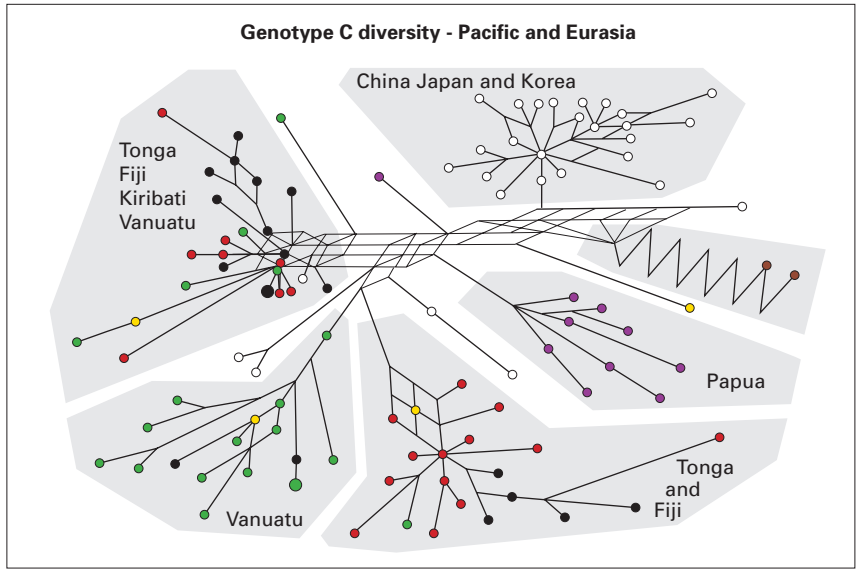

**Plate 14.2** Network analysis of C genotype S genes from a number of regions of the world, with particular emphasis on the Pacific. Note how strains are clearly localized geographically. In particular, note how Vanuatuan and Papuan strains are highly clustered, probably due to little movement to and from other islands (of those studied) in the region. On the other hand, some Fijian strains appear to have been derived from Tongan strains.

**Plate 25.1** Worldwide prevalence among blood donors.

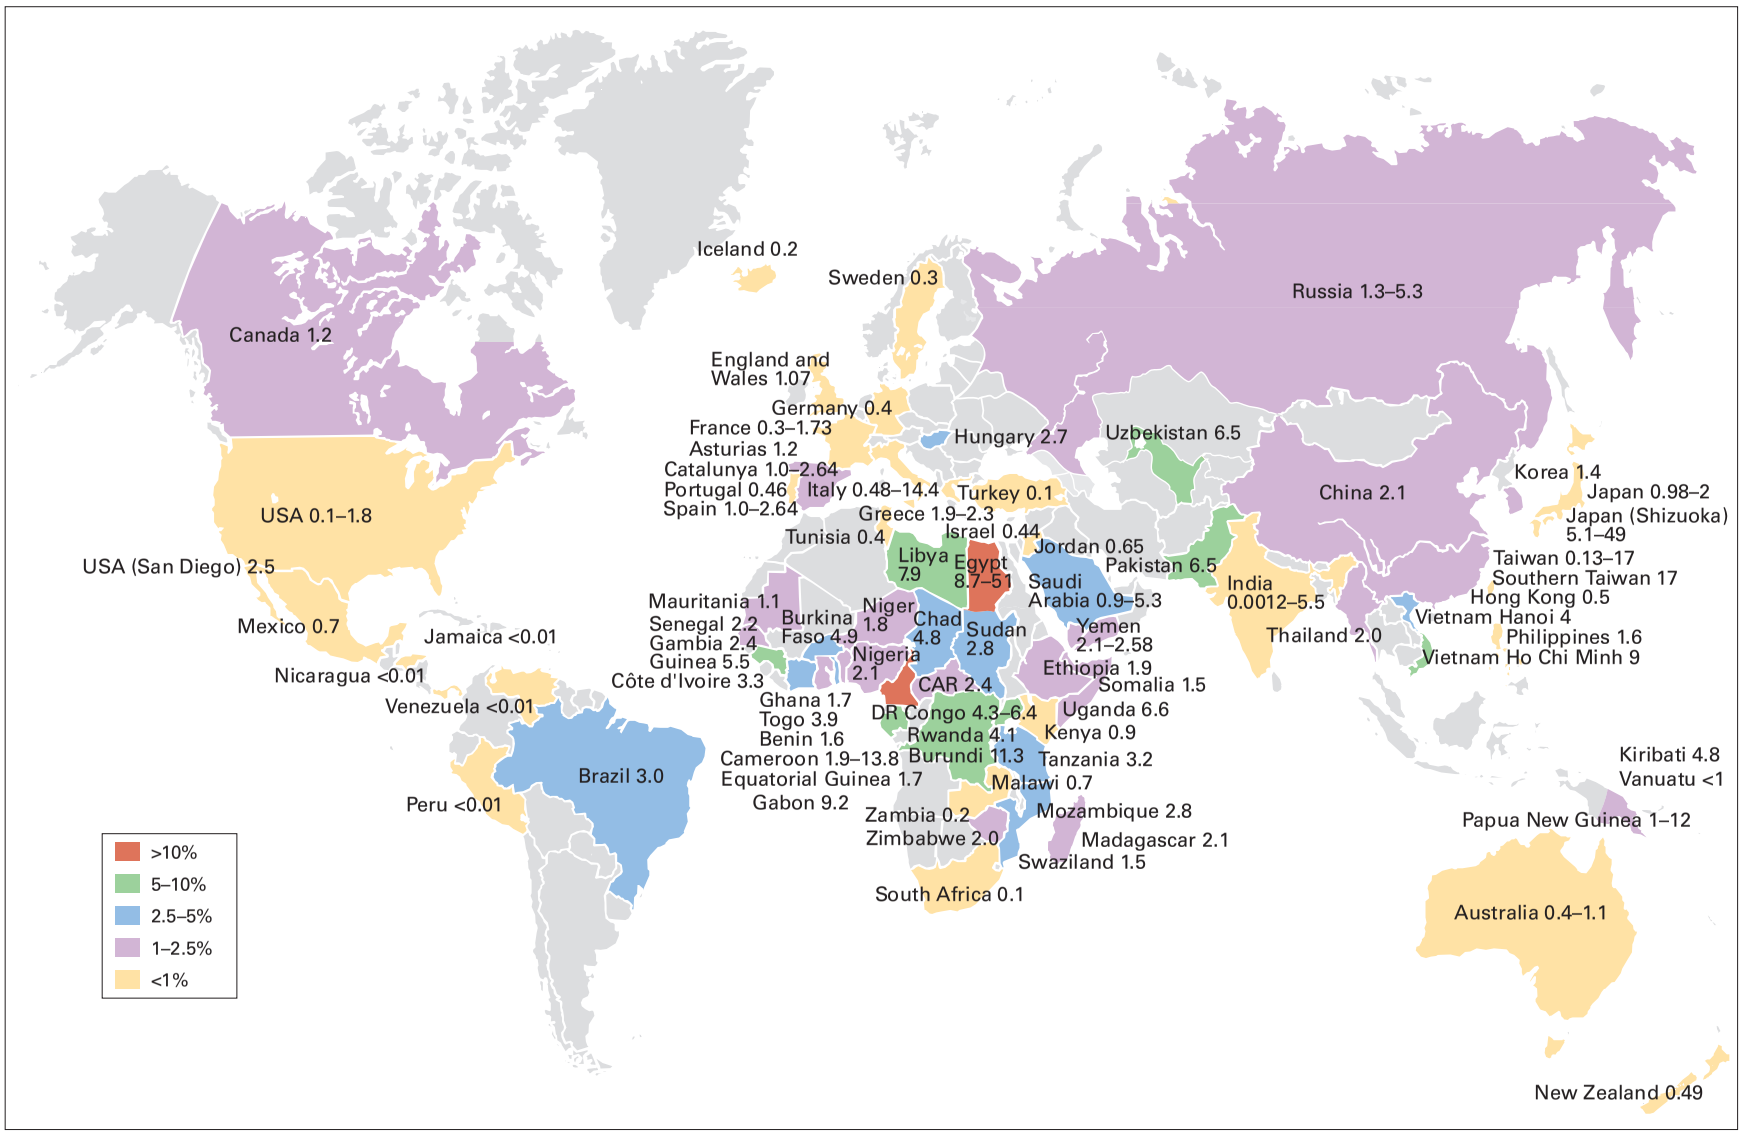

**Plate 25.2** Worldwide prevalence of HCV among general population cohorts.

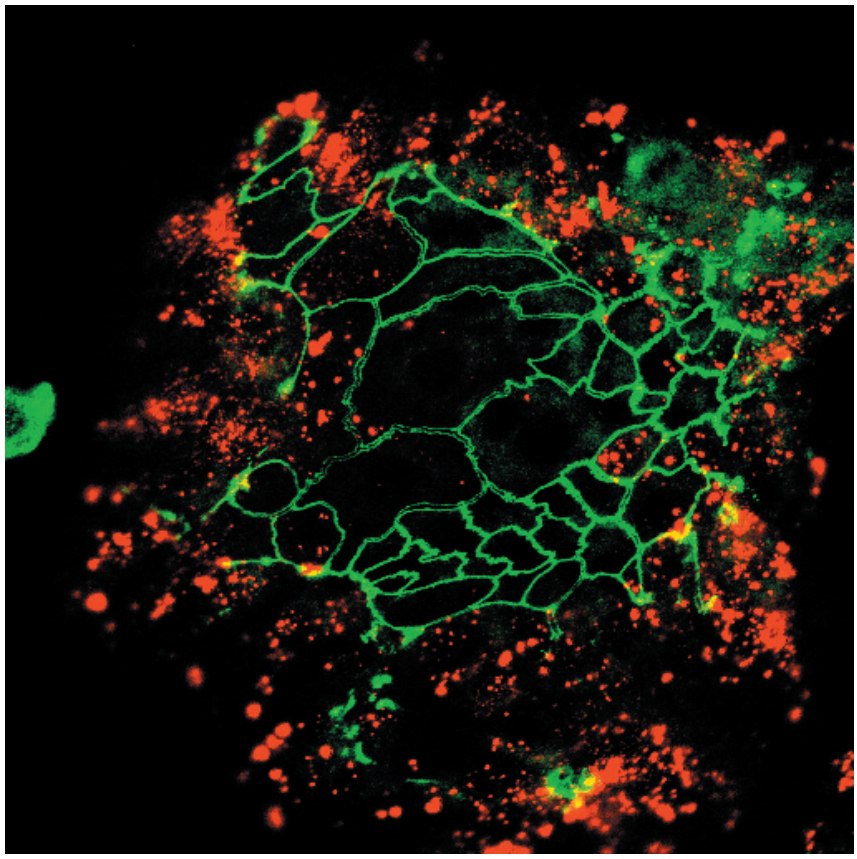

**Plate 39.1** Binding of HEV VLPs to polarized hepatocytes. A polarized subclone of HepG2 cells was grown as microcolonies on glass and incubated with 1 µg/mL HEV VLPs for 1 hour at 37 °C. Cells were fixed, stained with monoclonal antibody 2E2 to detect HEV (red) and rabbit anti-Zo1 to detect tight junctions (green), and examined by confocal microscopy.[29,42] HEV VLPs bind to cells at the periphery of colonies, where cells are not yet polarized and thus apical and basolateral membrane proteins are exposed to the medium, but are unable to bind to the polarized, cells in the centre of the colonies where the basolateral domains are in contact with the glass rather than the medium. (Photo courtesy of Michelle Snooks, Burnet Institute.)

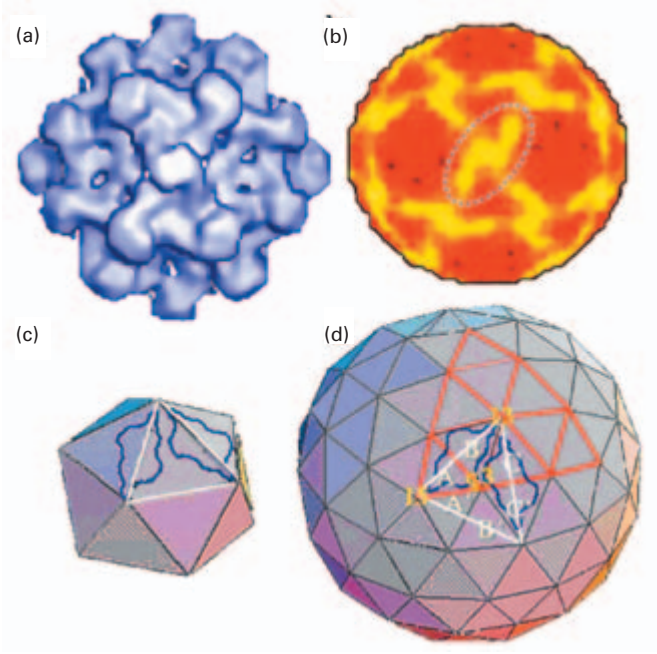

**Plate 39.2** The structure of HEV capsid, approximately 270 Å in diameter, was revealed by cryoelectron microscopy and 3D reconstruction (a).[47] The self-assembled VLP of truncated PORF2 peptide (residues 112–608), is composed with 30 predominant protrusions around the icosahedral surface. The protruding spike forms a balcony of 38.6 $nm^3$, while the thickness of the protein shell varies from 85 Å at twofold positions to 10 Å at fivefold positions. Detailed structural analysis reveals how the individual dimeric units (b, one marked by a dashed circle) establish contacts across the icosahedral twofold axes.[47] Two icosahedral surface lattices, showing the packing of 30 dimers at a strictly icosahedral twofold position in a $T = 1$ lattice of 270 Å in diameter (c) or the assembly of 90 of the same size dimers in a $T = 3$ lattice of 390 Å in diameter (d). The white triangle in the $T = 3$ lattice corresponds to one equivalent icosahedral face in the $T = 1$ lattice. The detailed organization of PORF2, the dimeric contact interface and the configurations of both N- and C-termini are still under investigation with high-resolution structural analysis (Xing, Miyazaki, Wang and Cheng, unpublished results).
